Antidepressants (ATD) are a largely prescribed group of pharmaceuticals, mainly used on treatment of depressive syndrome symptoms. ATD acts on the central nervous system temporarily changing brain function, behaviour and consciousness. ATD have three principal classes: tricyclic, serotonin selective reuptake inhibitors (SSRI) and monoamine oxidase inhibitors (MAOIs). After administration, ATD can be metabolized, biotransformed, conjugate and excreted in urine and faeces. The excreted amount of antidepressants/metabolites will depend on the type of compound, dosage, route of application. Once excreted, the ATDs will reach aquatic ecosystems mainly through domestic effluents. It makes the domestic sewage the major source of ATD for water contamination. This occurs due to the low removing rate of several ATD in sewage water treatment plants. In this scenario, the present study aims to evaluate the acute and embryotoxicity of different ATD, namely fluoxetine (FLX, Generic), sertraline (SERT, Generic), agomelatine (AGLT, Valdoxan), mirtazapine (MIR, Sandoz), nortriptyline (NTP, Generic) and bupropion (BPP, Generic). To do so, zebrafish embryos were used as model organisms. Toxicity tests were performed based on the Fish Embryo Toxicity test OCDE nº 236. The organisms were exposed to 2 mL of solution of at least six concentrations, including a negative control group. All tests were performed in a climatic chamber (26 °C and 12 h of light) with a minimum of 4 days. The concentrations ranged from 0.1 - 15 mg/L for FLX, 0.007 - 0.24 mg/L for SERT, 1 - 100 mg/L for AGLT, 4.68 - 300 mg/L for BPP, 1 - 100 mg / L for MIR, 1 - 73.3 mg / L for NTP. Based on the obtained results, and considering only the mortality, a following toxicity ranking could be established: SERT (96h-LC<sub>50</sub> = 0.022 ± 0.001 mg/L), FLX (96h-LC<sub>50</sub> = 6.05 ± 0.19 mg/L), BPP (96h-LC<sub>50</sub> = 11.62 ± 3.68 mg/L), NTP (96h-LC<sub>50</sub> = 14.75 ± 0.00 mg/L), AGLT (96h-LC<sub>50</sub> = 29.61 ± 0.00 mg/L), and MIR (96h-LC<sub>50</sub> = 30.72 ± 0.01 mg/L). ATD exposure caused changes in the development of zebrafish (tail deformities, lack of equilibrium, and hatching delay). Lethal and embryotoxic effects observed in this study can occur in low doses (e.g. SERT case) indicating a high risk of exposure to antidepressants. Future studies should focus on chronic toxicity of ATD for fish and the toxicity to aquatic organisms belonging to other trophic levels.

##### **Total and differential count of blood cells of *Oreochromis niloticus* exposed to azithromycin in chronic toxicity and efficacy tests**

N.S. Shigiri, DCF; C.V. Ikefuti, FCAV UNESP; S.P. Carraschi, C. da Cruz, São Paulo State University UNESP; M.N. Fernandes, Universidade Federal de São Carlos / Ciências Fisiológicas

The intensive culture of fish is a sector in expansion and is highly vulnerable to infectious diseases. The intensive use of antibiotics to control bacterial diseases may cause negative impacts to the aquatic environment, including to fish. So, the aim of this study was to evaluate chronic effects on the total erythrocytes and the percentage of leukocytes in tilapia (*Oreochromis niloticus*) (Wt: 70 - 100 g) exposed to 1, 50 and 100 mg L<sup>-1</sup> of azithromycin (AZT). The AZT were previously diluted in ethanol then, two control groups (with and without ethanol) were used. The exposure system was static, three replicates and lasted 14 days. In addition, was performed an experiment of efficacy of AZT, where fish were treated with AZT administered by food for five days. Fish were infected with the bacteria *Aeromonas sp.* (6.2 x 10<sup>11</sup> UFC mL<sup>-1</sup>) and the treatments were health control, health control that received food with AZT, control with saline 7%, infected untreated fish, and AZT treatments with 100 mg and 125 mg of AZT per kilo of food. Total erythrocytes and the percentage of leukocytes were analyzed. In the chronic toxicity experiment, the number of thrombocytes and leukocytes presented a significant increase in the treatment of 100 mg AZT L<sup>-1</sup> compared with the control without ethanol. The differential count presented an elevated percentage of lymphocytes compared to other leukocytes types (monocytes, basophils, eosinophil, neutrophils and immature leukocytes) in all concentrations. The leukocyte cells presented similar data in all concentrations. In the efficacy experiment, the number of thrombocytes increased significantly in the treatment of 125 mg AZT Kg<sup>-1</sup> when compared to the health control. The total leukocyte number did not presented significant difference. The differential count of leukocytes presented elevated percentage of lymphocytes, but in infected untreated, the percentage of lymphocytes decreased and the percentage of neutrophils increased, proving that an infection was happening, since this type of cell is the first to appear in an infection site. In chronic exposure, the

levels of thrombocytes and leukocytes increased indicating that AZT, at the highest concentration studied, can stimulate this system, but among the different kind of leukocytes didn't have difference indicating that there was no infection happening. In the efficacy test was observed that the AZT did not affected this immune system. Financial support: FAPESP Proc. 2011/21552-6.

#### MO112

##### **Relationships in trace metals between water, tissues and otolith of juvenile flounder: a 3-month experimental approach to validate the use of otolith as natural tracer of metal contamination**

J. selleslagh; a. échard, Université Bordeaux; P. Gourves, University of Bordeaux 1; M. Baudrimont, Université Bordeaux 1; f. daverat, Irstea Bordeaux  
Estuaries are natural sinks for a wide range of contaminants that accumulate at potentially highly toxic concentrations for fish populations and hence could affect recruitment and stocks, despite recent management efforts and decreasing efforts. While metal analysis of soft tissues or water requires continuous and long-time sampling to assess the ongoing status of an aquatic environment, otolith may offer a permanent record of metal exposure. Aiming to look into this aspect, the focus of this study was to demonstrate the potential use of otolith as natural tracer of metal contamination. Thus, bioaccumulation of metal (cocktail of Cd, Pb and Ni) in tissues (liver, kidney and gills) and otolith of 230 juvenile flounders (*Platichthys flesus*) were analysed after increasing levels (natural, 5-time, 10-time and null) along a 3-month direct exposure under controlled conditions. Chemical analyses were carried out by ICP-OES and GTA-AAS for water and tissues and otolith chemistry analyses were performed with a femtosecond laser ablation – high resolution inductively coupled plasma mass spectrometry (fsLA-ICPMS-HR). Differences in the metal content of tissues were detected between contaminated and control fish along the exposure period. Juvenile fish progressively exposed to higher concentrations of metals also showed increasing metal levels in their otoliths. Then, concentrations observed in tissues and otolith approximated values similar to reference fish after three weeks of decontamination. This study suggests the possibility to use otolith as natural tracer to assess and retrace metal pollution in aquatic environment. Taken into consideration present results, otoliths of juvenile collections from decades would be analysed to retrace mi/long-term metal contamination in a specific estuarine system.

#### MO113

##### **Screening for immunotoxic potentials of environmental chemicals in fish: a literature review**

K. Rehberger, University of Bern / FiWi; L.A. Baumann, University of Bern / Centre for Fish and Wildlife Health; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; B. Hitzfeld, FOEN / Federal Office for the Environment; H. Segner, University of Bern / Centre for Fish and Wildlife Health

Numerous environmental chemicals, including long known toxicants such as persistent organic pollutants as well as emerging contaminants like pharmaceuticals or nanoparticles, are known to modulate immune parameters of wildlife species. Despite frequent field observations of impaired immunocompetence and increased disease incidence in contaminant-exposed wildlife populations, the potential relevance of immunotoxic effects for the ecological impact of chemicals is rarely considered in ecotoxicological risk assessment. For human toxicology, tiered testing frameworks are in place, which rely on a range of immunological tests and endpoint to assess immunotoxic effects of chemicals. In contrast, ecotoxicology does not possess an established inventory for the detection of chemical-induced immunomodulation and evaluation of the associated toxicological consequences. Therefore, the aim of the present study was to analyse the existing literature on immunotoxic effects of chemicals in fish to evaluate which immune assays and endpoints are most commonly used and responsive and may have potential to serve as immunotoxicity markers in screening assays. A total of 131 journal articles on immunotoxicity in fish were found in the databases of „pubmed“ and „sciencedirect“. Every article was analyzed in detail concerning methods and results. Data were categorized into different groups, e.g. immune effects in relation to immune endpoints and function, chemical class, fish species, life stage, or exposure time. The most frequently analysed immune parameters included phagocyte functions like respiratory burst, or responses of cytokines such as interleukins and tumour necrosis factors. The most extensively investigated classes of chemicals were endocrine disruptors, pesticides, and to a lesser degree, toxic metals, pharmaceuticals and (chlorinated) aromatic hydrocarbons. The results of the literature analysis suggest that no single assay or endpoint is enough to rule immunotoxicity “in” or “out”, but instead a testing panel covering a range of immune functions would be needed.

#### MO114

##### ***Nothobranchius furzeri*, a potential new model for long-term ecotoxicity testing: first results**

C. Philippe, Laboratory of Aquatic Ecology Evolution and Conservation; A. Grégoir, KU Leuven / Laboratory of Aquatic Ecology Evolution and Conservation; G. De Boeck, University of Antwerp; L. Brendonck, KU Leuven

##### ***Nothobranchius furzeri*, a potential new model for long-term ecotoxicity testing: first results**

*Nothobranchius furzeri* is a rising and promising vertebrate model for both fundamental and applied research. The species is currently used in

physiological and biomedical research and its genome was recently sequenced. With a full generation time of  $\leq 37$  days, *N. furzeri* offers a great potential to perform time- and cost-efficient long-term and multigenerational ecotoxicological studies compared to other fish-model species (zebrafish 60-75 days, medaka 70-81 days). Another advantage is their production of drought resistant dormant eggs that can be stored 'on the shelf', overcoming the need and costs of a continuous culture. Whenever needed, fish can be recruited within hours by wetting the eggs. This potential of *N. furzeri* has not yet been sufficiently explored in ecotoxicology, partly due to the continuing lack of important basic ecotoxicological information. Therefore, we here aim at providing an initial assessment of this promising ecotoxicological model. The sensitivity of *N. furzeri* to copper ( $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$ ) was assessed in an acute and chronic toxicity test. In these experiments, fish were continuously exposed to a range of copper concentrations, starting from 48h after hatching. In the acute toxicity test, mortality and buoyancy were scored to quantify  $\text{LC}_{50}$  and  $\text{EC}_{50}$  values during an exposure period of 14 days. The chronic toxicity exposure lasted for the whole lifetime and effects on growth and reproduction were quantified. Results of the acute toxicity test with *N. furzeri* demonstrate an overlap in sensitivity range with that of current fish models in ecotoxicology. In addition, long-term exposure to a sublethal concentration (inferred from the acute test), resulted in 100% mortality after 3 weeks. These concentrations also had a significant effect on growth and maturation time. Overall, through its unique trait-set (short maturation time and dormant eggs) and a sensitivity to a well studied toxicant that is comparable to conventional fish models, *N. furzeri* could rapidly be developed as a valuable ecotoxicological model for chronic and multigenerational toxicity testing. To draw more general conclusions on its sensitivity, more experimenting with different types of pollutants will however be needed.

#### MO115

##### Olfactory toxicity in fish - a scarcely regarded topic

S. Volz, RWTH Aachen University; H. Hollert, RWTH Aachen University / Institute for Environmental Research

According to the German Federal Environmental Agency, in Germany alone about 43.000 tons of pesticides are sold and 2.5 kg of active ingredient are applied per hectare agricultural surface each year. By avulsions following heavy rain or via drainage systems these pesticides can find their way into the aquatic environment and as they often exhibit a lack of target specificity, they could negatively affect the aquatic flora and fauna. For fish, the olfactory system is of great importance, as it mediates a variety of essential activities and behaviors, for instance food detection, kin recognition, homing, the predator response and mating habits. Consequently, an impairment of olfaction can affect individual fish as well as whole populations. The olfactory epithelium of fish is located in two olfactory pits, which are flooded constantly by the surrounding water. The olfactory receptor neurons, which are responsible for the detection of odorants, are situated within the olfactory epithelium. These bipolar neurons are only separated from the surrounding water by a thin layer of mucous. In such an exposed situation, dissolved xenobiotics can interact with them as easily as natural odorants do. In the last years some studies concerning the impact of xenobiotics on fish olfaction have shown that several metals and pesticides are able to influence the olfactory system of fish in environmentally relevant concentrations. Despite the crucial role the olfactory system plays in fish, to date there are only few studies addressing an impairment of the latter. Neither does the European regulation of chemicals include risk assessment concerning olfactory toxicity in fish. Furthermore very little is known about the mechanisms underlying an olfactory impairment. Hence, there is a great need for understanding the molecular mechanisms which lead to an effect on the olfaction in fish in order to be able to find and evaluate suitable endpoints that could be included in the testing of chemicals.

#### MO116

##### Micro-scale elemental mapping of brain structures in glass eel *Anguilla anguilla* exposed to Chromium, Copper and Lead

R.M. Godinho, Centro de Ciências e Tecnologias Nucleares Instituto Superior Técnico; P. Pereira, Department of Biology and CESAM; T. Pinheiro, Universidade Lisboa / Instituto de Bioengenharia e Biociências Instituto Superior Técnico; M. Pacheco, University of Aveiro / Dept of Biology Recently brain was pointed as a potential target tissue of environmental metal contamination but the influence of trace elements in fish neurophysiology has been scarcely addressed. Alterations in brain function due to metal imbalances may endanger not only the individual but poses risks to the population. This is relevant considering population dynamics of fisheries. This study investigates elemental distributions changes in brains of juvenile eel *Anguilla anguilla* exposed to Cr, Cu and Pb providing insights into brain vulnerability to metal pollution. Eel is widely studied as sentinel organism and as a teleost fish, has been used as a model to study the central nervous system of vertebrate species. Eels (glass eel stage) were captured in an uncontaminated site at Minho river mouth, Caminha, Portugal, and kept in filtered tap water in 1L aerated flasks. Groups of five eels were exposed to Pb, Cu and Cr at final nominal concentration of  $50 \mu\text{g L}^{-1}$ . A control group was maintained in tap water. Media was replaced daily. The experience run for 2 weeks during which the animal were not fed. At the end of experiment animals were deep-frozen in liquid nitrogen. Transversal sections of  $20 \mu\text{m}$  at the head region were obtained in a cryo-microtome and freeze dried. The elemental distributions were assessed quantitatively using nuclear microscopy techniques. Mass density

images were obtained with STIM (scanning transmission ion microscopy) and elemental quantification was carried out by combining PIXE (particle induced X-ray emission) and RBS (Rutherford backscattering spectrometry). Major brain regions were identified using both mass density variations and elemental distributions, having optical micrographs of stained sections as reference. Cellular arrangements could be identified by trace elemental profiles and concentrations. Elemental maps, namely Ca, Fe and Zn, enabled to distinguish the grey matter, white matter and cellular layers. Exposed animals showed altered elemental distributions that highlight homeostasis modification, altered permeability of the blood-brain barrier and suggest risk for neurological toxicity. The inventory of physiological measures containing images and elemental compositions of brain regions of fish exposed to different environmental conditions will help defining total and local brain vulnerability to metals and pollution levels.

#### MO117

##### Integration of multi-level biomarker responses of the pale chub exposed to wastewater effluents in Miho stream

W. Kim, Korea Institute of Toxicology (KIT) / Environmental Toxicology Research; S. Lee, Korea Institute of Toxicology / Ecotoxicology research team; J. Jung, Korea University / Environmental Science and Ecological Engineering This study evaluated the effects of an wastewater treatment plant (WWTP) effluents on multi-level biomarker responses at molecular, biochemical, histological and physiological levels in freshwater pale chub, *Zacco platypus*. At the same time, the contents of polycyclic aromatic hydrocarbons (PAHs), perfluorinated organic compounds (PFCs), alkyl phenols and heavy metals in the surface water and in the liver of fish at biomonitoring sites were measured. Heavy metal Cu ranged 1.4-1.8  $\mu\text{g/L}$ , Zn ranged 1.7-5.6  $\mu\text{g/L}$ , but other metals, PAHs, PFCs, alkyl phenols did not detected. Our findings showed that various molecular and biochemical or physiological response were significantly increased at the downstream site compared to those of the upstream, and these responses primarily depended on accumulated metal concentrations. The mRNA expression of glutathione S-transferase (GST) and metallothionein (MT) at the molecular level were significantly increased but catalase (CAT), superoxide dismutase (SOD) and 7-ethoxoresorufin-O-deethylase (EROD) enzymatic activity at the biochemical levels were significantly decreased excepting increase of MT in downstream site compared to those of the upstream. In addition, significant changes to the liver somatic index at the physiological level were observed in downstream. The current findings demonstrate that the primary causes affecting fish health in the downstream site are through cascade of adverse effects caused by accumulated heavy metals from effluents. According to multivariate analysis, oxidative stress markers and physiological parameters were key biomarkers to contribute in effluent site from upstream and downstream sites. The results demonstrated that combined bioaccumulation and multi-level biomarker responses could offer great promises for providing information that can contribute to effluent assessment.

#### MO118

##### Evaluating the effects of ocean acidification on sand-smelt larvae: a case study addressing biochemical biomarkers and swimming ability

C.S. Esteves da Silva, Polytechnic Institute of Leiria / Marine Resources Research Group; S.C. Novais, Polytechnic Institute of Leiria / ESTM and GIRM; A.R. Lopes, Faculdade de Engenharia - Universidade do Porto / LEPABE Laboratório de Engenharia de Processos Ambiente Biotecnologia e Energia; M.F. Lemos, Instituto Politécnico de Leiria / Dept Biology; E.J. Gonçalves, A.M. Faria, ISPA Instituto Universitário / EcoEthology Research Unit

Although ocean acidification is a critical global problem known for decades, scientific investigation of its effects is still in its infancy. To date, most research has been conducted on calcifying organisms and little attention has been given to the potential impact on other ecosystem processes and components like early life-stages (larvae and juveniles) of non-calcifying organisms. Due to their vulnerable physiological state, small body size and high sensitivity to environmental variation, the effects of acidification are most likely to be detected at these early developmental stages. The main aim of this study was to investigate the effects of three different concentrations of  $\text{pCO}_2$  in the early stages of sand-smelt, *Atherina presbyter*, a temperate fish species common in Atlantic European coastal waters with some economic interest. Wild larvae in flexion and post-flexion were caught in Arrábida Marine Park, Portugal and were kept in controlled conditions with different  $\text{pCO}_2$  levels (Control:  $\sim 400 \mu\text{atm}$ ; Medium:  $\sim 1000 \mu\text{atm}$ ; High:  $\sim 1800 \mu\text{atm}$ ) between 7-10 days. The swimming ability ( $U_{crit}$ ) of larvae was evaluated as a behavioural endpoint, together with biochemical biomarkers related with oxidative stress (superoxide dismutase, catalase, lipid peroxidation, DNA damage and superoxide anion) and energy metabolism (carbohydrate levels, electron transport system activity, lactate dehydrogenase and isocitrate dehydrogenase). Results showed significant differences in some of endpoints studied, suggesting effects of ocean acidification. The information obtained on this species sensitivity to ocean acidification, in early life stages, is of great importance to predict behavioural responses (feeding habits, dispersal mechanisms, habitat selection, orientation, recruitment and predator avoidance) that can influence societal processes, biodiversity and ecosystem function.

#### MO119

##### Endocrine disrupting effects of Tritan™ copolyester using *Oryzias latipes*,

## H295R cell line, and GH3 cell line

S. Jang, Dept Occupational and Environmental Health; B. Kwon, Dept. Occupational and Environmental Health / Department of Environmental Health; K. Ji, Yonjin University

In response to the restriction of the use of bisphenol A, a novel plastic form called Tritan™ copolyester was manufactured by Eastman company as an alternative for the production of polycarbonate plastics and resins. While three main monomers of Tritan™ are high production volume chemicals both in the US and the European Union, only limited information is available on their endocrine disrupting effects. In the present study, we investigated the endocrine disruption potentials and underlying mechanisms of cyclohexanedimethanol (CHDM) and terephthalic acid (TPA). Early-life stage toxicity test of Japanese medaka (*Oryzias latipes*) was performed in accordance with OECD test guideline 210, and survival, growth, and changes in gene expression were observed after the 40 d exposure to CHDM and TPA. Human adenocarcinoma (H295R) cell line and GH3 cell line were also employed for the quantitative evaluation of xenobiotic effects on steroidogenesis and thyroid endocrine system, respectively. In early-life stage exposure to *O. latipes*, significant decrease of juvenile survival and weight were observed in fish exposed to 10 mg/L and ≥1 mg/L CHDM, respectively. Expressions of *cyp19b*, *cyp19a*, and *era* mRNAs in fish exposed to CHDM were significantly up-regulated in a dose-response manner. The results of H295R cell assay also showed that both chemicals could alter steroidogenic pathway and increase estrogenicity. CHDM and TPA did not cause significant effects on proliferation rate of GH3 cells in the range of concentration tested. Given the extensive use of tritan™ and their loadings to the environment, their long-term ecological consequences at environmentally relevant concentrations deserve further studies. **Keyword:** Early life stage test, H295R cell, GH3 cell, Tritan *Acknowledgement* – This study was supported by National Research Foundation of Korea (NRF; Project no. 2013R1A1A1061684).

## MO120

### Effects of selected PhACs at environmentally relevant concentrations on rainbow trout (*Oncorhynchus mykiss*)

T. Randak, University of South Bohemia in Ceske Budejovice Faculty of Fisheries and Protection of Waters / Laboratory of Environmental Chemistry and Biochemistry; V. Burkina, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses Vodnany Czech Republic; C. Steinbach, University of South Bohemia in Ceske Budejovice; K. Grabicova, University of South Bohemia in CB; R. Grabic, University of South Bohemia in CB / Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses; G. Fedorova, University of South Bohemia in CB / Faculty of Fisheries and Protection of Waters South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses Vodnany Czech Republic; V. Zlabek, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters LECHB  
In recent years, potential risks associated with the release of pharmaceutically active compounds (PhACs) into the aquatic environment have become an increasingly important issue for environmental regulators and the pharmaceutical industry. The aim of this study was to find the effects of selected PhACs mainly at environmentally relevant concentrations on rainbow trout (*Oncorhynchus mykiss*). Four representatives of the most used classes of human pharmaceuticals atenolol (AT), verapamil (VRP), clotrimazole (CLO) and diltiazem (DIL) were chosen for this study. Selection was based on the consumption, published data and our screening studies performed in surface water. Chronic toxicity tests with individual pharmaceutical were performed. The tested concentrations included environmentally relevant concentration, 1% 96-h LC 50 and 10% 96-h LC 50. The test fish were sampled after 21 and 42 days of exposure. In these tests, the effects on fish were studied using following endpoints: haematological parameters and biochemical profile of blood, oxidative stress biomarkers and antioxidant enzymes activities, histology, vitellogenin concentration in blood plasma, enzymatic activity of CYPs in liver and chemical analyses. At the environmentally relevant concentration, AT caused a decrease in the haemoglobin concentration, an increase in the lactate content of the blood plasma and congestion suggesting a reduction in oxygen supply. Although we did not observe any effects of VRP on studied endpoints at environmentally relevant concentration in the present study, we cannot exclude the possibility that it might affect fish after a longer exposure. Our study demonstrated that CLO altered structural histological and intracellular events in rainbow trout. At environmentally relevant level, DIL affected the biochemical profile of the blood and altered the activities of the antioxidant enzymes in gills and liver. Our findings indicate that tested PhACs could have a potential for causing sub-lethal effects in fish living in the aquatic environment. *Acknowledgement* - The study was financially supported by the MEYS of the CR - projects „CENAKVA“ (No. CZ.1.05/2.1.00/01.0024) and „CENAKVA II“ (No. LO1205 under the NPU I program), by the Grant Agency of USB GAJU 087/2013/Z and the Grant Agency of Czech Republic P503/11/1130.

## MO121

### Effects of Diuron and its main biodegradation products to Nile tilapias, in the presence or absence of alkylphenols

A. Felicio, Department of Chemistry and Environmental Sciences; T. Piloto Duarte, E. Alves de Almeida, São Paulo State University UNESP / Department of

Chemistry and Environmental Sciences; D. Schlenk, University of California-Riverside / Department of Environmental Sciences  
Diuron is one of the most commonly used herbicide in sugarcane cultivation in the São Paulo State. The risks that this compound represent for aquatic organisms that inhabit rivers and lagoons close to sugarcane crops are tough not well understood, despite it have been found in rivers and also subterranean water. Although diuron have a relative low persistence in the environment, its biodegradation metabolites, such as dichloroaniline (DCA), dichlorophenyl-urea (DCPU) and dichlorophenyl-methyl-urea (DCPMU) could also represent a risk for the exposed biota. Moreover, commercial formulations of diuron generally present adjuvants that could further alter the effects and fate of diuron in fishes, despite all these aspects were not studied yet in these organisms. Considering the extensive use of diuron in sugarcane cultivation in the São Paulo State and the potential risks that this compound and its derived metabolites and adjuvants could pose to fish, in this work we measured a series of biochemical parameters in liver, gills and blood of Nile tilapias, in order to evaluate the negative effects that these compounds might exert in fish, at environmentally relevant concentrations. A series of experiments were done by exposing Nile tilapias to Diuron, DCA, DCPU, DCPMU and two alkylphenol surfactants commonly used as dispersants in pesticide formulations, octylphenol (OP) and nonylphenol (NP), alone or mixed, for seven days. Our results showed that both diuron and its biodegradation metabolites are prone to alter antioxidant defense systems and biotransformation enzymes, and were in some cases genotoxic to fish, changing DNA damage levels. Mixtures of Diuron with its metabolites caused slight differences in biomarkers responses compared to the effect of isolated compounds, but a stronger effect was observed for mixtures with OP and NP. Diuron and its metabolites, showed to be slightly estrogenic, since changed the enzymes involved in estrogen hormone metabolism (aromatase and CYP3A4) and vitellogenin levels, as well as alterations in testosterone level were observed. Taken together, our results clearly demonstrated that diuron or its biodegradation metabolites, at concentrations found in aquatic environments, can impair the metabolism of Nile tilapias, especially in the presence of alkylphenols, indicating that the presence of these compounds in environmental may represent a risk for the aquatic biota.

## MO122

### Effects of Copper on the Serum Parameters of Freshwater Fish (*Oreochromis niloticus*) in Differing Calcium Levels

M. Canli, Cukurova University / Biology; E.G. CANLI, University of Cukurova / Biology

One of the most important factors affecting metal toxicity in the aquatic environment is the free ion levels of waters. Calcium ( $\text{Ca}^{+2}$ ) is the predominant ion in freshwater. Thus, in the present study, the freshwater fish *Oreochromis niloticus* were exposed to copper in differing  $\text{Ca}^{+2}$  levels (15, 30 and 90 mg/L) using acute (0.3  $\mu\text{M}$ , 72 h) and chronic (0.03  $\mu\text{M}$ , 30 d) exposure protocols. Following the exposures, serum parameters (ALP, ALT, AST, protein, glucose, cholesterol, triglyceride,  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{+2}$ ,  $\text{Cl}^-$ ) of fish were measured. Data showed that there was no significant alteration ( $P>0.05$ ) in any of the studied parameters in control conditions in which only  $\text{Ca}^{+2}$  levels changed. However, there were several alterations following copper exposure, especially at the lowest  $\text{Ca}^{+2}$  level. Activities of ALP, ALT and AST decreased significantly at the lower  $\text{Ca}^{+2}$  levels in chronic exposure. Protein levels did not differ significantly in any of the exposure conditions. However, Cu exposure at the lowest  $\text{Ca}^{+2}$  level sharply increased the levels of glucose in the acute exposure, while there was no significant difference in the chronic exposure. Cholesterol levels decreased only at the lower  $\text{Ca}^{+2}$  levels in chronic exposure, but not in acute exposure. Similarly, triglyceride levels only altered at the lowest  $\text{Ca}^{+2}$  level both in acute and chronic exposures. In conclusion, this study showed that copper exposure of fish at lower  $\text{Ca}^{+2}$  levels caused more toxicities, comparing to the higher  $\text{Ca}^{+2}$  levels. Data suggest that  $\text{Ca}^{+2}$  levels of waters may be used in the evaluation of metal toxicity data from different waters with different chemical characteristics. **Keywords:** Copper, Calcium, Serum, Fish

## MO123

### Cytotoxicity of herbicide clomazone and two formulations of this substance on rainbow trout gills cell line

M. Stevanovic, K. Hilscherova, Masaryk University, Faculty of Science, RECETOX / RECETOX Research Centre for Toxic Compounds in the Environment; M. Michelova, Masaryk University, RECETOX / Faculty of Science RECETOX; L. Blahova, Research Center for Toxic Compounds in Environment; D. Brkic, Institute for Pesticides and Environmental Protection; S. Gasic, Institute of Pesticides and Environmental Protection

Clomazone is herbicide substance used in controlling grass and broad leaf weeds. Due to its high mobility and solubility clomazone can reach water bodies and affect organisms. Frequently, toxicity data for formulated pesticide products are based only on toxicity testing of the active substance, despite possible great difference between formulation and active substance. Fish gills are one of the first organs in contact with waterborne chemicals, and as a site of gases exchange their function can be disturbed. With respect to 3R base approach, in vitro assays are being evaluated as an alternative for acute toxicity testing on adult fishes. The aim of this work was to assess and compare toxicity of herbicide substance clomazone and two commercial formulations of this substance (Rampa and GAT36CS) on cell line RTgill-W1 derived from gills of rainbow trout (*Oncorhynchus mykiss*). For that

purpose three cytotoxicity endpoints were evaluated: decline in metabolic activity, disturbance of plasma membrane integrity and disruption of lysosomes. Fish gill cells were exposed to above mentioned substances for 24h in dark using 96-well microplates. After exposure period, based on percentage of cell viability in comparison with negative control, the EC50 was calculated. Metabolic activity was the most affected endpoint for active substance - clomazone (EC50=78.6 mg/l). While GAT36CS did not show any cytotoxicity up to 100 mg/l, the effective concentration of Rampa regarding inhibition of metabolic activity was 12 fold lower than active substance (EC50=6.7 mg/l). The same rank of toxicity was confirmed by test focused on disruption of lysosomes with EC50 of 6.4 mg/l for Rampa, 95.8 mg/l for clomazone and >100 mg/l for GAT36CS, respectively. Obtained results indicate that toxicity of active substance and formulated products differ. Depending on the technology of formulation and included coformulants toxicity of product can increase or decrease. Therefore, the limits based on the effects of active substance can severely underestimate the effects of formulation, which could at the concentration safe for the active substance lead to adverse effects on organisms in affected environment. On the other hand, the testing approach based on specific formulations can identify the applications least affecting the environment and help to revise the doses of pesticide recommended for application. Acknowledgements: This investigation was financially supported by the Ministry of Education, Science and Technological Development of the Republic of Serbia under the project No. III46008 and RECETOX Research Infrastructure (project of the Ministry of Education of Czech Republic LM2011028) and project LO1214.

## MO124

### Chemical treatment to reduce sugarcane vinasse toxicity: mortality and micronucleus decrease in *Oreochromis niloticus* (Pisces)

J.E. Correia, Universidade Estadual Paulista Julio de Mesquita Filho / Environmental Mutagenesis; C.A. Christoforetti, Fundacao Herminio Ometto / Environmental Mutagenesis; Y. Ansoar-Rodríguez, UNESP- São Paulo State University / Biology; T.A. Guedes; A.d. Marcato, N. Riguetto-neto, C.M. de Sousa, São Paulo State University UNESP / Department of Biology; R.B. Souza, C. Fontanetti, Sao Paulo State University - UNESP / Biology

The production of industrial wastes and their disposal are topics of great relevance nowadays. In Brazil, the vinasse, a residue from the distillation of sugarcane to ethanol, stands out because for every liter of alcohol produced is generated 10-15 liters of vinasse as waste. Of all liquid effluents of the alcohol industry, the vinasse is the one with the highest pollution load, about a hundred times greater than the raw sewage; has large amount of organic matter, low pH, high power corrosion and high rates of biochemical demand oxygen (BOD), ranging from 20,000 to 35,000 mg/L. An alternative for the disposal of this waste is fertigation in sugarcane culture, but the high amounts released can saturate the soil and by leaching/percolation contaminate water resources. Thus, this study aimed to verify the toxic potential of vinasse using tilapia (*Oreochromis niloticus*) exposed to different dilutions of this residue in water and the effectiveness of physical-chemical treatment of these residue through pH adjustment with lime (CaOH). For toxicity analysis were used micronucleus test in erythrocytes. Fish were exposed to dilutions of 1%, 2.5%, 5% and 10% for 96 hours; the negative control was done in clean water and in the positive control, cyclophosphamide was injected. Two bioassays were performed with non-treated vinasse and the experiment with treated vinasse was carried out in reply. Data were statistically analyzed by the Shapiro-Wilk test methods and Kruskal-Wallis. Bioassays with non-treated vinasse dilutions indicated a toxic and genotoxic potential of vinasse; in the highest concentration all fish died before 48 hours of exposure; the incidence of micronucleus was significant for all dilutions. After exposure of tilapia to the chemically treated vinasse, three fish at 10% dilution died. The neutral pH (7.0) has not remained stable during the experiment. There were no significant differences between the values of micronuclei and nuclear abnormalities between dilutions and negative control; comparing these results to those of bioassays with non-treated vinasse, a decrease of the micronuclei values was observed. Chemical treatment of vinasse by adjusting of pH with lime was effective and it is an economically viable alternative in reducing the toxicity of this waste, since reduce fish mortality at the highest concentrations and the incidence of micronuclei. ## MO125

### Are fish from polluted hyper-eutrophic impoundments healthy and safe for human consumption?

I. Wagenaar, B. Bester, J. van Dyk, University of Johannesburg / Department of Zoology

The Bojanala Platinum District in the North West Province is a well-established mining and agricultural region of South Africa. These activities result in surface runoffs that cause pollution in the nearby freshwater impoundments namely the Roodekopjes (RD) and Vaalkop Dams (VD). These impoundments support subsistence fishing, where the fish caught, are often the sole source of dietary protein for local communities. The aim of this study was *firstly* to assess the health status of fish in the RD and VD, known to be polluted with unacceptable levels of organochlorine pesticides. *Secondly* to assess the potential health risk through consumption of fish from these polluted hyper-eutrophic impoundments. Two freshwater fish species *Clarias gariepinus* and *Cyprinus carpio* were sampled with gill nets. For the health status a necropsy-based macroscopic evaluation was

conducted, the biometric indices were calculated and a semi-quantitative histology-based fish health assessment was performed on six target organs. Water, sediment and muscle samples were analysed for organic and inorganic pollutants. In order to determine whether the fish were safe for human consumption, the bio-accumulated levels of the organic and inorganic toxicants within the muscle of the fish were used and the potential health risk/s through consumption of these fish was calculated. Results from the two assessment sites (RD & VD) were assessed against a reference site, the Marico-Bosveld Dam (MD). The chemical analysis showed numerous organic and inorganic toxicants in both the water and sediments with the RD more polluted than the VD. The microscopic assessment showed few to moderate structural alterations in four of the six target organs of both species at all sites. Under worst-case scenario conditions, a slight toxic risk was posed through the consumption of either *C. gariepinus* from RD, VD and MD or *C. carpio* from RD and VD as a result of the high arsenic levels detected within each fish species. There were a cumulative toxic risks posed from a combination of the detected toxicants present in the fish muscle in both species from each impoundment. A cancer risk was evident due to the arsenic and the carcinogenic effects of beryllium (Be) and  $\beta$ -HCH.

## MO126

### Analytical characterization of new arsenolipids in herring fish

C. Piechotta, BAM- Federal Institute Materials Research and Testing / Analytical Chemistry Reference Materials; U. Arroyo-Abad, BAM Federal Institute Materials Research and Testing / Analytical Chemistry; J. Mattusch, Helmholtz Centre for Environmental Research UFZ / Analytical Chemistry Department; S. Lischka, BAM Federal Institute Materials Research and Testing / Analytical Chemistry Department

1. Introduction Since 1968 it is postulated by Gulbrand Lunde that lipid-soluble arsenic compounds can accumulate in the muscle tissue of fatty fish, such as herring (*Clupea harengus*). [1] Although marine organisms have been studied extensively but only a few reports on the analytical characterization of these species have been published recently. In the 60s Lunde was the first who determined an arsenic content in different fish oils up to 20 mg?kg<sup>-1</sup>. [2, 3] Since then three classes of arsenolipids could be identified and characterized: arsenic hydrocarbons (As-HC), [4] arsenic containing fatty acids (As-FA) [5] and arsenosugar phospholipids (As-Sug PL). [1, 6, 7] 2. Materials and methods In this current work more than 20 fat-soluble arsenolipids could be identified and semi-quantified in herring fillet by using hyphenated techniques like HPLC-ICP-MS and ESI-Q-TOF-MS. By structural assignment depending on the exact masses and targeted MS-MS experiments, the fragments allowed an unambiguous characterization. Seven previously unknown arsenolipids in herring could be identified. An investigation of other fish species showed that these arsenic compounds are distributed in different marine fishes and sea food. 3. Results and discussion Metabolic studies have shown that there is an increased concentration of carcinogenic dimethylarsinat (DMA) in human urine after consumption of herring. Furthermore inorganic arsenic, DMA and MMA could be excluded from the results as a potential cause. [8, 9] Since arsenobetaine has shown that it is not metabolized *in vivo*, the results achieved in this work are useful to strengthen the hypothesis that the identified arsenolipids can be degraded to DMA. ## MO127

### Appropriateness of largemouth bass (*Micropterus salmoides*) as a model species for detection of endocrine disruption

A. Leasca, W. Liu, C. Kim, S. Patel, L. Poulsen, S. Shah, T. Throwe, R. Tripu, University of Maryland College Park; L.T. Yonkos, University of Maryland / Environmental Science and Technology

The discovery of intersex in the form of testicular oocytes (TO) and frequent detection of vitellogenin (Vtg) in male smallmouth and largemouth bass (*Micropterus dolomieu* and *M. salmoides*, respectively) in the Chesapeake Bay watershed has raised concerns for the aquatic food web and for the quality of regional drinking water resources. Intersex has been correlated with regional intensity of anthropogenic activity (e.g., agricultural land use, CAFOs, WWTP outfalls) but not causally linked to any specific endocrine disrupting chemical. Likewise, windows of particular sensitivity to TO and Vtg induction are not well understood. To address this knowledge gap discrete groups of hatchery-reared largemouth bass (LMB) were exposed at ages of 2-3 months post hatch (mph), 5 mph, 12 mph, and 18 mph for 14-d to aqueous poultry litter mixtures, a 17 $\beta$ -estradiol (E2) positive control, and a negative control. A subset of fish was sacrificed at the end of each exposure and plasma analyzed for Vtg. Remaining fish were maintained under control conditions to an age of 21 months before sacrifice and tissue fixation for histological detection and enumeration of TO. Adult male fathead minnows (*Pimephales promelas*) were also exposed to allow inter-species comparison of sensitivity to Vtg induction. Histological examination of LMB gonads suggests only minimal prevalence of TO (< 5%) and no apparent treatment

effect. Plasma analysis via ELISA found significant Vtg induction in mature male fathead minnows (FHM) exposed to the E2 positive control. In contrast, only minimal Vtg induction was found in male LMB at any exposure age. This disparity in response between the two species to aqueous estrogenic stimuli was further explored by exposing mature male FHM and mixed-gender juvenile (3 mpm) LMB to a series of E2 treatments (~ 2.0 ng/L, 10 ng/L and 40 ng/L) with groups (n = 8) subsampled at 4-d, 7-d, 10-d and 14-d and plasma collected for Vtg analysis. Resulting response surfaces indicate a dose-response in FHM Vtg induction as a function of both duration of exposure and E2 concentration. In contrast, LMB produced minimal Vtg at all sample durations and exposure levels. Despite frequent occurrence of TO and detection of Vtg in native male LMB, this species may be poorly suited as a model for investigations into endocrine disruption under standard laboratory exposure scenarios.

## MO128

### **Trophic transfer of the neurotoxin BMAA from the bivalve *Dreissena polymorpha* to the fish *Rutilus rutilus* and impact on the fish**

E. Lance, University Reims Champagne Ardennes / Biology and Biochemistry; S. Lage, University of Stockholm / Dept of Ecology; S. Jolly, URCA/Ineris; O. Palluel, INERIS / Unité détoxicologie in vitro et in vivo; O. Dedouge-Geffard, University of Reims Champagne-Ardenne / UMRI Unité Stress Environnementaux et BIOSurveillance des milieux aquatiques; J. Porcher, INERIS / UMRI SEBIO; S. JONASSON-RYDBERG, U. Rasmussen, University Stockholm / Department of Ecology; A. Geffard, Université de Reims Champagne Ardenne / Interactions Animal-Environnement (IAE)

Due to eutrophication of freshwaters, the frequency of cyanobacteria proliferations is increasing worldwide and the presence of associated cyanotoxins represent a threat for ecosystems and for human health. Most cyanobacteria produce a neurotoxic amino acid  $\beta$ -methylamino-L-alanine (BMAA) linked to serious neurodegenerative diseases (amyotrophic lateral sclerosis (ALS), Alzheimer and Parkinsonism). Knowledge should be extended about the scale of BMAA accumulation in the foodweb and also about its impact on aquatic organisms. We previously demonstrated that the bivalve *Dreissena polymorpha* accumulated free and bound BMAA in tissues during an exposure to dissolved BMAA. Therefore *D. polymorpha* is potentially a BMAA-vector through the food web. This study focus on the trophic transfer of BMAA between *D. polymorpha* and the fish *Rutilus rutilus* and the consequences on this latter in terms of: 1) BMAA accumulation and elimination in the liver, brain and muscle, 2) acetylcholinesterase (AChE) activity in the brain and muscle, 3) oxidative stress response in the liver via activities of enzymes catalase (CAT), superoxide dismutase (SOD), Ethoxyresorufin-O-deethylase (EROD), glutathione peroxidase (GPx), glutathione (GSH), and glutathione-S-transferase (GST), and 4) activity of digestive enzymes (amylase and trypsin) in the gut. Fish were fed with BMAA-intoxicated mussels during a 2-weeks intoxication period followed by 1 week of depuration. Results show a BMAA trophic transfer from the bivalve to the fish with an accumulation of BMAA in the brain, liver and muscle of fish after 4 days of ingestion of BMAA-intoxicated mussels. BMAA content in fish organs increased from day 4 to day 14 of exposure with a maximum of  $3.16 \pm 2.07 \mu\text{g BMAA g}^{-1}$  protein in muscle. BMAA content decreased during the depuration period in the fish liver and in the brain but increased in muscle up to  $5.7 \pm 4.53 \mu\text{g BMAA g}^{-1}$  protein at the day 7 of depuration. No significant alteration in the activity of amylase, trypsin, SOD, GSH and GST enzymes was reported. In the liver GPx and EROD activity were respectively decreased and increased after 4 days of exposure, whereas CAT activity was decreased after 14 days. The neurotransmitter AChE showed a decreased activity in the brain at the end of the depuration period.

## MO129

### **A preliminary exploration of the relationship between LC50 and individual body weight for fishes**

C. Lu, Beijing Normal University / Beijing Normal University Academy of Disaster Reduction and Emergency Management

Prediction of lethal effect on organism of interest that lacks of test data is critical for risk assessment of chemicals on aquatic ecosystems. The authors considered body weight of organism plays an important role in counteracting toxic stress imposed by certain chemical. To explore the influence of body weight to toxic effect, Ecotox database for zinc and lead were retrieved and the 96-hr LC50 values for fishes were correlated to corresponding body weights. No significant correlation was found if all records were used. In light of the knowledge that test circumstances such as pH, temperature, hardness, dissolved oxygen may throw remarkable influence on the observed toxicity, the test results that were obtained beyond a normal condition were excluded so as to reduce data variability. The remaining zinc LC50 data including 618 records and lead LC50 data including 581 records were subjected again to a correlation analysis with respective body weight data, and the results showed that both correlations were statistically significant. For example, the wet weight (mg) of saltwater fish in low test temperature ( $\leq 14$  degree Celsius) has a very significant power correlation with the 96-hr LC50 (mg/L) of zinc ( $R^2=0.92$ ,  $n=37$ ). However, in high test temperature ( $\geq 19.3$  degree Celsius), the wet weight (mg) of saltwater fish has a significant linear correlation with the 96-hr LC50 (mg/L) of zinc ( $R^2=0.71$ ,  $n=53$ ). As a preliminary exploration of the relationship between toxic effects and individual body metric, this research seemed prospective for ecological risk assessment and merits further investigation. Keywords: Body

weight, LC50, Lead, Zinc

## MO130

### **Effect of dietary 2,2',4,4'-tetrabromodiphenyl ether (BDE-47) exposure in developing medaka fish (*Oryzias latipes*).**

M. Gonzalez-Doncel, National Institute for Agricultural and Food Research and Technology / of the Environment; G. Carbonell, Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria / Department of Environment; S. Sastre, National Institute for Agricultural and Food Research and Technology / Department of Forest Ecology; E. Beltrán, National Institute for Agricultural and Food Research and Technology / Department of the Environment; C. del Rio, INIA; C. Fernandez-Torija, National Institute for Agricultural and Food Research and Technology / Department of the Environment

Previous investigations conducted in our laboratory with medaka embryos showed low toxicity when exposed under semi-static conditions to waterborne BDE-47. This was probably due to its fast dissipation from the water column limiting its bioavailability. This dissipation made BDE-47 presence unachievable at constant concentrations thus concluding the invalidity of this approach of embryonic exposure. We therefore encouraged the use of more realistic exposure routes to BDE-47 or other similar PBDEs. Here, we are addressing the effects of a 40-day food dose with BDE-47 (0, 10, 100, 1000 ng/g). We dosed medaka as early as from 7 days post hatch (dph) to 47 dph and accumulation, overall growth and swimming were evaluated throughout the dosing period and during the subsequent 50 dph. This environmentally realistic exposure route resulted in a dose-response accumulation as well as increasing BDE-47 accumulated in fish. However, accumulated BDE-47 decreased after doses ended. However, we did not observe significant effects on general growth and on swimming performance during the whole observational period. This work was made possible by Spanish Government Grant CTM2013-44986-R.

## MO131

### **Extending the Application of Arabian Gulf Killifish Embryo Test for Risk Assessment of Heavy Metals in Qatari waters**

S. Saeed, D. Deb, D. Dupont, ExxonMobil Research Qatar

Fish embryos are excellent models for studies aimed at the understanding of toxic mechanisms and the indication of possible acute and chronic effects. For the past 3 years, an Arabian killifish fish embryo test (FET) has been developed in our laboratory as a routine ecotoxicological test for risk assessment of potential contaminants in the Arabian Gulf around Qatar. To further explore the applicability of the killifish embryos as a model for the Arabian Gulf conditions, we tested the toxicity of heavy metals such as zinc and copper using Arabian seawater conditions. A breeding stock of sexually mature killifish, variable in age, was used for egg production. Eggs from several females were pooled and placed in salt water. Embryos were examined under a dissecting microscope and viable embryos that were less than 6 h were selected. Eggs were distributed in replicates by stratified random assortment into 24 well plates. Observation was performed in 48-hour increments ( $\pm 2$  hours). Endpoints included: coagulated eggs, absence of heartbeat, tail deformity and delayed hatching. Literature review was compiled for fish species that have been recommended for ELS toxicity testing. The data collected was then used for comparison to the current findings and the sensitivity was then extrapolated for the killifish embryos. Past findings indicate that toxicity is reduced in higher salinity waters. This was confirmed in this study where at salinity 40 psu there were no apparent effects on embryos for any concentration tested and all embryos hatched at expected duration. When salinity was reduced from 40 to 20 psu metal toxicity increased significantly ( $P > 0.05$ ). Examination of the existing literature on acute Zn and Cu toxicity to fish and larvae showed similar results to the findings in this study using killifish embryos. The findings further support the use of killifish embryos as indicator organisms for environmental risk assessments of Qatari waters. Benefits include; sensitivity to wide range of substances and conditions, animal alternative, ease of fish breeding, clarity of the embryos, reduced sample size, reduced waste generation and shorter study duration. By expanding this test to evaluate its sensitivity towards other potential contaminants in the Arabian Gulf, we will further enhance the potential of killifish embryos to be adopted as a model species in marine ecotoxicology and risk assessment in this region.

## MO132

### **Manganese sulfate decreases the survival of whitefish (*Coregonus lavaretus* L.) embryos and larvae**

H.E. Arola, University of Jyväskylä / Department of Biological and Environmental Science; J. Karjalainen, University of Jyväskylä; J.V. Kukkonen, University of Jyväskylä / Biological and Environmental Science; E. Vehniäinen, University of Jyväskylä / Department of Biological and Environmental Science; A. Väisänen, University of Jyväskylä / Department of Chemistry; A. Karjalainen, ECHA-European Chemicals Agency

Metal mining can have significant and long lasting effects on aquatic environment. Recently, the focus has turned towards the excessive loads of natural substances caused by metal mining. Elevated manganese (Mn) and sulfate ( $\text{SO}_4$ ) concentrations have been observed in water bodies receiving metal mining effluents, and at worst  $\text{SO}_4$  induced salinization has led to halocline development, and thus hypoxia or anoxia in the hypolimnion of the recipient lakes. However, the

effects of such natural substances on aquatic organisms are not that well known. We studied the effects of manganese sulfate ( $\text{MnSO}_4$ ) on whitefish (*Coregonus lavaretus* L.) embryos and larvae, and the significance of parental effect on observed responses. Early development in fish is considered the most sensitive phase to environmental stressors, with fertilization and hatching the most sensitive stages of the early development. Metal exposure during any stage of early development is known to weaken the larval quality and quantity. Also abnormally elevated salinity can decrease the survival of freshwater fish embryos throughout their development. Whitefish embryos and larvae were exposed to eight ecologically relevant  $\text{MnSO}_4$  concentrations in geometric series from 0.007 to 568.4  $\text{mg L}^{-1}$  of  $\text{SO}_4$  and 0.004 to 325.0  $\text{mg L}^{-1}$  of Mn under semi-static conditions. The continuous exposure was started from the fertilization, and larvae were reared for three days after hatching. Embryonic mortality was observed 2 - 3 times per week and number of hatched and dead larvae were observed daily. Embryo samples for metal uptake and gene expression analyses were collected before the water temperature rising was initiated to induce hatching. The  $\text{MnSO}_4$  exposure did not have clear effect on the total fertilization success, but it decreased the total survival of embryos and larvae. None of the embryos hatched successfully in the highest  $\text{MnSO}_4$  concentration (568.4  $\text{mg SO}_4 \text{ L}^{-1}$ , 325.0  $\text{mg Mn L}^{-1}$ ), and hatching and survival of the larvae was significantly decreased in the second highest concentration (113.7  $\text{mg SO}_4 \text{ L}^{-1}$ , 65.0  $\text{mg Mn L}^{-1}$ ) as well. Even though the effects on survival were most evident in the highest concentrations, the preliminary embryonic metal uptake results showed elevated Mn levels in embryos in nearly all exposure concentrations. The ongoing gene expression analyses of the embryos may reveal possible stress response dynamics. The role of parental effect on the observed responses will also be defined.

### MO133

#### **Toward identification of fish specific estrogens through effect-directed analysis based on zebrafish *in vitro* and *in vivo* reporter gene assays**

M. Sonavane, INERIS / Department of Ecotoxicology; F. Brion, INERIS / Ecotoxicology Unit; N. Creusot, C. Turies, INERIS; J. Porcher, INERIS / UMRI SEBIO; S. Ait-Aissa, INERIS / Ecotoxicology Unit  
Estrogens are present in all vertebrates, from teleosts to mammals, which can bind to and activate estrogen receptors (ERs) through a conserved mechanism. However, existence of cross-species differences as regards ER subtypes and the binding affinity of (xeno)estrogens on ERs, as well as the cellular context may lead to differential ER activation by environmental contaminants when assessing hazard on aquatic organisms. For this purpose, we previously developed, characterized and demonstrated the functionality of stable zebrafish (zf)-ER subtypes (zfER $\alpha$ , zfER $\beta$ 1, zfER $\beta$ 2) in the zebrafish liver (ZFL) cell line and transgenic cyp19a1b-GFP zf embryosto quantify estrogenic activity in complex mixtures. In the present study, we used **zebrafish (zf)-based *in vitro* and *in vivo* bioassays** to assess estrogenic activity in surface waters by investigating 20 French river sites using polar organic chemical integrative sampling (POCIS). Simultaneously, the human MELN bioassay (MCF-7 cells-based, expressing hER $\alpha$ ) was used to study cross-species differences. POCIS-based bio-monitoring provide significant information on zf-based *in vitro* bioassays as zfERs and hER $\alpha$  assays significantly differed at some sites, identifying zf-specific estrogenic activities in surface waters. Higher numbers of POCIS extracts were found to be more active on zfER $\beta$ s than on zfER $\alpha$ , which is in line with the better sensitivity of zfER $\beta$ s to steroid estrogens. The responsiveness of zfER $\beta$ 2 to environmental samples is important as this ER subtype is present in fish species but not in humans. In complementary to *in vitro* assays, the estrogenic activities at the organism level were observed using zf embryo assay at sites that were highly active on *in vitro* bioassays. These *in vivo* results are relevant for hazard assessment as they reveal that detected active compounds target radial glial cells expressing brain aromatase which are known to be involved in neurogenesis. In addition, combining these zf-based tools within an EDA approach, we were able to isolate fractions that were active only on zfER $\beta$ 2 subtype, hence reinforcing the hypothesis of species-specificity for, yet unknown, ER ligands. Further investigation using mass spectrometry techniques is foreseen to identify fish-specific active compounds which will allow improving bioassay-based environmental risk assessment towards aquatic species.

### MO134

#### **The effect of five quaternary ammonium ionic liquids on *Danio rerio* embryos: do they cause oxidative stress?**

A. Jakubowska, Silesian University of Technology / Environmental Biotechnology Department; E. Kuster, Helmholtz Centre for Environmental Research (UFZ); E. Grabińska-Sota, Silesian University of Technology / Environmental Biotechnology Department

Amongst many industrial applications quaternary ammonium ionic liquids (QAILs) are being tested as novel pesticides. They were proven very effective against many fungi and bacteria strains, as well as insects. Nevertheless they can constitute a threat towards non-target organisms after introducing to the market. They can reach the environment with factory effluents, waste water treatment plants effluents, accidental spills, as well as after being washed out of the site of application into the ground or surface waters. QAILs with didecylmethylammonium cations were already detected in different environmental compartments. The toxic mode of ionic liquids' action is still not well described. The molecular target of ionic liquids with long alkyl chains are membranes but also oxidative stress is thought as a mode of

action. We aimed to evaluate toxic effects of five QAILs towards zebrafish (*Danio rerio*) embryos both on the levels of lethal and oxidative stress in search of correlation with toxicity. Depending on the molecule the formulas involved one, two or three didecylmethylammonium cations ([DDA]) and nitrite, nitrate or citrate anions. To assess the toxic effects of the five compounds the standard 96 h fish embryo acute toxicity (FET) test was performed according to the OECD 236 Guideline. We also measured the reactive oxygen species (ROS) levels in embryos using 2',7'-dichlorodihydrofluorescein diacetate (DCHF-DA) after treating them with the most toxic compound in concentrations of LC<sub>5</sub>, LC<sub>10</sub>, LC<sub>25</sub> and LC<sub>50</sub> for 6 and 24 h. Tert-butyl hydroperoxide (TBHP), a well-known prooxidant was used as a reference compound. The fluorescence proportional to the level of ROS was measured. Five QAILs are highly toxic to *Danio rerio* embryos. The obtained LC<sub>50</sub> values were in the low  $\mu\text{M}$  range. Their lethal action is rapid and occurs before 24 h of the test duration. Hence, the lethal effects were expressed as 24 h- LC<sub>50</sub>. The toxicity highly depends on the number of [DDA] cations and is not correlated with the anion type. The most toxic compound can cause oxidative stress after 24 h of exposure to low effect concentrations.

### MO135

#### **Mechanism of PFOS effects on posterior swim bladder chamber inflation in zebrafish larvae**

D. Vergauwen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences; A. Hagenaars, Zebrafishlab Dept Veterinary Sciences; E. Stinckens, Zebrafishlab Veterinary Physiology and Biochemistry Department of Veterinary Sciences; L. Bervoets, University of Antwerp / Biology; N. Vinas, Mississippi State University; D. Knappen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences  
Perfluorooctane sulphonate (PFOS) is one of the most commonly detected perfluorinated alkylated substances in the aquatic environment due to its persistence and the degradation of less stable compounds to PFOS. PFOS is known to cause developmental effects in fish. The main effect of PFOS in zebrafish larvae is an uninflated swim bladder. As no previous studies have focused on the effect of PFOS on zebrafish swim bladder inflation, the exact mechanisms leading to this effect are currently unknown. The objective of this study was to investigate the mechanism by which PFOS impairs swim bladder inflation. To this end, we first determined the exposure windows during early zebrafish development that are sensitive to PFOS exposure and result in impaired swim bladder inflation. Seven different time windows of exposure (1–48, 1–72, 1–120, 1–144, 48–144, 72–144, 120–144 h post fertilization (hpf)) were tested based on the different developmental stages of the swim bladder. These seven time windows were tested for four concentrations corresponding to the EC-values of 1, 10, 80 and 95% impaired swim bladder inflation (EC<sub>1</sub>= 0.70  $\text{mg L}^{-1}$ , EC<sub>10</sub>= 1.14  $\text{mg L}^{-1}$ , EC<sub>80</sub>= 3.07  $\text{mg L}^{-1}$  and EC<sub>95</sub>= 4.28  $\text{mg L}^{-1}$ ). At 6 days post fertilization, effects on survival, hatching, swim bladder inflation and size, larval length and swimming performance were assessed. For 0.70  $\text{mg L}^{-1}$ , no significant effects were found for the tested parameters while 1.14  $\text{mg L}^{-1}$  resulted in a reduction of larval length. For 3.07 and 4.28  $\text{mg L}^{-1}$ , the number of larvae affected and the severity of effects caused by PFOS were dependent on the time window of exposure. Larvae that were only exposed early (1–48 hpf) or late (120–144 hpf) during development showed no effects on the studied endpoints. The results demonstrate that PFOS does not affect the budding phase, and does not cause deflation of already inflated swim bladders. PFOS clearly affects processes that take place during the inflation phase and might also have an effect on the formation of the tissue layers forming the swim bladder. Currently, we are further investigating these processes by performing microarray analyses and relating our findings to accumulated doses.

### MO136

#### **Evaluation of the Adverse Outcome Pathway (AOP) of aromatase inhibition from the molecular initiating event to the adverse outcome affecting the sexual maturation of zebrafish**

E. Muth-Köhne, M. Teigeler, Fraunhofer IME / Ecotoxicology; V. Schiller, Fraunhofer IME / Institute for Molecular Biotechnology Biology VII; J. Brueckner, German Federal Environment Agency UBA; S. Konradi, Federal Environment Agency (Umweltbundesamt) / Section IV Pharmaceuticals; K. Westphal, Federal Environmental Agency Germany; M. Fenske, Fraunhofer Gesellschaft IME / Ecotoxicology; C. Schaefer, Fraunhofer-Institut / Ecotoxicology  
Adverse outcome pathways (AOPs) describe the linkage of effects of environmental hazards on the molecular level, based on their mode-of-action, to their outcome on organismal/population level. AOPs are intended to provide information on molecular as well as apical level and thus can be considered as useful tool for interpretation of results from ecotoxicological studies. However, it is prerequisite to develop test approaches for analysing molecular events that provide unequivocal links to the corresponding apical endpoint. To date, most studies either focus on the apical endpoints of standard tests or the evaluation of effects at the molecular level. Combined studies are short-handed. We here present the data of a proof-of-principle study with the non-steroidal aromatase inhibitor fadrozole (test concentrations: 10  $\mu\text{g/L}$ , 32  $\mu\text{g/L}$ , 100  $\mu\text{g/L}$ ) in a Fish Sexual Development Test (FSDT) with zebrafish (*Danio rerio*) in compliance with the OECD TG 234 and in combination with gene expression analyses at different time points (48 hpf, 96 hpf, 28 dpf, 96 dpf). The purpose was to define molecular endpoints altered by aromatase treatment and resulting in adverse apical effects. Observed apical effects of fadrozole during the sexual development of fish include a complete shift of the

sex ratio towards males and accelerated maturation already at low concentrations (10 µg/L fadrozole). This is due to the mode of action of fadrozole, which specifically inhibits the activity of Cyp19a1 (aromatase), leading to an inhibition of the conversion of C19-androgens to C18-estrogens, and thus, modulating the steroid hormone concentrations controlling the sex ratio. A molecular key event is the regulation of genes possessing an estrogen-responsive element (ERE) in their promoter region. According to this assumption, we found a significant down-regulation of *vtg1* at the mRNA level in treatments compared to the control as early as 48 hpf and 96 hpf. Further, a regulation of *cyp19a1b* mRNA was observed at 63 dpf, a gene also possessing an ERE. Other regulated genes cumulate in the steroid and terpenoid synthesis pathway (e.g. *mvd*, *lss*, *sc4mol*) and in lipid transport/ metabolic processes (*star*, *apoA1a*, *vtg1*), pathways likely to be controlled by endocrine mechanisms. Taken together, we were able to identify molecular as well as apical endpoints affected by fadrozole and provide evidence for a more comprehensive AOP of aromatase inhibition during sexual development of fish in a single study.

## Systems Biology: increasing the capacity, understanding ecosystems and response mechanisms to model chemicals (including nanomaterials) (P)

### MO137

#### Sorting the signals: meta-analysis of transcriptome data of zebrafish embryos after chemical exposure

A. Schuettler, Department of Bioanalytical Ecotoxicology; R. Altenburger, UFC Centre for Environmental Research / Department of Bioanalytical Ecotoxicology; W. Busch, Helmholtz centre for environmental research - UFZ / Bioanalytical Ecotoxicology

Adverse effects of chemicals on cells and organisms are in many cases either preceded by or result in gene-expression changes. This makes transcriptome analysis a promising tool in ecotoxicological research, e.g. as future bioassay or diagnostic tool for biomonitoring. There are several advantages in comparison to established tools, e.g. the non-targeted approach, allowing assessment of several modes-of-action at the same time, or the possibility to combine assessment of adverse effects with identification of effect-drivers, which will also be helpful in the establishment of adverse outcome pathways (AOPs). Several studies have found specific gene-expression changes in zebrafish embryos after exposure to single chemicals. This shows that the zebrafish embryo – already an established model organism in ecotoxicology – might also have the potential to become an *in vivo* model for ecotoxicogenomics. To take a step from proof-of-principle studies towards usability of transcriptome analysis in biomonitoring or toxicity assessments of chemicals, a systematic and comparative insight into expression signatures of chemical exposure seems promising. We therefore perform a meta-analysis of already published transcriptome data. The analysis will combine the data of several studies using different chemicals, concentrations and timepoints. The aim is to get an overview of commonly or specifically affected genes and pathways. This will hopefully allow the separation of general stress answers and developmental disturbances from specific effects of chemicals. Additionally, specific focus will also be put on the influence of factors like chemical concentration, exposure time and duration or array design on the gene-expression pattern. The results of the meta-analysis will also help to build hypotheses on toxicity of mixtures on a molecular level.

### MO138

#### Metabolic profiling of chicken embryos exposed to PFOA or to PPARα and PPARγ activators

A. Mattsson, Uppsala University / Dept of Environmental Toxicology; A. Kärman, Örebro Universitet / SCHOOL OF SCIENCE AND TECHNOLOGY; B. Brunstroem, University of Uppsala / Dept of Environmental Toxicology

Metabolomics (or metabonomics) is the profiling of hundreds or thousands of metabolites in a tissue or body fluid and how it changes in response to, for instance, treatment with chemicals. Avian embryos develop in the eggs separately from their mothers. Thus the embryonated chicken egg provides a convenient model for exploring effects of compounds on embryonic development without confounding maternal factors. The allantois is an extra embryonic membrane that collects urine and metabolic waste and serves as a reservoir for nutrients. Blood and allantoic fluid can easily be sampled for metabolic profiling. The metabolic profile in the allantoic fluid likely reflects changes over a longer period while blood plasma gives a more instant picture of the metabolome. The overall objective of this study was to explore the chicken egg as a model system for studying pollutant-induced changes in the metabolic profile of the developing embryo. Perfluorooctanoic acid (PFOA) is an embryotoxic environmental pollutant and some of its effects are thought to be mediated by peroxisome proliferator-activated receptors (PPARs), which are lipid sensors and regulate energy metabolism and tissue differentiation. We tested the hypothesis that PFOA induces metabolic changes similar to those induced by PPARα- and/or PPARγ-activation. Chicken embryos were exposed via egg injection on embryonic day 7 (E7) to 50 or 250 µg PFOA/egg or to 150 µg/egg of GW7647 (PPARα-agonist) or rosiglitazone (PPARγ-agonist). Blood plasma and allantoic fluid were collected on E12 and metabolite concentrations were analyzed

using GC/MS and LC/MS. Multivariate data analysis of allantoic fluid revealed drastic changes in metabolic profiles by GW7647 and rosiglitazone; these groups formed two completely separate clusters in OPLS-DA plots. In plasma, only GW7647 separated significantly from the controls. Concentrations of only a few metabolites were significantly changed by PFOA and these were not affected by the PPAR-agonists. The injected doses of 50 and 250 µg PFOA/egg resulted in liver concentrations of ~1 and 4 µg PFOA/g, respectively. Thus, in spite of internal PFOA doses exceeding those found in wild birds we found only little effects on metabolite concentrations. Our results suggest that both allantoic fluid and plasma are useful matrixes for analyzing metabolic perturbations in the chicken embryo. We found no evidence from the metabolic profile that PFOA activates PPARs in chicken embryos.

### MO139

#### Effects of diamine putrescine on biochemical blood parameters in Wistar rats.

F. Campos Pereira, R. Vaz Hara, Unesp - Institute of Biology / Biology; L.C. Gonçalves, L. Souza Franco, R. Ferraz Curtolo, G.A. Alves, G.D. Severi-Aguiar, Uniararas / Programa de PósGraduação em Ciências Biomédicas; M.A. Marin-Morales, UNIVERSIDADE ESTADUAL PAULISTA - UNESP / Department of Biology

Cemeteries have been emerged as a major source of soil and groundwater contamination due to percolation of the necrochurume resulting from cadaveric putrefaction. This compound is rich in several chemical substances, among them the diamine putrescine (C<sub>4</sub>H<sub>12</sub>N<sub>2</sub>), a polyamine that plays an important physiological role in the cell processes of growth, differentiation and apoptosis, besides to participating in DNA synthesis and replication, and RNA transcription. Recently, it have been reported that human exposure to necrochurume could lead to health risks. This study has evaluated biochemical parameters of blood samples from animal submitted to different concentration of diamine putrescine. Four experimental groups were conducted: Control group (Co- distilled water), group 1 (T1- 231.5 mg/kg), group 2 (T2- 138.9 mg/kg), and group 3 (T3- 46.3 mg/kg). The putrescine was administered orally (gavage), and the blood was collected 15, 30 e 56 days after the treatment. The samples were centrifuged at 2,500 xg, in order to obtain the plasma. The plasmatic levels of glucose, total cholesterol, HDL and triglycerides were determined with commercial kits Laborclin®. Biochemical analyzes were performed by spectrophotometry, using the Asys Expert plus Microplate reader, and the significance analysis of the results was performed by ANOVA (test/Tukey, p < 0.05). The blood levels of glucose, total cholesterol, HDL and triglycerides were evaluated in the control groups in three distinct periods. The levels of total cholesterol, HDL and triglycerides showed a significant decrease in the animals treated for 15 days with the lowest concentration. There was a significant decrease in glucose blood levels at all concentrations tested for 30 days. The other results showed no significant differences for any of the parameters. Based on the present work, we highlight the importance of developing further studies with this substance, since it was able to induce a hypoglycemic state and reduce the levels of non-esterified fatty acids and total lipids. These results suggest that increasing blood levels of putrescine may induce disorders in the physiological regulation of triglycerides and the connection between carbohydrate and lipid metabolism. Additionally, our data might indicate that around 56 days of treatment, the organism may be presenting a compensatory biochemical response for recovering homeostasis.

### MO140

#### Effect of ethanol, methanol or dimethyl sulfoxide on cytochrome P4501A activity

S. Sakalli, Faculty of Fisheries and Protection of Waters; V. Burkina, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters

South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses Vodnany Czech Republic; V. Zlabek, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters LECHB; G. Zamaratskaia, Swedish University of Agricultural Sciences / Department of Food Science

The impact of three organic solvents on cytochrome P450 (CYP) 1A enzyme activity was investigated in hepatic microsomes of rainbow trout. Liver samples collected from nine fish and hepatic microsomal fraction was prepared by differential centrifugation. Incubation mixture in a total volume of 260 µl consisted of 0.2 mg microsomal protein, incubation buffer (50 mM potassium phosphate, pH 7.4), the substrate 7-ethoxyresorufin (2 µM) and NADPH (1 mM).

CYP1A-mediated formation of resorufin from 7-ethoxyresorufin (EROD) was measured in the presence of methanol, ethanol and dimethyl sulfoxide (DMSO) at concentrations from 0.01% to 3%. **We observed a significant reduction in EROD activity when ethanol, methanol or DMSO at the concentrations above 0.5% was added. In the presence of 3% of ethanol, EROD activity was completely blocked, as suggested by undetectable formation of resorufin. No changes in EROD activity were observed in the presence of organic solvents at concentrations below 0.5%. To the best of our knowledge, this is the first study to show a strong in vitro effect of organic solvents on EROD activity in the microsomes from rainbow trout. These findings should be considered when designing in vitro metabolic studies with fish hepatic microsomes. Ideally, the concentration of these organic solvents, which might affect CYP1A activity, for solubilisation of substrates and inhibitors in in vitro microsomal**

**studies should be avoided. Further studies are needed to identify organic solvents with no or minimal effect on CYP450 activity. Such studies should involve all commonly used probe reactions that represent activity of specific CYP450 isoforms.**  
**Keywords:** Organic solvents; 7-ethoxyresorufin-O-deethylase; In vitro model; rainbow trout.  
**Acknowledgement :** The study was financially supported by the MEYS of the CR - projects „CENAKVA“ (No. CZ.1.05/2.1.00/01.0024) and “CENAKVA II“ (No. LO1205 under the NPU I program), by the Grant Agency of the University of South Bohemia in Ceske Budejovice (No. 087/2013/Z) and by the Czech Science Foundation (No. P503/11/1130).

#### MO141

##### **Gender-biased responses in *Gammarus pulex* exposed to BDE-47: a gel-free proteomic approach**

**E. Gismondi**, Laboratory of Animal Ecology and Ecotoxicology; G. Mazzucchelli, University of Liege; E. DePauw, Liege University / Laboratory of Mass Spectrometry; J. Thome, Liege University / Laboratory of Animal Ecology et Ecotoxicology

Until now, only few ecotoxicological studies have taken into account toxic effects on both male and female organisms, whereas gender represents a confounding factor, and that effects on both genders could allow to better understand the impacts on populations. In addition, during the last decades, proteomics has been developed in the field of ecotoxicology due to the fact that proteomic allows to evaluate changes in protein expressions and thus, to provide information about the mechanism of actions of xenobiotics. Here, we have investigated variations of protein expression in caeca tissue of the freshwater amphipod *Gammarus pulex* males and females in unstress condition (i.e. Volvic water) and exposed to BDE-47, by using a “gel-free” proteomic analysis. The gel-free proteomic analysis has identified 45 proteins, whose 25 proteins were significantly differently expressed according to gender and/or BDE-47 exposure. These proteins were involved in several biological processes such as energy metabolism, chaperone proteins, or transcription/translation. In control condition, 11 proteins were significantly over-expressed in females, and 6 proteins over-expressed in males. In stress condition, 7 proteins were differently impacted by BDE-47 according to gender. For example, catalase was over-expressed in exposed females and under-expressed in exposed males, as compared to respective controls. Conversely, energy metabolism proteins were up-regulated in males and down-regulated in females. Our proteomic study highlights gender-biased impact of BDE-47 exposure, emphasizing gender as a confounding factor important to take into account in ecotoxicology effects assessment. Moreover, this study shows that the gel-free proteomic seems to be a promising proteomic method that it would be interesting to develop in future ecotoxicological studies to increase protein variations information, and thus, better understand the mechanism of action of xenobiotics.

#### MO142

##### **Understanding mechanisms of action of pesticides in *Folsomia candida* using a proteomics approach**

**S.C. Novais**, Polytechnic Institute of Leiria / ESTM and GIRM; T.F. Simoes, Polytechnic Institute of Leiria / ESTM GIRM; T. Natal-da-Luz; J. Renaud, Department of Life Sciences; J.M. Sousa, Faculty of Engineering of University of Porto / Chemical Engineering; B. Devreese, Ghent University / Unit for Structural Biology Laboratory for Protein Biochemistry and Biomolecular Engineering LProBE; M.F. Lemos, Instituto Politécnico de Leiria / Dept Biology  
 Collembolans have been traditionally used as soil health indicators through the assessment of effects at the population level. To further understand the mechanisms of toxicity behind pesticide contamination and elucidate the chemical modes of action, it is important to complement such information with responses at lower levels of biological organization. Ecotoxicoproteomics provides adequate and pillar techniques for such holistic understanding of the interaction of stressors with organisms. *Folsomia candida* is a common and widespread arthropod that has been extensively used as a “standard” test species for estimating the effects of pesticides and environmental pollutants on non-target soil arthropods, being very sensitive to organic compounds. The main aim of the present work was to address the mechanisms of toxicity of two pesticides, widely used in agriculture, on *F. candida* by trying to establish the link between the effects on reproduction with protein expression patterns. For the assessment of survival and reproduction effects (ISO 11267:1999), the organisms were exposed to the herbicide glyphosate (30.8 % Montana®) and the fungicide chlorothalonil (38.8% Bravo®500) in a Portuguese agricultural soil and several effect concentration values (EC<sub>x</sub>) were estimated. Organisms were then exposed to the reproduction EC<sub>50</sub> of each pesticide (glyphosate: 4.95 mg a.i./kg; chlorothalonil: 127.31 mg a.i./kg), as well as to control conditions, and several time points were tested: 2, 4, 7 and 10 days. After protein extraction and quantification, each sample of control and pesticide-exposed organisms followed a shotgun proteomic approach based on liquid chromatography and tandem mass spectrometry (LC–MS/MS), combined with iTRAQ (isobaric tags for relative and absolute quantitation) labeling that allows comparative quantitative multiplex analysis. Different sets of differentially expressed proteins were identified after exposure to each pesticide, indicating the distinct biological and metabolic pathways that are being affected. It was also possible to verify that the pattern of protein expression changed over time. The present results represent the first attempt to link individual responses of *F. candida* (effects on reproduction)

with the proteome modifications, providing the scientific basis for a more comprehensive understanding of the mechanisms underlying the individual responses to the pesticides.

#### MO143

##### **A systems biological approach to understanding narcosis using *C. elegans* and RT gill cell lines**

**E.K. Brockmeier**, University of Liverpool / Functional and Comparative Genomics; D. Basili, University of Liverpool / Institute of Integrative Biology; G. Hodges, Unilever Research / Safety and Environmental Assurance Centre; E. Butler, Cranfield University; S. Gutsell, Unilever / SEAC; F. Falciani, University of Liverpool / Functional Genomics

Narcotic chemicals act on fundamental cellular functions which can impact a wide range of species when they enter into the environment. These chemicals represent a large volume and number of the chemicals used in industrial applications. Currently there is no mechanistic understanding of narcosis and how this baseline toxicity occurs on a molecular level. The objective of this project is to use the RT gill cell line and *Caenorhabditis elegans* to develop an adverse outcome pathway (AOP) for narcosis which will be relevant across multiple species. For this project, LC50 data was generated from both *C. elegans* and the RT gill cell line from a panel of 30 chemicals, which include 15 proposed non-polar narcotics and 15 proposed polar narcotics. Based on regression correlations with the existing USEPA LC50 data for fathead minnow (*Pimephales promelas*), these predicted narcotics appear to act via a narcosis mechanism albeit for the nematocidal chemical 2-hydroxyethyl ether. For molecular endpoints, we exposed *C. elegans* to 1/10 of the LC50 for 24 hours and extracted RNA for microarray analysis. From this data set we are able to determine the impacts of narcotic exposure on this organism as well as to depict the differences in molecular responses between polar and non-polar narcotics. Using the SeahorseBiosciences™ platform, which utilizes fluorescent probes for *in vitro* testing of oxygen consumption, we are able to correlate these molecular responses and lethality concentrations to impacts at the physiological level. Inclusion of *in vitro* data from the RT gill cell line provides a complement to these results and enables the comparison of nematode to aquatic animal responses without the need for animal testing. These data will be coupled with metabolomics data sets in order to develop an adverse outcome pathway for narcosis toxicity for comparison with proposed existing fish based narcosis AOPs. They will also be linked with parallel studies to be conducted in *Daphnia magna* to better understand the impacts of this class of chemical across multiple species. Through this project we will gain a better understanding using a systems biological approach of the toxic mechanism of action of this expansive class of environmental toxicants.

#### MO144

##### **Toxicological studies of polymeric nanoparticles containing essential oil of neem**

**L.F. Fraceto**, Sao Paulo State University - UNESP / Environmental Chemistry; T. Pasquoto, Universidade Federal de São Carlos; A. Gonzalez, São Paulo State University - UNESP; E.V. Campos, Sao Paulo State University - UNESP / Engenharia Ambiental; J.L. Oliveira, São Paulo State University - UNESP; R. de Lima, Universidade de Sorocaba

Neem (*Azadirachta indica*) is a tree belonging to the Meliaceae family. Azadirachtin, a tetraterpene, is the major active ingredient isolated from neem, which is known to disrupt the metamorphosis of insects. However, the major problem is its sensitivity to photodegradation so it is rapidly lost when exposed to sunlight. This limits its use in agriculture because an insecticide should persist long enough to cause effect in the insect pest. Polymeric nanocapsules are vesicular system, in which the entrapped substances are confined to an oil core surrounded by a polymeric wall. The aim of this study was to prepare and characterize polymeric nanocapsules as a modified release system for neem essential oil in order to evaluate the toxic effect of these nanoparticles with and without neem oil. The preparation of the nanocapsules containing different concentrations of neem oil (1, 1.5 and 2%) was performed according to the method of water/oil emulsion and evaporation of the solvent. The stability of nanoparticles formulations (with and without neem oil) was investigated by the measurements of some physico-chemical properties such as mean size diameter, polydispersivity, zeta potential and encapsulation efficiency as function of time (120 days). The toxicological assays were done through cytotoxic assays (MTT and Cytometer Image) and genotoxic assays (comet assay and chromosomal aberrations using *Allium cepa*). The results showed that nanocapsules loading neem oil showed good colloidal parameters. All prepared nanoparticles presented polydispersivity lower than 0.2 showed good homogeneity of the formulation, zeta potential around -27 mV. The encapsulation efficiency of neem oil in nanocapsules was higher than 80%. Toxicological assays showed that in the 3T3 cells the nanoparticles were not cytotoxicity. All nanoparticles were able to reduce cell viability in HeLa cancer cell type. The MTT assays showed that nanoparticles with and without neem oil were cytotoxic to human lymphocytes. According to the *Allium cepa* results nanoparticles loading neem oil did not alter the mitotic index and the damages have not index significant. These preliminary results indicate that the encapsulation of neem oil in polymeric nanoparticles could be an interesting alternative to control pests in agriculture, however, the toxicological results indicate that these nanoparticles could be toxic to non-target organisms. Acknowledgments: Fapesp, Fundunesp, CNPq and CAPES.

## MO145

### Identification toxic pathways of graphene nanomaterials in the nematode, *Caenorhabditis elegans* using integrated multi-OMICS approach

J. Yang, N. Chatterjee, University of Seoul; S. Kim, Pusan National University; J. Hong, Kyung Hee University; C.P. Roca, Universitat Rovira i Virgili / Department of Chemical Engineering; F. Giralt, Universitat Rovira i Virgili; J. Choi, School of Environmental Engineering Graduate School of Energy and Environmental system Engineering

Graphene and its derivatives have attracted great research interest for their potential applications in electronics, energy, materials and biomedical areas. However, little information of their toxicity and bio-compatibility is available. The system toxicology approach using 'multi-OMICS-profiling-techniques' (transcriptomics, proteomics and metabolomics) has proven to be a robust tool for unraveling complex molecular machinery underlying various physiological, and pathophysiological processes, and they have been successfully utilized in various fields, including stress biology and toxicology. The integration of these OMICS technologies has the potential to reveal a much more detailed view of homeostasis and regulatory networks than when used individually, which is particularly powerful for elucidating potential mechanisms of toxicity of new chemicals, such as graphene nanomaterials. In this study, using an integrated multi-OMICS approach, potential mechanisms of toxicity of graphene nanomaterials were investigated in the nematode *Caenorhabditis elegans*. We first screened the toxic potential and uptake of five different graphene nanomaterials (three kind of graphene nanoplatelets –pristine, amine and carboxylated and single layered graphene oxide and few layered graphene oxide) in *C. elegans* and found that graphene oxide led to a significant decrease of reproduction. Then, we selected graphene oxide for further in-depth multi-OMICS study to elucidate the underlying mechanism of reproductive toxicity. Microarray followed by pathway analysis was conducted on *C. elegans* exposed to graphene oxide. Non-targeted NMR based metabolomics as well as targeted GC-MS based lipidomics, were subsequently conducted. Multi-OMICS pathway analysis based on networks and with MetaboAnalyst were also conducted to identify altered pathways by graphene oxide. Several pathways related to reproduction, such as WNT and MAPK, emerged from the integrated OMICS analyses. We tried to confirm the link between these pathways and reproduction decline by using the *C. elegans* functional genomics tool. Loss-of-function mutants of genes from these pathways were exposed to graphene oxide and their responses were compared with that of *wildtype*. Overall results suggest that integrated multi-OMICS approaches provide comprehensive insights of the toxicity of graphene oxide, which will guide further mechanism study.

## MO146

### Assessing the effects of silver nanomaterials in *Caenorhabditis elegans*: adverse effects, and possible mechanisms of toxicity

P. Samutritai, D.A. Dyrinda, T.F. Fernandes, Heriot-Watt University / School of Life Sciences

Given the rise in applications of nanotechnology to a wide range of industries, it is likely that released nanomaterials will end in the environment. However, the effects, as well as, the mechanistic pathways of toxicity of engineered nanomaterials in the environment are not thoroughly known. Therefore, it is important to investigate any effects induced by these nanomaterials. In this research, two silver nanomaterials (NM300K and NM302) from the European Commission's Joint Research Centre (JRC), as well as the effects of a silver salt were used to assess and compare their toxicities in the nematode *Caenorhabditis elegans*. The effect of silver nanomaterials was assessed by studying lethality and reproduction of particular nematode strains with the absence in specific genes. In addition, the authors assessed whether oxidative stress was one of the major pathways involved in the toxicity from nanomaterials by examining the activities of particular enzymes whose action is to remove reactive oxygen species. However, other mechanisms that might need to be taken into account in this context are still being addressed. Therefore, future work will address gene and protein expression in these nematodes following exposure to these silver nanomaterials. Results from this work will provide further information on the mechanisms of toxicities from engineered nanomaterials. This project is funded by Royal Thai government.

## MO147

### Toxicity evaluation of nanopesticides in model organism *Caenorhabditis elegans*

M. Jacques, Federal University of Pampa; J. Oliveira, Unesp / Environmental Chemistry; E.V. Campos, Sao Paulo State University - UNESP / Engenharia Ambiental; R. Grillo, J lio de Mesquita Filho S o Paulo State University; L.F. Fraceto, Sao Paulo State University - UNESP / Environmental Chemistry; D.S. Avila, J lio de Mesquita Filho S o Paulo State University

The nanotechnology has developed new formulations containing herbicides in order to be used in agriculture<sup>1</sup>. In this context, nanoparticles can increase the solubility of the bioactive compounds, provide slow release and protect against premature degradation<sup>2</sup>. The advantages of nanoparticles as carrier systems are related to the reduction in the amount of herbicide necessary and diminish the risk of contamination of water resources due to herbicide leaching<sup>2,3</sup>. The main objective of this study was prepare and characterize different nanoparticles (solid lipid nanoparticles and polymeric nanoparticles) loaded with herbicides (atrazine,

simazine) and investigate the toxicological effects of these formulations using the *Caenorhabditis elegans* organism (nematode founded in soil rich in organic matter). The preparation of the solid lipid nanoparticles containing herbicides (atrazine and simazine) was performed according to the method of oil/water emulsion and evaporation of the solvent<sup>4</sup>. The polymeric nanoparticles of poly( $\epsilon$ -caprolactone)nanocapsules containing the atrazine herbicide were prepared according to the interfacial deposition of pre-formed polymer method<sup>5</sup>. The technique of dynamic light-scattering and nanoparticles tracking analysis were used to determine the size distribution, zeta potential and concentration of nanoparticles. The worms were exposed to different concentrations of the nanoparticles or commercial formulation for 48h in NGM (Nematode growth media) plates. Then, survival, brood size and size of the worms were analyzed. The results showed that solid lipid nanoparticles and poly( $\epsilon$ -caprolactone) nanocapsules with and without herbicides presented good colloidal properties. The toxicological assays showed that the nanoparticles (loading or not herbicides) presented toxic effect, such as mortality in all concentrations, reduction in the viability of eggs laid and the size of the worm, when compared with commercial formulation of herbicides. The toxic effects of the nanoparticles (loaded or not with herbicides) could be related to the interaction of the nanoparticles with the *C. Elegans* organisms and further investigation is need in order to understand the toxic mechanism of these systems. These preliminary results are very important in order to obtain information about the security of these nano carriers before their use in agriculture.

Acknowledgments: Fapesp, Fundunesp, CNPq and CAPES.

## MO148

### DNA damage in *Enchytraeus crypticus* - optimization and assessment in Ag materials

V.L. Maria, Biology Department of Aveiro University / Biology CESAM; S. Guilherme, Universidade de Aveiro / Biology; M. Amorim, Universidade de Aveiro / Department of Biology and CESAM

*Enchytraeids* are representative of the terrestrial ecosystem and have been standardized for soil ecotoxicology (survival, reproduction). Further, various additional tools at molecular and biochemical level have been optimised making it a key model species. Nevertheless genotoxic effects have not yet been optimized and assessed. Hence, the primary aim of the current study was to implement and validate the genotoxicity assessment using (i) a recognized genotoxic compound as positive control, (ii) a negative control with organisms from cultures to assess background DNA damage, and (iii) testing Ag materials. DNA strand-breaks related to Ag NM exposure are already well-known for invertebrates (i.e. nematodes, mussels). DNA damage was estimated applying the *in vivo* alkaline Comet assay with whole organisms exposed to a range of reproduction effect concentrations (EC20, EC50 and EC80) of Ag during 0, 3 and 7 days. A time-course genotoxic dynamics was shown as well as a dose response; hence DNA damage can be an important endpoint for *E. crypticus* ecotoxicological assays.

## MO149

### Toxicogenomic profile linked to higher level of the soil invertebrate *Enchytraeus crypticus* to Ni nanoparticles

S.I. Gomes, University of Aveiro / Department of Biology CESAM; J.J. Scott-Fordsmand, Aarhus University / Department of Bioscience Terrestrial Ecology; M. Amorim, Universidade de Aveiro / Department of Biology and CESAM

The potential impact and the mechanisms of toxicity of Ni-Nanomaterials (Ni-NMs) on the environment is still poorly understood, in particular in soil organisms. The understanding of the mechanisms of toxicity enabled by -omic techniques may provide tools which enable the prediction of long-term effects, based on shorter term measures, thus improving the ability to predict risk of NMs. The aims of the present study are to understand the mechanisms of response (based on gene expression analysis) of the soil invertebrate *Enchytraeus crypticus* (Oligochaeta, Enchytraeidae) to Ni-NPs (in comparison with NiNO<sub>3</sub>) and to link the knowledge provided by gene expression analysis with effects at higher levels of biological organization (e.g. energy budgets, reproduction, survival). To investigate this, organisms were exposed to the reproduction-effect concentrations EC<sub>20</sub> and EC<sub>50</sub> of Ni-NPs (and NiNO<sub>3</sub> for comparison) for 3 and 7 days, and the effects on organisms' gene expression were investigated using a 4x44K custom Agilent microarray (developed for the test species). Results showed a clear differentiation between times of exposure, with a higher number of genes being affected after 3 days of exposure. Further, a clear separation between NPs and Ni salt was profiled, indicating specific mechanisms of response or different time events. The mechanistic information provided by gene expression analysis was integrated with effects at higher level of biological organization in an Adverse Outcome Pathway (AOP) format allowing a visualisation and integration of knowledge. **Keywords:** High-throughput, modes of action, nickel nanoparticles, soil

## MO150

### TiO<sub>2</sub> nanoparticles alter iron homeostasis as revealed by PrrF sRNA modulation with *Pseudomonas brassicacearum*

W. Liu, School of Environmental Science and Technology, Dalian University of Technology / School of Environmental Science and Technology; M. Bertrand, CNRS / Laboratory of Microbial Ecology of the Rhizosphere Extreme Environments LEMiRE UMR CNRSCEAAix Marseille University CEA

Cadarache SaintPaulLezDurance iCEINT CEREGE Europole de larbois Aix e; C. Chaneac, LCMCP - UPMC (Paris VI); C. SANTAELLA, CNRSCEAAix-Marseille Université / Plant Biology and Microbial Biotechnology; W. Achouak, UMR 7265 CNRS-CEA-Aix Marseille Univ / LLaboratory of Microbial Ecology of the Rhizosphere Extreme Environments LEMiRE UMR CNRSCEAAix Marseille University CEA Cadarache SaintPaulLezDurance iCEINT CEREGE Europole de larbois Aix

Titanium dioxide nanoparticles (NPs) have been widely applied in daily life. They are used, mainly in pigments, with 70% of its production volume applied in paints, plastics, inks, foods, and toothpastes. Due to its larger use in the industry and daily life, many TiO<sub>2</sub> residues are released into the environment, and currently, TiO<sub>2</sub> NPs are being considered an emerging environmental contaminant. The aim of this study was to question whether TiO<sub>2</sub> NPs with different size-range, crystalline form could affect iron homeostasis with *Pseudomonas brassicacearum* a plant root-associated bacterium (Achouak *et al.* 2000). Under iron-limitation, *Escherichia coli* produces a small regulatory RNA (sRNA) RyhB, which functions to facilitate degradation of the mRNAs of several target genes encoding iron-utilizing enzymes, iron acquisition systems, and iron storage factors (Masse and Gottesman 2002). This phenomenon is now referred to as an “iron-sparing” response. In *Pseudomonas* species, regulation of iron homeostasis involves two (or more) sRNA named PrrF (for *Pseudomonas* regulatory RNA involving iron), which are functionally analogues to RyhB (Wilderman *et al.* 2004). Two PrrF sRNAs were identified in the genome of *P. brassicacearum* (Ortet *et al.* 2011), prrF1 and prrF2. To investigate the role of TiO<sub>2</sub> NPs in iron homeostasis with *P. brassicacearum*, we prepared two shapes of anatase titania particles, and determined their biological activity by analysing TiO<sub>2</sub> NPs-bacterial interaction, their impact on iron content and prrF1 and prrF2 sRNA expression. It was essential to properly prepare and characterize nanoparticles before and after utilization *in vitro*. To overcome the analytical challenges associated to the tracing unlabelled TiO<sub>2</sub> NPs, we used hyperspectral microscopy and inductively coupled plasma mass spectrometry (ICP-MS). Overall, the results of the present study demonstrated that TiO<sub>2</sub> NPs did not show any impact on bacterial growth, however they altered the bacterial physiology as they induced an oxidant stress and altered iron homeostasis. Although we used two different crystalline forms that differ by the size and the shape, we noticed almost the same mechanism of toxicity towards bacteria. Our findings yield new insights into the mechanism underlying the TiO<sub>2</sub> NPs toxicity toward bacteria. The expression of prrF sRNA represented a good indicator of intracellular iron status and consequently of the mode of TiO<sub>2</sub> NPs action. //

#### MO151

##### **TiO<sub>2</sub> Nanoparticles: evaluation of the cyto and genotoxicity and effects on soil microbiota**

M. Pascoli, University of Sorocaba; T. Pasquoto, Federal University of Sao Carlos UFSCar Soroca / Biotechnology; D.T. Rheder, Uniso / Biotechnology; E.V. Campos, Sao Paulo State University - UNESP / Engenharia Ambiental; C.R. Maruyama, Federal University of Sao Carlos UFSCar Soroca / Biotechnology; L.F. Fraceto, Sao Paulo State University - UNESP / Environmental Chemistry; R.d. Lima, Uniso / Biotechnology

Among all metallic nanomaterials Titanium Dioxide (NP-TiO<sub>2</sub>) is one of the most worrying due to its high production and use in commercial goods. In both soil and water the nanoparticles can suffer alterations and interact with soil components, increasing its toxicity. Within this context, this work has investigated titanium dioxide nanoparticles 100% Anatase (Aldrich) and a mixture of 80% Anatase and 20% Rutile (Aeroxide - P25 Degusta) and its physicochemical alterations and the relation to the medium in which it disperses, as well as the toxicity. For the evaluation some molecular and feasibility analyses were performed (MIC and UFC counting) of soil microbiota, as well as analyses on the cytotoxicity and genotoxicity through *Allium cepa* analyses, Comet analyses, MTT and Image Cytometry. The behavior of physicochemical titanium dioxide nanoparticles in different mediums (DMEN, McCoy, RPMI and water) in the presence or absence of UV light presented alterations, that reflected in some cytotoxicity and genotoxicity tests, once NP-TiO<sub>2</sub> (Anatase e Aeroxide) show different behavior depending on the medium they are dispersed. In *Allium cepa* tests the nanoparticles presented significant alterations in the concentrations tested (1, 10 e 100 µg/mL). The results related to the analyses of comet at 1 and 10µg/mL presented damage rates significantly different when compared to the control in all treatments. Regarding the differences found between the two types of nanoparticles we could observe that the results presented significant differences for concentrations at 10µg/mL without exposure to ultraviolet light, being the damages on Anatase nanoparticles stronger and at the concentration at 1 and 10µg/mL with exposure to ultraviolet light, being NP-TiO<sub>2</sub> (Anatase) always more genotoxic than NP-TiO<sub>2</sub> (Aeroxide). The studies performed with soil microbiota showed that over time some variation occurred in relation to the type of existing bacteria variation, which has also occurred among the different NP-TiO<sub>2</sub> tested. The physicochemical characterization proved to be essential for the best understanding of the biological effects of NPs. The contribution of the present work for the area of nanoparticles toxicity is of great value once it helps on the understanding of the behavior of these materials, what is essential for their use in a safe way, causing minimum damage to the environment and human beings.

SANTAELLA, CNRSCEAAix-Marseille Université / Plant Biology and Microbial Biotechnology

With a global production of 10,000 metric tons/yr, CeO<sub>2</sub> nanomaterials have a wide scope of applications in industrial processes and in everyday consumer products<sup>1</sup>. The dissemination of these nanoparticles raises environmental concerns especially for soils through the disposal of biosolids<sup>2</sup>. Soil is a complex system that hosts a complex food web, which will include plants and bacteria. In the literature, there are already strong evidences that CeO<sub>2</sub> nanomaterials have deleterious effects on plants and on soil bacterial communities. Recently, Ge *et al.*<sup>3</sup> showed that nano-CeO<sub>2</sub> (0.1 g kg<sup>-1</sup>) did not affect soil microbial communities, but altered soil bacterial communities in soybean planted soils, showing that plants interactively stimulate nano-CeO<sub>2</sub> effects in soil, possibly due to belowground C shifts since plant growth was impacted<sup>3</sup>. Still, current knowledge on CeO<sub>2</sub> nanomaterials on soil-based ecosystem comes from exposure to concentration of NMs that are far from those predicted in soil (0.28 - 1.12 mg kg<sup>-1</sup>)<sup>4</sup> or even in biosolids (0.53–9.10 mg kg<sup>-1</sup>)<sup>5</sup>. In order to focus on more realistic exposure, we have explored the response of canola (*Brassica napus*) to nanoCeO<sub>2</sub> added in soil at 1 mg kg<sup>-1</sup>. Pristine or citrate-coated nanoCeO<sub>2</sub>, with different average particle sizes and surface reactivity were used to assess relationships between nano-design and impacts on a soil-plant-microbe ecosystem. We examined the response of three different compartments that form this system, *i.e.* the unplanted soil, the rhizosphere and the plant roots. We analyzed microbial enzymatic activities for carbon, nitrogen, phosphorus recycling and the microbial community structure by pyrosequencing of 16S rRNA genes. The presentation will focus on how nanoCeO<sub>2</sub> nanomaterials differentially alter microbial activities and/or microbial communities structure depending on the compartment (unplanted, rhizosphere or root) that is considered, and without effect on plant growth. The design and physico-chemical properties of the CeO<sub>2</sub> nanomaterials also strongly modulate the impacts. ##### **Molecular assessment of bacterial community dynamics and functional endpoints during sediment bioaccumulation tests**

N. Diepens, Wageningen University / Department of Aquatic Ecology and Water Quality Management; M.R. Dimitrov, Wageningen University and Research Centre; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group; H. Smidt, Wageningen University / Laboratory of Microbiology

Whole sediment toxicity tests play an important role in the environmental risk assessment of chemicals. It is not clear, however, to what extent changing microbial community composition and associated functions affect test results. We assessed the development of bacterial communities in artificial sediment during all stages of a 28 d bioaccumulation test with PCBs and chlorpyrifos and four marine benthic invertebrates. Denaturing gradient gel electrophoresis and 454-pyrosequencing of PCR-amplified 16S ribosomal RNA genes were used to characterise bacterial community structure. Abundance of total bacteria and selected genes involved in important microbial mediated ecosystem functions were measured by quantitative PCR. Variables such as sediment organic matter, invertebrate species, and time affected bacterial diversity, community composition, and ecologically relevant functional endpoints, such as abundance of nitrogen-fixing bacteria, ammonia-oxidizing bacteria, denitrifying bacteria, sulphate-reducing bacteria, and bacteria capable of hydrolyzing organophosphate compounds. This implies that microbial dynamics is likely to affect chemical degradation, biotransformation, and water quality variables that in turn can affect the outcomes of sediment tests for the target species and consequentially the risk assessment. To our knowledge, this is the first work to describe dynamics of bacterial community structure and associated functional attributes during a bioaccumulation test using complementary molecular tools.

#### MO154

##### **Evaluation of native microbial soil populations at a trichloroethylene contaminated Superfund site in the presence of a permeable reactive barrier (biowall) using a metagenomics approach.**

G.T. Nino de Guzman, Department of Civil and Environmental Engineering; C.J. Hapeman, USDA-ARS; L. McConnell, USDA Agricultural Research Service / Environmental Management and Biporoduct Utilization Laboratory; P. Millner, United States Department of Agriculture / ARS; A. Torrents, University of Maryland / Civil and Environmental Eng; B. Kjellerup, Goucher College

The Beaverdam Road Landfill occupies 3.5 acres and was an active disposal site for miscellaneous non-hazardous waste from 1943 to 1990, before being capped. In 1994, this site was included on the Nation Priorities List (NPL) for periodic inspection and remediation in accordance with the program regulations. In 2002, trichloroethylene (TCE) was identified in the groundwater as high as 435 ppb, whereas the Maximum Contaminant Level (MCL) in drinking water is 5 ppb. The contaminant source remains unidentified. The construction of a permeable reactive barrier (PRB) was determined to be the least invasive method of remediation. Previous research in this field has focused on rudimentary interactions between PRB materials and TCE either *in situ* or in lab-scale reactors under ideal conditions, instead of the temperature range common to groundwater (10-15°C), a critical component to TCE behavior. Furthermore, the subsequent microbial colonization of the PRB material from the surrounding soil microbiota has not been sufficiently investigated. The objectives of this study were to determine if any TCE-degrading microbial communities could be found in the site soil and if they could ultimately colonize the PRB material to increase the degradation capability of the engineered structure. DNA was extracted from native soil samples from a highly, a moderately, and an uncontaminated area at the site to evaluate the microbial communities for TCE degradation potential. DNA was also extracted from the PRB building material shortly after installation and one year later, to track the colonization of the material. Microbial identification and monitoring has been done utilizing 16S rRNA sequencing and taxonomic analysis (Illumina HiSeq2500). The presence of *tceA*, *vcrA*, and *bvcA* genes, linked to TCE degradation, were applied for quantitative analysis using qPCR. A commercially available consortium, SDC-9 (Shaw Environmental, Inc., Lawrenceville, NJ), was used as a control to gauge *Dehalococcoides* spp. behavior and presence in this environment. Anaerobic batch reactors (12°C) were subsequently constructed and packed with mulch, compost, and general-purpose sand either with or without zero-valent iron (ZVI) and/or glycerol to determine TCE degradation potential. If TCE degrading microbial communities were not able to colonize the PRB materials in the field, augmentation options will be explored at the bench scale then evaluated for deployment in the field.

### Microbiome analysis to identify species and biomarkers for water quality monitoring and bioremediation

T. Van Rossum, Simon Fraser University / Department of Molecular Biology and Biochemistry; M.A. Peabody, Simon Fraser University / Department of Molecular Biology and Biochemistry; M.I. Uyaguari Diaz, University of British Columbia; M. Pylatuk, Simon Fraser University / Biology; K. Cronin, M.A. Croxen, University of British Columbia; A. Crisan, British Columbia Centre for Disease Control; E.J. Griffiths, R. Lo, Simon Fraser University; H.L. Osachoff, BC Ministry of Environment / Land Remediation Section; X.A. Tian, W.W. Hsiao, C.A. Suttle, N.A. Prystajek, J.L. Isaac-Renton, P.K. Tang, University of British Columbia; C. Kennedy, Simon Fraser University; E.S. Brinkman, Simon Fraser University / Molecular Biology and Biochemistry

Using metagenomic sequencing, we are profiling microbial taxa and genes across contaminated watersheds to identify specific genetic biomarkers of pollution associated with agriculture, urbanization, and mining. We have collected a year of monthly river water samples from seven sites in protected, urban, and agricultural watersheds around the Southwestern coast of Canada, plus hourly samples in selected months. We have also collected river-bed biofilm samples from up and downstream of a point source of copper contamination. For each sample, we have recorded physical, chemical and biological water quality data and are surveying protists, fungi, bacteria and viruses by sequencing both phylogenetic marker genes and shotgun metagenomic DNA. Using this data, we are identifying taxa and genes that are differentially abundant between sampling sites and that correlate with environmental conditions. We are using these relationships in the agriculturally- and urban-affected data to develop a panel of quantitative polymerase chain reaction (qPCR) biomarkers to assess water quality. In the metal-affected data, we are investigating how these relationships might reveal a microbial role in this instance of natural copper depletion and whether this system could inform further bioremediation strategies. This work is the most comprehensive analysis of watershed microbiomes over space and time to date, and may aid identification of more diverse forms of contamination and their likely sources, as well as potential bioremediation tools. This work demonstrates how new community-level microbiome sequencing can be leveraged to improve existing applications of biomarkers for environmental monitoring.

## MO156

### Microbial responses to diffusive pollution in seawater

m. vila-costa; M. Fernández-Pinos, IDAEA CSIC; T. Alioto, CNAG; B. Pina, IDAEA-CSIC / Environmental Chemistry; X. Irigoyen, King Abdullah University of Science and Technology; J. Dachs, IDAEA-CSIC / Environmental Chemistry

Increasing trace amounts of thousands of man-made organic pollutants (OPs) and hydrocarbons reach seawaters mainly through run-off, riverine and diffuse

atmospheric inputs. The fraction of marine dissolved organic matter (DOM) accounted by OPs remains unknown due to the analytical complexity to analyse both pools. However, this assessment is important because OPs are hydrophobic, and thus tend to concentrate in marine biota at higher intracellular concentrations than in seawater. Besides bioconcentration, prokaryotes (the main consumers of DOM) can degrade some OPs as indicated by few indirect field evidences. Whereas a handful studies have seen an important impact on phytoplankton by the myriad of OP present in seawater (and not when considering just few OPs), the effects of OPs on heterotrophic microorganisms biodiversity and functionality is unknown. We have applied metatranscriptomic approach in enrichments of seawater from the Atlantic and Pacific oceans adding a complex mixture of naturally occurring organic pollutants at similar concentrations than those found in seawater in order to analyze the effects of the known and unknown fraction of pollutants to the marine picoplankton, including the phototrophic and heterotrophic fraction. Preliminary results show that the pool of organic pollutants had a higher inhibitory effect on cell performance of phototrophic cells although their abundances were slightly affected, consistent with the non-lethal effects of the low concentrations of pollutant mixtures in the treatments. On the other hand, heterotrophic groups of bacteria benefited from the carbon supply of POPs to increase their activities.

## MO157

### Individual, physiological and molecular stress responses exposed to ionising radiation in *Lemna minor*

a. van hoeck; N. Horemans, Belgian Nuclear Research Centre (SCK-CEN) / Biosphere Impact Studies; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology; D. Knapen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences; H. Vandenhove, Belgian Nuclear Research Centre SCKCEN / Biosphere Impact Studies

The biological effects and interactions of different radiation types in plants are still far from understood. Additional knowledge on the impact of ionising radiation in plants on individual, biochemical and molecular level will help to unravel the toxic mode of action. Among different radiation types, gamma radiation treatments have been mostly studied both in lab and field studies to derive the biological impact of radiation toxicity in organisms. However, environmental relevant studies on chronic low-dose gamma exposures are scarce. Exposure to gamma radiation can induce ionisation events causing an increase in reactive oxygen species (ROS) and inducing damage to biological material like DNA, lipids and structural proteins. The present study aimed at evaluating individual, physiological and molecular endpoints to understand the mode of action of ionising radiation stress in plants. The floating freshwater plant *Lemna minor* was chosen as model system. In an effort to strengthen duckweed genomic research, we sequenced the genome of *Lemna minor* using Illumina sequencing platform. Plants were being exposed to an external gamma radiation source for seven days. The classic growth related endpoints on plant biomass and frond area and frond number, were measured and compared with biochemical and molecular endpoints. A dose-response curve with 60% growth inhibition was obtained on plant growth. Additionally, *Lemna* plants showed also dose-dependent responses in anti-oxidative defense activities, nucleic acid modifications and a shift in ploidy level. Transcriptomic data of recently performed RNAseq runs are currently analyzed to evaluate protein-coding gene expression levels. The observed physiological changes and ongoing RNA-seq investigations will help to unravel response mechanisms for ionising radiation in plant systems. As multiple levels in biological organisation of the organism were considered, and also different dose rates taken into account, this approach allows a better understanding of the toxic mode of action of radiation stress in higher plants. *This research was supported by the European Commission Contract Fission-2010-3.5.1-269672 to Strategy for Allied Radioecology (www.star-radioecology.org) and a project of the Fund for Scientific Research (FWO-Vlaanderen, G.A040.11N)*

## MO158

### High-resolution arrays to investigate the occurrence of a stress syndrome in mussel caged in the Baltic Sea

F. Dondero, Università del Piemonte Orientale Avogadro / DiSIT; I. Saggese, University of Piemonte Orientale / Department of Sciences and Technological Innovation; R. Turja, Finnish Environment Institute, SYKE / Marine Research Centre; K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre

We used a newly developed high-resolution arrays based on Agilent Technologies Inc. SureDesign to investigate high-throughput transcriptional changes in *Mytilus* spp tissues (digestive gland) obtained from specimens caged in four previously characterized field sites (S1, S2 in Sundsvall; G1, G2 in Gavle) receiving different pollutant loads and located in the Baltic Sea, Sweden. The new *Mytilus* spp microarray encompasses 15744 annotated mussel genes originated from RNA-seq and further sequence data assembly of about 22 million short reads (100 bp paired end sequences) obtained from multi-tissue libraries of either *M. galloprovincialis* or *M. trossulus*. The new microarray has been functionally annotated for biological processes, molecular functions and cellular components using the Crassostrea gigas genome data (Zhang et al., 2012, doi:10.1038/nature11413). RNA samples obtained from the four specimen groups were hybridized onto the array in single color mode and further analyzed to identify differentially expressed genes and pathway analysis based on the Gene Ontology. Our results showed statistically significant differences (1W, 2W ANOVA) for gene expression patterns along with

the occurrence of adverse outcome pathways as highlighted from a hyper-geometric statistics of GO terms associated to differentially expressed genes. In particular in tissues from specimens sampled at S1 site, pathway analysis showed the implication of genes that may be involved in metabolic disorders linked to aminosugar utilization, endosomal trafficking, humoral immune response, typical of a pollutant stress-response. Correlation with complementary molecular approach (quantitative PCR) and functional data obtained from physiological markers is ongoing to identify robust predictors of stress syndrome occurring in a low salinity environment such as the Baltic Sea.

#### MO159

##### **Application of RNA-seq in *Brassica oleracea* toward molecular ecotoxicological studies**

S. Dumez, University Lille2 / Laboratory of plant and fungal sciences; F. Brulle, Unité Expertise en Toxicologie Ecotoxicologie of Substances DRC VIVA ETES; D. Cuny, University of Lille 2

*Brassica oleracea* (cabbage) is one of the selected species recommended by OECD for the testing of chemicals in soils but this plant has also already been employed for atmospheric pollution biomonitoring purposes. Despite its close relationship with the model plant *Arabidopsis thaliana*, and saw its genome partially been sequenced, few sequences are available in the Genbank nucleotide database and a precise functional annotation is still missing. Nowadays, New Generation Sequencing methods (NGS) represent useful technologies that respond quickly to a lack of molecular data in non-model species and allow a fast obtaining of a huge amount of nucleotide sequence information. These techniques allow the sequencing of all or a part of a genome or a transcriptome, the latter in order to get extensive cDNA information. Here we introduce the transcriptome sequencing of *Brassica oleracea* var. *viridis* leaves by using 454 pyrosequencing. Normalized cDNAs from 9 different experimental conditions yielded 275 446 expressed sequence tags (ESTs), assembled in 33 925 contigs and 42 654 singletons. By using Blast2Go online software, 86.2 % of the sequences got positive results in BlastX searches (E-value  $\leq 1.10^{-6}$ ) and, based on Gene Ontology classification, functional annotations were recovered for 76.3% of them. 43% of blasted sequences found homologies with those of the model-plant *A. thaliana*. KEGG searches show that the annotated sequences are associated with 140 metabolic pathways including xenobiotics biodegradation and metabolism, signaling molecules, etc... and upon all the transcripts produced, we found numbered stress responsive genes and cell defense related genes (enzymatic anti-oxidative machinery, DNA repair, cytochromes P450 coding genes...), all being potentially of interest for monitoring the effects of pollutants at the molecular level in the leaf of *B. oleracea*. All of these results make ecotoxicogenomic studies now possible in this plant species.

#### MO160

##### **Comparison of different DNA extraction methods for marine periphyton and its implications for ecotoxicogenomic studies**

N. Corcoll, Department of Biological and Environmental Science; M.K. Eriksson, Chalmers University of Technology / Department of Shipping and Marine Technology; T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences

This is a time with unprecedented capacity of DNA sequencing technologies for metagenomic analysis (identifying new genes and species living in environmental samples) in natural communities. However, sequencing efforts on non-model organisms or communities, such as marine periphyton communities, are still scarce in ecotoxicology. Also, uncertainties in basic aspects, such as choice of appropriate DNA extraction method, are still not resolved. This study aims to compare the effects of different DNA extraction methods for marine periphyton in terms of DNA yield, purity and integrity, as well as eukaryotic and prokaryotic diversity. Cost-effectiveness among the methods was also assessed. Four different methods (the Plant DNAzol reagent (Invitrogen), the Fast DNA Spin kit for soil (MP Biomedicals), the PowerPlant and the PowerBiofilm DNA Isolation Kits (MoBio Laboratories)) commonly used for DNA extraction of eukaryotic and prokaryotic microorganisms from marine periphyton were compared. Results showed that the commercial method Plant DNAzol reagent and the Fast DNA Spin kit for soil appear to be the best to extract high quantities of DNA (> 50 ng/ $\mu$ L). DNA fragments obtained with these methods cover a wide range of sizes, from 250 to 15000 bp. With the PowerPlant and the PowerBiofilm DNA Isolation Kits, lower amounts of DNA were obtained (< 23 ng/ $\mu$ L), but the purity of these extractions, in terms of protein and polysaccharide contamination, was higher. Extractions from these latter kits also produced DNA size distributions with larger sizes, between 3000 and 15000 bp. Obtained DNA products were used for amplicon sequencing of the 18S rRNA and 16S rRNA genes, targeting eukaryotes and prokaryotes, respectively. Such DNA amplicon sequencing will be a powerful tool to compare community composition and biodiversity across samples, and to select DNA extraction method for further metagenomics of periphyton communities exposed to toxicants.

#### MO161

##### **Lead exposure induces changes in 5-hydroxymethylcytosine clusters in CpG islands in human embryonic stem cells and umbilical cord blood.**

A. Sen, Wayne State University / Department of ObGyn; P. Cingolani, McGill University / School of Computer Science; M. Senut, Wayne State University /

Institute of Environmental Health; S. Land, Wayne State University / Department of Obstetrics and Gynaecology; R. Wright, Mount Sinai School of Medicine; A. Baccarelli, Harvard School of Public Health; D. Ruden, Wayne State University / Department of ObGyn

Prenatal exposure to neurotoxicants such as Lead (Pb) may cause stable changes in the DNA methylation (5mC) profile of the fetal genome. Several studies have reported correlation between modification of DNA methylation early during development and predisposition an individual to adult onset diseases. However, only a handful of studies have examined its effect on the DNA de-methylation pathway, specifically the dynamic changes of the 5-hydroxymethylcytosine (5hmC) profile. The Next generation sequencing techniques for detection of differences in 5hmC are cost prohibitive and cannot be used routinely for epidemiological studies. Therefore, we developed a novel implementation of Infinium™ Human methylation 450K array, which we named the HMeDIP-450K array, to explore Pb-exposure dependent 5hmC changes in-vitro model and later in a small human cohort. The HMeDIP-450K array we first perform a 5hmC enrichment with 5hmC specific antibodies and analyze the enriched DNA with HM450K array. For downstream analysis we model 5hmC as clusters of correlated, adjacent CpG sites, which are co-regulated by Pb exposure (A-clustering) which we define as high density 5hmC regions. We further validate the 5hmC clusters by a bisulfite independent 5hmC detection technique called Pvu-Seq. To determine the functional consequence of the change in Pb dependent change in 5hmC in high density clusters, we are currently conducting the gene expression studies. Our data from the in-vitro model Pb-exposure suggest that the HMeDIP-450K array might be able to predict functionally relevant changes in 5hmC profile. To determine if the HMeDIP-450K array is useful tool for study Pb-dependent 5hmC changes in a human cohort; we expand our study to include umbilical cord blood DNA from 48 mother-infant pairs from the ELEMENT cohort from Mexico city, Mexico. Our data show that Pb-associated changes in the 5hmC profiles can be divided into sex-dependent and sex-independent categories. In conclusion, in this study, using a novel implementation of HM450K array, we have identified several 5hmC genomic loci, which we believe might have some potential as early biomarkers of Pb-exposure.

#### MO162

##### **Impact of Cd and Pb impregnation on the health of an adult population neighbouring a landfill : a case study.**

M. Cabral, Université Cheikh Anta Diop; A. Verdin, Université du Littoral Côte d'Opale / Unité de Chimie Environnementale et Interactions sur le Vivant UCEIV EA; G. Garçon, University of Lille 2; A. Touré, C. Diop, M. Fall, Université Cheikh Anta Diop; S. Bouhsina, D. Dewaele, F. Cazier, Université du Littoral Côte d'Opale; A. Tall Dia, Université Cheikh Anta Diop; P. Shirali, Université du Littoral Côte d'Opale; A. Diouf, Université Cheikh Anta Diop

This case-control study dealt with the health adverse effects within the population neighboring the Mbeubeuss waste dump, which is located near the district of Malika (Diamalaye II) in Dakar (Senegal). All the household and industrial waste arising from Dakar are stored in this open landfill without being covered and are therefore possible sources of Pb and Cd contaminated air emissions and lixiviates. The objective of this study is part of improving the health of the population neighboring Mbeubeuss by determining Pb and Cd concentrations both in environment and humans, and studying possible renal function alterations within the adults. Soil and air samples were collected in the control site (Darou Salam) and the waste dump neighboring site (Diamalaye II). Control and exposed adults were recruited as living in Darou Salam (n = 52) and in Diamalaye II (n = 77). Pb and Cd concentrations in soil, air and biological samples were determined. Moreover, we were interested in analyzing some impregnation (zinc protoporphyrin, d-aminolevulinic acid dehydratase) and oxidative stress biomarkers (malondialdehyde, glutathione status), in addition to several nephrotoxicity parameters (creatinuria, proteinuria, lactate dehydrogenase, CC16 protein, glutathione S-transferase-alpha and retinol binding protein) in blood and/or urine. The results showed the significant Pb and Cd contamination of the soil and air samples derived from the landfill, and therefore of the neighboring population of adults. This critical exposure to environmental Pb and Cd had some harmful consequences for their health, as shown by the reported oxidative stress and nephrotoxicity signs.

#### MO163

##### **-Omic profiles of *Xenopus* A6 kidney cells by ATR-FTIR or Raman spectroscopy and LC-MS with computational analysis**

E. Gorrochategui, Analytical Environmental Chemistry; C. Porte, CSIC - IIQAB / Environmental Chemistry; R. Strong, Lancaster University / Centre for Biophotonics; S. Lacorte, IDAEA-CSIC / Environmental Chemistry; R. Tauler, IDAEA-CSIC; F. Martin, Lancaster University

**Keywords:** Omic LC-MS/IR/Raman profiles, *Xenopus laevis* (A6), Chemometrics  
The exposure of organisms to environmental pollutants, such as perfluoroalkylated substances (PFASs), can result in **unknown effects** in their mRNA, protein or metabolite systems. Thus, the study of their **-omic profiles** appears as an urgent issue since it can provide very meaningful information about the biological responses of the organisms exposed to potentially toxic environmental insults.  
**Infrared or Raman** spectroscopy techniques have been developed as excellent tools for initial characterisation, providing information of the molecular

composition of the interrogated biological specimens<sup>1</sup>. Moreover, **high resolution mass spectrometric** techniques appear to be powerful tools for further characterisation, providing information on elemental composition and thus, allowing the identification of **potential biomarkers**. However, the large amounts of data generated with such techniques complicates the extraction of distinguishing features. **Chemometric methods**, such as principal component analysis (PCA), have evolved as powerful tools to address this issue, enabling fast data processing. Moreover, multivariate curve resolution-alternating least squares (MCR-ALS)<sup>2,3</sup> allows for a distinct resolution of the profiling problem in LC-MS, which results in a better identification of unknowns<sup>4</sup>. In the present study, the effects of **four PFASs**, named perfluorobutanesulfonate (PFBS), perfluorooctanesulfonate (PFOS), perfluorooctanoic acid (PFOA) and perfluorononanoic acid (PFNA) were studied in the *Xenopus laevis* (A6) **kidney cell line** by attenuated total reflection Fourier-transform infrared (ATR-FTIR) spectroscopy, Raman spectroscopy and ultra-high performance liquid chromatography coupled to time-of-flight mass spectrometry (UHPLC-TOF-MS). Particular emphasis was placed on the analysis of their effects on cellular lipids in an attempt to evaluate the individual effects of the four PFASs on cellular membranes, which were previously determined for a mixture of eight PFASs<sup>5</sup>. Results evidenced both a lipid and metabolite disruption produced by the xenobiotics, which occurred differentially in cells with and without domes<sup>6</sup>; cell layer elevations produced by a water inflow between basal membranes and culture flask. Finally, electron microscope images allowed the visualization of the structural changes produced in cellular membranes caused by the presence of PFASs.

#### MO164

##### **Development of an embryotoxicity test for *Enchytraeus crypticus* - unravelling the mechanisms of Cd**

M. Gonçalves, University of Aveiro, Department of Biology & CESAM / Biology; R.C. Bicho, Universidade de Aveiro / CESAM Department of Biology; A. Rêma, ICBAS University of Porto; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; A. Faustino, Universidade do Porto; M. Amorim, Universidade de Aveiro / Department of Biology and CESAM

The existing standard enchytraeid reproduction test (ERT) concerns the assessment of effects on survival and reproduction. In the present study we optimized and propose an embryotoxicity test using *Enchytraeus crypticus*. Cadmium (Cd) was used as a test substance. Endpoints evaluated were embryo development, number of embryonic structures, Calcium (Ca) channels quantification and hatching success with macroscopic monitoring, histological and immunohistochemistry analysis. Results showed that Cd is embryotoxic for this species, causing a decrease in the hatching success, a delay or disruption in formation of embryonic structures depending on concentrations (

##### **Performance evaluation of dimension reduction methods in improving the clustering of toxicants based on high dimensional toxicogenomic data**

S.M. Rahman, Northeastern University / Civil Environmental Engineering; C. Gao, Northeastern University / Bioengineering; A. Gu, Department of Civil & Env Engineering / Department of Civil Env Engineering Biotechnology Initiative Program

The information-rich toxicogenomic data not only enables potential toxicity mechanisms identification and prediction, but also allow chemical clustering based on their toxicogenomic profiles. Due to presence of many genes and their temporal patterns, high dimensional toxicogenomic data present data analysis challenges in terms of redundant and noisy information, complexity and availability of computation algorithms and computation time. Dimension reduction techniques project the high dimensional data into the lower dimensional subspace and can be applied to overcome the curse of dimensionality. The current study performed comparative evaluation of the clustering performances using two dimension reduction techniques, Principal Component Analysis (PCA) and Multi-dimensional Scaling (MDS). In addition, how the distance metric such as Euclidean and Correlation metric adopted during clustering analysis may impact their overall performances is evaluated. The stress response ensemble whole-cell library of 100 GFP-fused *E. coli* K12, MG1655 reporter strains was employed, which covers all known genes involved in stress response pathways in prokaryotes. Temporal altered gene expression profiles for 24 selected chemicals at 6 different dose concentrations were monitored over a period of 2 hours at 5 minutes intervals. Consensus clustering was applied to the original dataset with all 2450 dimensions which comprises with altered expression profiles of 98 genes over 25 time points, as well as the lower dimensional datasets derived from the application of both PCA and MDS. Clustering analyses of the lower dimensional datasets produce clusters with higher separations resulting higher no. of groups. PCA and MDS generated lower dimensional datasets consumed less than one-third of the time required to cluster the original higher dimensional dataset. Correlation distance based clustering led to low resolution separation with consensus index values but did not separate responses of the same chemicals based on their concentrations, as for each chemical all the 6 doses are grouped in the same partition. While, Euclidean distance based algorithm separates the lower and higher doses of same chemical in separate groups resulting higher no. of clusters. Finally clusters generated from different datasets were compared with the clusters of original dataset by estimating Rand index and Adjusted Rand index, which find the probability of agreement

among the clustering results.

#### MO166

##### **Identification of genes and enzymes involved in mesotrione biodegradation by *Bacillus megaterium***

L. CARLES; P. Besse-Hoggan, C. Bardot, I. Batisson, Université Blaise Pascal Mesotrione is a selective herbicide belonging to the triketone family commonly used in corn culture since 2003. In order to predict its potential toxicological impacts, the environmental fate of this herbicide and the molecular mechanisms underlying stress responses in non-target microorganisms have to be identified. These points are not well documented so far. A mesotrione-degrading strain, *Bacillus megaterium* IB11, isolated from an agricultural soil was used as a reference model to study the mesotrione biodegradation pathway [1]. Three metabolites were identified coming from the reduction of the nitro group of mesotrione leading to hydroxylamine derivatives, and then from hydrolysis reactions leading to the final accumulation of AMBA (2-amino-4-methylsulfonylbenzoic acid) in the medium. The aim of this research work was to study the metabolic shifts observed in strain IB11 after exposure to mesotrione and to identify the enzymes involved in its degradation. The metabolic response of the strain IB11 to mesotrione stress was studied by comparing the intracellular proteomes of mesotrione-treated and control cultures by a two Dimensional-Differential In Gel Electrophoresis approach (2D-DIGE). Sixteen proteins mainly involved in stress, metabolic and storage mechanisms were identified. However, the network of these differential proteins allowed us to emphasize a direct link with nitroreductase (NR) enzymes. These results are consistent with the chemical structures of metabolites produced during mesotrione degradation and suggest the implication of a NR in the transformation of mesotrione into AMBA. To test this hypothesis, 9 genes coding for nitroreductases, showing 11% to 64% of similarity in their amino acid sequences, were amplified in IB11 strain and the corresponding proteins produced in expression vector. Four of them have been purified and one showed 20% transformation of mesotrione. The activity tests of the other NR towards mesotrione are under progress. This study constitutes the first identification of genes/enzymes involved in mesotrione biodegradation, allowing a better knowledge of mesotrione biodegradation pathways. These genes and/or enzymes may also be used as biomarkers to predict the capacity of ecosystems to degrade mesotrione and to assess their contamination both by the parent molecule and/or by the metabolites. These enzyme biomarkers could thus provide a powerful tool to determine the environmental risk assessment of such herbicide.

##### **Prioritization and management of multiple stressors in river basins: effects of chemical contaminants and natural stressors (P)**

#### MO167

##### **Defining future scenarios to manage aquatic ecosystems and water resources under multiple stress**

M.F. Sanchez, Groundwater Management; H. Duel, A. Alejos Sampedro, DELTARES / Groundwater Management; K. Rankinen, M. Holmberg, Finnish Environment Institute SYKE; C. Prudhomme, J. Bloomfield, Centre for Ecology Hydrology NERC; R. Couture, Norwegian Institute for Water Research NIVA; Y. Panagopoulos, NTUA National Technical University of Athens; T. Ferreira, University of Azores / Department of Geosciences; M. Venohr, Das Leibniz-Institut für Gewässerökologie und Binnenfischerei (IGB); S. Birk, University of Duisburg-Essen / Aquatic Ecology In the project MARS (Managing Aquatic ecosystems and water Resources under multiple Stress), experiments and predictive models at local, basin, and European scale will be used to assess the combined impacts of multiple stressors affecting water quantity and quality, ecological status, ecological functions, and ecosystem services under contrasting scenarios. Various future climatic and socio-economic scenarios were chosen to define three storylines at the European level, based on the latest versions of the Shared Socioeconomic Pathways and the Representative Concentration Pathways. The combinations SSP5 and RCP8.5, SSP3 and RCP8.5 and SSP2 and RCP4.5 were selected through a participatory process as starting points. These storylines differ mainly in four main aspects; main drivers in the economy, economic growth, policies regarding the environment, and public concern about the environment and protection of ecosystem services. The storylines were downscaled to the three basin regions defined within MARS using the expert knowledge of the scientists working in the basins, and the stakeholders within those basin regions. In order to simulate the future scenarios at both basin and European scale, and to assess the impacts of multiple stressors, quantitative values for the input parameters and variables for each scenario are required. Several projects and modelling tools were reviewed with the aim of identifying quantitative data fitting the selected storylines. The data was derived mainly from the previous projects and tools, including CLIMSAVE, ISIMIP, BASE, SCENES, and IMAGE. Values for diverse climate variables, runoff, water abstraction, potential flood plains, nutrient diffuse source emission, land use, population and GDP were collected. The result is a suite of quantitative values for diverse parameters and variables in gridded or vector format, which range from daily to yearly time steps at resolutions ranging

from 5 by 5 arc minutes to a 0.5 by 0.5 degrees spatial resolution across Europe. These quantitative values can be used to drive the simulations of the three storylines defined within the MARS project.

#### MO168

##### **Valuation of ecosystem services of aquatic ecosystems under water scarcity - a methodological framework to elicit stakeholders' perspective**

P. Ker Rault; J. Luttik, Alterra

Freshwater ecosystems are under threat from the effects of multiple stressors, including organic and inorganic pollution, land use changes, water abstraction, invasive species and pathogens [1]. Little is known beyond the described effects of single stressors on the chemical and ecological status of water bodies and on their ecosystem functionality. This lack of knowledge limits our capacity to understand ecosystem responses to multiple stressors and to define a programme of measures that can improve the ecological status of a water body as sought by the European Water Framework Directive. Decision support system tools supporting the implementation of the WFD including land use scenarios are commonly based on the DPSIR model. The Economics of Ecosystems and Biodiversity (TEEB) approach provides a framework for assessing multiple stressor. Economic valuation includes monetary and non-monetary methods. Monetary methods although under continuous development and construction are well documented. Non-monetary valuation relies on perception and values of stakeholder at large. The objectives of this article are to i.) adapt the TEEB framework for the assessment of aquatic ecosystems under multiple stressors, ii.) to elicit Economic valuation of ecosystem services from the numerous perspectives of stakeholders in participative activities and to identify trade offs as well as multiple benefits and iii.) to provide a conceptual bridge between the DPSIR model and TEEB approach to enrich programme of measure to aim toward Good ecological status. The diagramme below presents the methodological framework to bridge TEEB framework with the DPSIR model along 3 fields work activities in 6 river basin affected by water scarcity: Ebro (Spain), Adige (Italy), Sava (Slovenia), Evrotas (Greece), Anglian (England) and Souss Massa (Morocco). The field works includes two participative workshop with the water framework directive community (stakeholders) in each river basin. The first participative workshop aims to elicit their perspectives, understandings and values, and to comments on scenarios and to test the plausibility of computer based model output. Follows the questionnaire based social survey, held to prioritise ecosystem services benefits and to test potential programme of measures amongst the river basin population. The final workshop aims to validate previous finding, to present output from land use model and to test acceptance for proposed measures with initial stakeholders.

#### MO169

##### **Development of an Integrated Methodology for the Sustainable Environmental and Socio-economic Management of the Water Resources Ecosystem.**

I. Souliotis; P. Koundouri, ATHENA

The development of the Water Framework Directive aimed to establish an integrated framework of water management at European level. This framework revolves around inland surface waters, transitional waters, coastal waters and ground waters. In the process of achieving the environment and ecological objectives set from the Directive, the role of economics is put in the core of the water management. An important feature of the Directive is the recovery of total economic cost of water services by all users. The total cost of water services can be disaggregated into environmental, financial and resource costs. Another important aspect of the directive is the identification of major drivers and pressures in each River Basin District. The presentation describes a methodology that can be followed in order to achieve sustainable and environmental and socioeconomic management of freshwater ecosystem services. The ecosystem services approach is in the core of the suggested methodology for the implementation of a more sustainable and efficient water management. In a nutshell, this approach consists of the following three steps: (i) socio-economic characterization of the River Basin area, (ii) assessment of the current recovery of water use cost, and (iii) identification and suggestion of appropriate programs of measures for sustainable water management over space and time. This methodology is consistent with a) the economic principles adopted explicitly by the Water Framework Directive (WFD), b) the three-step WFD implementation approach adopted in the WATECO document, c) the Ecosystem Service Approach to valuing freshwater goods and services to humans. The presentation starts with the economic aspect and implementation of WFD, continues with the description of Ecosystem Services Approach and ends with the description of the steps and sub-steps of the three-step methodology. Furthermore, the presentation analyses how the effects of multiple stressors and socio-economic development can be quantified in the context of freshwater resources management.

#### MO171

##### **Determining the release of hydrophobic organic contaminants from sediment by in-situ benthic flow-through chambers**

L. Mustajärvi, Stockholm University / Applied Environmental Science ITM; E. Eek, NGI / Environmental Technology; G. Cornelissen, NGI; A. Sobek, Applied Environmental Science ITM

This study presents a novel *in-situ* benthic flow-through chamber for determination

of release of hydrophobic organic contaminants (HOCs) from sediment to water. Sobek et al. (2014) observed high chemical activity ratios between pore water and bottom water for dioxins in coastal areas of the Baltic Sea, demonstrating a potential release of dioxins from sediment to the water column. Lab and modelling studies (Thibodeaux et al. 2003 and Granberg et al. 2008) have shown that bioturbation is an important parameter increasing the release of HOCs from sediment to water. *In-situ* measurements of the release of HOCs from sediment to water related to bioturbation have not been done previously. The design of our novel benthic flow-through chamber was developed based on a closed benthic chamber, which has proven useful in assessing diffusive flux of HOCs from sediment (Eek et al. 2010). Since the previous version of the chamber was closed to ambient water, oxygen deficiency in the chamber could stress the benthic fauna and lead to cessation of bioturbation activity. This means that the closed chamber does not measure the HOC flux as it occurs under natural conditions. The design of the flow-through benthic chamber enabled measurement of sediment to water flux while the water in the chamber was kept at ambient oxygen concentration by constantly pumping ambient water through the chamber. In order to measure flux from the sediment enclosed by the chamber, incoming water was stripped of its content of HOCs by pumping the water through a sorbent. HOCs released from the sediment was captured on a second sorbent in the water flow from the chamber. The relative importance of bioturbation can be studied by comparing flux measured with a flow-through chamber and flux measured by a closed chamber. The advantages of the *in-situ* determination of flux over flux determined in lab or by modeling are: 1) it yields a direct measurements of the flux with the least sample alteration; 2) it does not require assumptions that are necessary in modeling. Eek, E.; Cornelissen, G.; Breedveld, G. D. *Environ. Sci. Technol.* **2010**, 44, 6752–6759 Granberg, M. E.; Gunnarsson, J. S.; Hedman, J. E.; Rosenberg, R.; Jonsson, P. *Environ. Sci. MALDI-TOF is ideally suited for polymer analysis because of simple acquisition of the mass spectra which show mainly single-charged quasi-molecular ions with hardly any fragmentation. This technique requires that the polymer has a relatively narrow molecular weight distribution (MwD) [1250-10000]. Simple sample preparation, fast analysis times, the variety of available matrices, low sample consumption, and particularly the formation of singly charged ions, are some of the well known advantages of the MALDI technique. The present study aims to develop an analytical method for the study of biodegradation of different homo-polymers to be used as probe for the evaluation of the so called “river metabolism”. We have unequivocally identified and described the studied polymers, on the basis of their characteristic repeating units. Chain length shows a distribution approximately shaped as a Gaussian curve (Fig. 1a). Progress of biodegradation is reflected on the corresponding changes in the chain length distribution pattern (Fig. 1b). Here, we present the preliminary results obtained by MALDI-TOF MS characterization of different commercially available biodegradable homo-polymers subjected to biodegradation conditions, both at laboratory and field (river) scale. Results are discussed in the context of river functioning. **<strong>Fig. 1a.** MALDI-TOF MS spectra of Poly(caprolactone)diol 1250 **<strong>Fig. 1b.** MALDI-TOF MS spectra of Poly(caprolactone)diol 1250 at day 13 **Keywords:** Polymers, MALDI, Biodegradation, Rivers

##### **Spatial and temporal changes in multibiomarker responses of feral *Carcinus maenas* under scenarios of high abiotic variations and decreased metal contamination**

A.P. Rodrigues, CIIMAR / METOX Coastal and Marine Environmental Toxicology; M.T. Oliva-Teles, REQUIMTE; C. Monteiro, I.O. Abreu, CIIMAR Interdisciplinary Centre of Marine and Environmental Research; S.R. Mesquita, Center of Marine and Environmental Research CIIMAR / METOX Coastal and Marine Environmental Toxicology; C. Delerue-Matos, REQUIMTE; L.

Guimaraes, CIIMAR University of Porto / METOX Coastal and Marine Environmental Toxicology

A biomonitoring study was performed in 2010 and 2012 in two NW Iberian estuaries under different anthropogenic pressure. One is low impacted (Minho estuary) and the other is contaminated (Lima estuary) by metals, which are a continuous priority due to their persistence in the environment and life-threatening effects in aquatic organisms. However, in consequence of some protection measures and the economical crises that affected industrial activities (e.g., shipyard and harbour), contamination inputs to the Lima estuary appear to be decreasing. Moreover, high temperature variation and drought events were reported in the area. Our aim was, thus, to verify the usefulness of a multibiomarker approach, using *Carcinus maenas* as bioindicator species, to reflect diminishing environmental contamination and improvement of biomarker responses under abiotic variation. Sampling sites were assessed for metal levels in sediments and *C. maenas*, water abiotic factors and biomarkers of neurotoxicity, energy metabolism, biotransformation, antioxidant defences, and oxidative damage. High inter-annual and seasonal abiotic variation was observed. Water temperature and salinity, and nutrient levels (nitrites, nitrates, phosphates) increased in 2012, compared with 2010, denoting some eutrophication and loss in water quality. Data were consistent with the climatological context of 2012 in Portugal and the expected trends of occurrence of extreme climate events. Metal levels in sediments and crab tissues were markedly higher in 2010 than in 2012 in the contaminated estuary. Biomarkers indicated differences between the study sites and seasons and an improvement of effects measured in *C. maenas* from the polluted estuary in 2012. Integrated Biomarker Response (IBR) index depicted sites with higher stress levels whereas Principal Component Analysis (PCA) showed associations between biomarker responses and environmental variables. The multibiomarker approach and integrated assessments proved of potential usefulness to the early diagnosis of the success of remediation measures in impacted sites. Work funded by Project ECORISK (NORTE-07-0124FEDER-000055) within the SR&TD Integrated Program MARVALOR, supported by Programa Operacional Regional do Norte (ON.2 – O Novo Norte) and by the European Regional Development Fund; and by the Portuguese Foundation for Science and Technology (FCT) through project PEst-C/MAR/LA0015/2013.

## Metabolomics and Pollution Sourcing: Molecular Markers in the Field (P)

### MO174

#### Non-targeted HPLC-HRMS metabonomics for studying the effects of cadmium and copper exposure in Japanese rice

M. Navarro, IDAEA-CSIC / Environmental Chemistry; J. Jaumot, IDAEA CSIC / Environmental Chemistry; R. Tauler, IDAEA-CSIC

During the last centuries, the level of heavy metals on soil and surface water has increased significantly. These pollutants can be found as constituents of the Earth's crust and geological processes, but human activities, such as mining, agriculture and a wide range of industrial activities, can drastically alter heavy metal geochemical cycles [1]. Metal pollutants are easily absorbed by plants and can be bioaccumulated through the food chain. Since the diet is the main source of exposure to heavy metals for the general population, intensive research has been performed on the accumulation of these pollutants in edible plants, such as in rice [2-3-]. Metabolomics is as a powerful approach to study metabolic pathways and mechanism-of-action implicated in heavy metal toxicity and plant defense strategies against these pollutants. This work aims at identifying the principal molecular markers related to cadmium and copper exposure in Japanese rice (*Oryza sativa japonica*). For this purpose, rice was cultivated at optimal conditions during 10 days and after this period, it was exposed to different concentrations of cadmium and copper (from 10 to 1000 µM) for 10 days more. After harvesting, rice leaves were separated for analysis. A non-targeted HPLC-HRMS method has been employed coupling an HILIC TSK gel Amide-80 column (Tosoh Bioscience 5µm, 250 mm, 2.0 mm i.d.) with an LTQ-Orbitrap mass spectrometer (Thermo Scientific). Different multivariate data analysis tools (Principal Component Analysis, Partial Least Squares - Discriminant Analysis and Multivariate Curve Resolution) have been used to discriminate between control and treated samples and to identify which molecular markers were the most relevant for this classification. Finally, KEGG database was used to evaluate the metabolic pathways changes underlying cadmium and copper exposure. The research leading to these results has received funding from the European Research Council under the European Union's Seventh Framework Programme (FP/2007-2013) / ERC Grant Agreement n. 32073 [1] A. D'Alessandro, M. Taamalli, F. Gevi, A.M. Timperio, L. Zolla, T. Ghnaya, *J. Proteome Res.* 12 (2013) 4979-4997. [2] N. Ahsan, T. Nakamura, S. Komatsu, *Amino Acids* 42 (2012) 317-327. [3] F. #### Towards standardized validation and reporting of non-targeted metabolomics approaches for routine analysis and regulation

J. Riedl, Safety in the Food Chain; S. Esslinger, C. Fahl-Hassek, BfR Federal Institute for Risk Assessment / Safety in the Food Chain

Metabolomics approaches have been demonstrated to be successful in many research studies of various fields, but their application in routine analysis or implementation in regulatory frameworks is still in its infants. Regarding the huge amount of data that is generated by non-targeted metabolomics approaches, challenges that have to be faced are i) to distinguish study-relevant information from unintended systematic variation and noise and ii) to guarantee the robustness of the extracted data. Whereas for classical targeted methods used for routine analysis and regulatory purposes usually validation and standard operating protocols do exist, for non-targeted metabolomics, typically based on spectroscopic or spectrometric measurements and a subsequent multivariate statistical analysis, such strategies have not yet been developed. A review of literature with regard to validation strategies, in this case on food authentication using metabolic fingerprinting techniques, revealed two issues that may hinder a broader application of metabolomics approaches: a lack of validation strategies for the metabolomics workflow and limited reporting on data quality. In particular, model validation within the experiment was well addressed, but the accuracy of the results considering experiment-to-experiment, instrumental, operator or laboratory variation was hardly considered. Moreover, data processing was little transparent in many studies with hardly characterised metabolic fingerprints used for data evaluation. On this basis, recommendations and future work for validation and reporting of non-targeted metabolomics are derived to progress standardization for a potential implementation of such approaches in routine analysis for food control purposes. These suggestions of "good practice" for validation and reporting might also be relevant for other applications within regulatory frameworks.

### MO176

#### UNTARGETED METABOLOMIC ANALYSIS FOR THE ASSESSMENT OF BISPHENOL-A EFFECTS ON ZEBRAFISH EMBRYOS

E. Ortiz, IDAEA-CSIC / romataulercidescies; J. Jaumot, IDAEA CSIC / Environmental Chemistry; B. Pina, IDAEA-CSIC / Environmental Chemistry; F. Benavente, V. Sanz-Nebot, University of Barcelona; R. Tauler, IDAEA-CSIC

Zebrafish (*Danio rerio*) is a model vertebrate organism for biological, behavioural and biomedical research. In particular, zebrafish embryos are a well-recognized model for environmental risk assessment of chemicals due to their rapid development into larvae (within 48 hours) and to their high sensitivity to chemical treatment. In addition, their small size, wide distribution and easy growth conditions offer the possibility to perform small-scale and high-throughput analyses for -omics studies, including metabolic profiling [1]. Bisphenol A (BPA) is a chemical produced at large-scale for use in the production of plastics and epoxy resins. Furthermore, BPA is an endocrine disruptor that interferes in the endocrine system of aquatic biota at concentrations often found on certain ecosystems. In this work, the effects of bisphenol A (BPA) (at low concentration values: 1, 2 and 4 µg/mL which is LOEC (Lowest observed effect concentration)) on metabolic profiles of five-day-old zebrafish embryos had been evaluated. For this purpose, an untargeted metabolomic approach coupling chromatographic separation by hydrophilic interaction liquid chromatography (HILIC) with mass spectrometric detection and advanced chemometric tools was used to evaluate the metabolic changes induced by BPA exposure in the zebrafish embryos. HILIC-HPLC-MS data were analyzed by a combination of different chemometric tools such as Principal Component Analysis (PCA), Partial Least Squares Discriminant Analysis (PLS-DA) and Multivariate Curve Resolution (MCR) [2]. The results show a clear discrimination between control and stressed samples and also allow the identification of several metabolites potentially related to the BPA exposure on the basis of their characteristic mass spectra. Finally, this list of identified metabolites allows obtaining information on the metabolic pathways and mechanisms affected by the BPA exposure. This research has been funded by the European Research Council under the European Union's Seventh Framework Programme (FP/2007-2013) / ERC Grant Agreement n. 32073. [1] H. Xu, M. Yang, W. Qiu, C. Pan, M. Wu, *Environ. Toxicol. Chem.*, 32, 1793-1799 (2013). [2] R. Tauler, *J. Chemometrics*, 24, 87-90 (2010).

### MO177

#### Metabolomics responses to PAHs in the mussel *Mytilus galloprovincialis* under different nutritive conditions

M. Albentosa, Instituto Español de Oceanografía / Centro Oceanográfico de Murcia; A. Sevilla, University of Murcia; J.A. Campillo, Instituto Español de Oceanografía; C. González-Fernández, Spanish Institute of Oceanography / Marine ecosystems; L. Vinas, Spanish Institute of Oceanography; A. Franco, Instituto Español de Oceanografía; C. Bernal, University of Murcia; A. Lozano, Universidad de Murcia; M. Canovas, University of Murcia; J. Bellas, Centro Oceanográfico de Vigo / IEO (Instituto Español de Oceanografía)

The results of biological effects obtained in biomonitoring studies, mainly those covering a wide geographical area, are sometimes affected by the large amount of natural variables affecting the biological processes considered as indicators of pollution (biomarkers). One of major source of this natural variability is the particular trophic condition for each sampling site which can also vary between sampling times. Previous studies published by our group in large-scale programs highlighted the influence of nutritional mussel condition on traditional biomarkers measurements. Environmental metabolomic represents an emerging approach to assess the health status of organisms and the impact of marine pollution on them. This -omic aims to study a set of metabolites/low molecular weight intermediates,

which vary according to the physiology, development or pathological state of the target organ. Metabolomic is being considered a powerful tool to characterize the metabolic responses of an organism to both natural and anthropogenic variables that can occur in its environment. The main objective of this study was to determine the relative importance of two variables: food availability and the presence of toxicants, on the metabolic profile of digestive gland of the mussel, *Mytilus galloprovincialis*, in order to distinguish the changes in the metabolites levels due to the toxicant and/or the food condition. Three experimental trophic conditions were simulated by regulating daily food ration of mussels for 45 days: low food condition (N1), medium food condition (N2) and high food condition (N3) which promoted negative, and two positive mussel energy balances, respectively. In all cases, mussels were exposed to two nominal fluoranthene (FLU) concentrations (3 and 60  $\mu\text{g L}^{-1}$ ), for 3 weeks. On the whole, mussel nutritional condition showed a larger effect than pollutant exposure, on the metabolomic profile. However, there were some specific metabolites that responded both to animal condition and to the presence of the toxicant.

#### MO178

##### **Metabolite profiling of 3 benthic invertebrates exposed to wastewater treatment plant effluents by nanoLC-HRMS: a stepping stone to a better understanding of the inter-species response diversity**

A. Berlioz-Barbier, ISA; A. Bulete, Institut des Sciences Analytiques UMR TRACES Team / Service Central d'Analyse; J. Garric, Irstea Lyon; E. Vulliet, CNRS

Within the Water Framework Directive (WFD), there are now regulatory arguments in favor of using biota for assessing contamination trends in water body. However, for risk assessment purposes, biological effects on organisms depend on the species of sentinel organisms, the concentration of active toxicant that reaches the target site, and the exposure conditions. In this context, the understanding of the inter-species response diversity needs to be improved to assess the relevance of invertebrates (especially benthic invertebrate) as biomonitoring tools. Metabolite profiling is critical in many aspects of the life sciences and can be used in multiple ways to assess human impacts in the environment. However, obtaining precise information on the chemical composition of complex natural extract (metabolomes) that are primarily obtained from microorganisms is a challenging task that requires sophisticated analytical methods. In this respect, significant advances in hyphenated chromatographic technique such as LC-HRMS, as well as data mining and processing methods, have occurred over the last decade. Moreover, the developments of miniaturized LC strategies such as nanoLC have been studied to improve the sensitivity and increased the number of detected compounds, especially endogenous compounds that are present in small amount. The general aim of this study was to develop a metabolite fingerprinting by using an innovative approaches based on injection of sub-microliter volumes of benthic invertebrate extracts directly on to a nanoLC-nanoESI- HRMS platform. This high-throughput analysis allowed a rapid classification of different samples. The samples consisted of several organism extracts belonging to three benthic invertebrate species. Test organisms were exposed to waste water treatment plant effluents via caging procedures and laboratory experiments. The purpose of this method was not to identify each individual metabolite, but to compare patterns of metabolite that change in given biological systems. Multivariate data analyses have been applied in fingerprinting to determine differences and classify samples.

#### MO179

##### **Chemical Pollution Source Markers for Animal and Pharmaceutical Wastes**

J.J. Harwood, J. Hendricks, S.L. Narayanan, Tennessee Technological University / Chemistry

We are developing and testing LC-MS analytical methods to identify the sources of organic pollution in streams and rivers. The methods use "molecular markers", compounds which indicate specific sources of pollution. The artificial sweetener sucralose is an excellent candidate marker of human wastewater input. The compound is stable, resisting both metabolism and degradation in wastewater treatment, and is present in analyzable concentration in waters. We are investigating correlation of this marker with the presence of estrogenic compounds and carbamazepine in domestic wastewater. In our initial study we sampled influent and effluent from three municipal wastewater treatment plants in Tennessee. The samples were analyzed by LC-MS/MS with the electrospray ionization source (ESI). Both grab and POCIS samples were obtained and analyzed for the estrogens estrone 17- $\beta$ -estradiol and 17 $\alpha$ -ethinylestradiol. The profiles of fecal sterols associated with particulates have been used to identify waste inputs from specific animals. We are investigating adding bile acids to this sterol profile for more definitive source identification of animal pollution. The sterols we have chosen, cholesterol, stigmastanol, stigmastanol and coprostanol, are characteristic of human and agricultural animal waste. These sterols do not ionize in the LC-MS ESI source, and we have developed the common alternative atmospheric pressure ionization (APCI) for this application. The characteristic bile acids we analyze are cholic acid, chenodeoxycholic acid, deoxycholic acid, hyodeoxycholic acid and lithocholic acid. We have developed methodology to separate and analyze the bile acids and fecal sterols commonly suggested as molecular markers to distinguish pollution from different animal species can be separated and analyzed in a single LC-MS analysis. Results for analysis of municipal wastewater and a local stream impacted by cattle production will be presented.

#### MO180

##### **Assessment of artificial sweeteners as molecular markers to detect sewage contamination in Asian and African waters in comparison to traditional and emerging markers**

H. Takada, Tokyo University of Agriculture and Technology / Laboratory of Organic Geochemistry LOG; K. Yoshimatsu, S. Isogai, K. Seki, T. Koike, A. Shimizu, Tokyo University of Agriculture and Technology  
We surveyed Vietnam, Thailand, Philippines, Indonesia, Japan, Mozambique, South Africa, Kenya, and Ghana by visiting 358 locations in 2010 – 2014. The water samples including sewage, urban and rural river water, and groundwater were analyzed for artificial sweeteners (Acesulfame : ACE; sucralose : SUC; saccharin : SAC; cyclamate: CYC). Antibiotics were also measured. In addition, linear alkylbenzenes (LABs) and coprostanols were determined. LC-MS/MS coupled with online solid-phase extraction enabled sensitive analysis of ACE with 2 ng/L of detection limit and 5 ng/L of LOQ. Among 4 artificial sweeteners, ACE was most frequently detected (228 samples among 358 samples) due to their wide usage and low detection limit. ACE concentrations in sewage and heavily-sewage impacted water were ~ 50,000 ng/L in the countries studied, except for Ghana, Kenya, and Thailand with ~ 5,000 ng/L. SUC was less frequently detected (59/358) due to their higher detection limit (100 ng/L) and less usage in some low-income countries probably because of their higher price. Because CYC and SAC are susceptible to biodegradation, they were also less frequently detected in surface waters. However, their higher abundance (e.g., higher CYC/ACE ratio) together with lower I/E ratio of LABs was observed at some locations, suggesting fresh sewage inputs. In some rural rivers in Ghana, no ACE was detected whereas veterinary antibiotics (i.e., tetracyclines) were detected, suggesting the inputs of animal waste. In groundwater in Japan, ACE was widely detected in shallower (~ 10 m) aquifer whereas CYC was detected in deeper (~ 100 m) aquifer because later was used in the past (~ 1960s). However, artificial sweeteners were rarely detected in groundwater in African countries (13/58) and Vietnam (0/12). This is probably due to more recent introduction of ASs to the markets and, therefore, artificial sweeteners have not reached at the deep (down to 200 m) aquifer. On the other hand, sulfonamide antibiotics were widely (41/58) detected in groundwater in African countries, suggesting the utility of the antibiotics as indicator of sewage in groundwater in African countries. In conclusion, ACE has proved to be the most sensitive and reliable marker to assess sewage inputs to surface waters in Asian and African countries. Combination of multiple markers increased ability and reliability of the detection and provided further information on types of sewage.

##### **Sewage effluent discharges as a driver of activity and pathogenicity change in the microbiome of Kokemäenjoki River watershed**

T. Pitkänen, National Institute for Health and Welfare / Water and Health Unit; B. Jayaprakash, National Institute for Health and Welfare / Environmental Microbiology Unit; J.K. Juntunen, Finnish Environment Institute / Freshwater Centre; A. Kauppinen, National Institute for Health and Welfare / Water and Health Unit; N. Perkola, Finnish Environment Institute SYKE / Laboratory Centre; A. Hokajärvi; J.W. Santo Domingo, US Environmental Protection Agency / Cincinnati; T. Huttula, Finnish Environment Institute / Freshwater Centre; I.T. Miettinen, National Institute for Health and Welfare / Water and Health Unit  
The transmission pathways of waterborne pathogens and their markers were studied in the Kokemäenjoki River water course in Finland. The water flows through hydropower plants and the river waters are used for producing artificial ground water. Besides energy and water supply, the whole river reach is providing also other important ecosystem services like beaches (e.g. three large EU-level bathing sites), water sports and summer cottage sites. Their values are affected by human-induced contamination as the purified waste waters are led to the Kokemäenjoki River. In this study, the fate of faecal pollution was followed from treated sewage effluent discharges to the raw waters used for drinking water production. We used molecular source tracking markers and consumer chemicals to determine the extent of human-induced contamination in several surface water locations alongside the Kokemäenjoki River. Pathogen specific viral and bacterial analyses as well as deep sequencing (NGS) of 16S rRNA transcripts (rRNA) and 16S rRNA genes (rDNA) of microbial communities were conducted. The hydrological transport model of the river was used to evaluate the transmission pathways of the treated sewage at the selected reaches of the river. The associations between the numbers of human-specific molecular and chemical markers (i.e. HF183, PMMOV and acesulfame-K), microbiome activity levels (i.e. rRNA:rDNA ratios) and the presence of pathogenic microbes (i.e. *Campylobacter*, *Salmonella*, norovirus, adenovirus) were studied. As many of the studied contaminants are associated with faecal pollution, *Bacteroides*-like sequences were identified from the NGS data of the sewage effluent and surface water samples. Furthermore, the influence of the non-human microbial pollution sources was evaluated by applying ruminant-, swine- and gull-specific molecular markers targeted to rRNA and rDNA. The characterization of the environmental water microbiome structure using 16S ribosomal gene and transcript targeted next generation sequencing approach showed that factors other than human impacts may affect most of the active members of the water microbiome. However, the pathogen- and host-specific analyses were crucial in identifying the link between wastewater discharges and the microbial activity and pathogenicity detected in the Kokemäenjoki River water

course. The results of this study provide a unique insight on the fate and transport of faecal bacteria in this watershed.

## Metals in the Environment: Fate, Speciation and Bioavailability in Water, Soil and Sediment (P)

### MO182

#### Trace metals (Zn and Hg) and Metallothionein content in wild Black Tilapia (*Oreochromis mossambicus*)

A. Naji; M. Yousefzadi, University of Hormozgan

Metallothionein (MT) concentrations in gill and liver tissues of *Oreochromis mossambicus* were determined to assess biological response of fish to levels of some metals. Metal concentrations in gill and liver tissues of *O. mossambicus* ranged from 16 to 52 for Zn, and 2 to 67 for T-Hg (all in  $\mu\text{g/g}$  wet weight, except for T-Hg in  $\text{ng/g}$  wet weight). Accumulation of Cd, Zn, Cu and Hg ( $\mu\text{g/g}$  wet weight) in the liver and gills of *O. mossambicus* were in the order of liver > gills. The concentrations of Cd, Zn, Cu and Hg in fish tissues were correlated with MT content. The increases in MT levels from the reference area Puchong Tengah compared to the polluted area Kampung Seri Kenangan were 3.4- and 3.8-fold for gills and livers, respectively. The results indicate that MT concentrations were tissue-specific, with the highest levels in the liver. Therefore, the liver can act as a tissue indicator in *O. mossambicus* in the study area.

#### Chemical fractionation of Cu and Cd in surface sediments of the southern part of Caspian Sea, Iran

A. Naji; T. Sohrabi, Inland Water Aquaculture Research Institute; M. Yousefzadi, Marine Biology

This study concentrates on the speciation and distribution patterns of some heavy metals (Cu and Cd) in surface sediments in the southern part of the Caspian Sea, the biggest lake in the world, to obtain an overall classification for the origins of metals in the area using a sequential extraction technique. All Sampling stations, Cu were mostly (>50%) accumulated in the resistant fraction, which indicated that there were no significant anthropogenic inputs of Cu into the surface sediments of the south Caspian Sea. Mazandaran and Golestan provinces in the middle and western parts of the Caspian Sea, in the Iranian zone, accumulated higher percentages of non-resistant fractions of Cu. The present study revealed that the coastal area of the south Caspian Sea is still not seriously contaminated. Cadmium in Guilan and Golestan provinces were dominated by non-resistant fractions (55 to 69%), which indicated more anthropogenic inputs of Cd on the south coast of the Caspian Sea in comparison with other metals (Figure 2). In the present study, the concentrations of heavy metals were compared with ERL and ERM values to estimate the possible toxic effects of heavy metals at different stations. Cd was distributed between the <em>

#### Mobility of Cd in soils fertilized with sewage sludge containing Cd pigments

N. Bandow, Federal Institute for Materials Research and Testing / Contaminant Transfer and Environmental Technologies; A. Meißner-Wiesner, Freie Universität Berlin; F.G. Simon, BAM Federal Institute Materials Research and Testing / Contaminant Transfer and Environmental Technologies

Cd sulfide pigments are used for artists' paints (PY35, Cadmium yellow) and are possibly introduced to sewage treatment plants by cleaning used brushes with water. After settling together with the activated sludge in the sedimentation basin, the pigments may be transferred to soils as sewage sludge is often used as fertilizer due to its high nutrient content. It is well known that Cd sulfides are sparingly soluble, however the cadmium can be mobilized by oxidizing or acidic conditions. Mobilized Cd can be transported to the groundwater or be introduced in the human food chain after up take by plants. Cd is highly toxic, suspected to cause cancer and harmful to the bone structure. For a proper risk assessment it is necessary to determine the mobilization potential of Cd under realistic environmental conditions. In this work column percolation test were used for determination of the mobility of the cadmium pigments under different redox conditions in an accelerated test. For this purpose sewage sludge was spiked with Cd pigment and spiked to soils containing different amount of organic carbon. These soil materials were percolated using artificial rain water. Eluates were sampled over a period of 68 h and in all eluates the pH value, conductivity, turbidity, DOC and Cd-concentration were analyzed. The redox potential was measured in selected columns on-column directly after the outflow. The redox potential is decreasing fast after start of the percolation and shows a clear relation to the organic carbon content of the soil material: eluates of columns with higher organic carbon show a slower decrease in redox potential. In accordance with these results more Cd is released for soils with high organic carbon content.

### MO185

#### Metals accumulation in enchytraeids exposed to metal-polluted soils under different scenarios of climate change

M. González-Alcaraz, Faculty of Earth and Life Sciences, VU University / Ecological Science; R. Verweij, Faculty of Earth and Life Sciences VU University / Department of Ecological Science; C. van Gestel, VU University Amsterdam /

### Ecological Science

The present study aimed to assess the effects of climate change (temperature and soil moisture content) on the accumulation of metals (Cd, Pb and Zn) in enchytraeids exposed to soils polluted by metal mine wastes. Bioassays with *Enchytraeus crypticus* were performed under different combinations of temperature (20 and 25 °C) and soil moisture content (50 and 30% of the soil water holding capacity -WHC) in dilution series of three polluted soils (mine tailing, forest and watercourse). Soils were diluted with Lufa 2.2 soil. After 21 days exposure to the different climate conditions, metal levels in the enchytraeids were determined. Soil samples without enchytraeids and incubated under the same conditions were analysed to assess the effect on soil pH and available metal concentrations (extracted with 0.01M  $\text{CaCl}_2$ ). Soil pH did not change during the experiment. A general decrease in available metal concentrations was shown during the incubation period. The latter was more evident in the watercourse soil, where the available concentrations decreased from 678 to 217-301  $\mu\text{g Cd kg}^{-1}$ , 807 to 229-530  $\mu\text{g Pb kg}^{-1}$  and 31020 to 9849-16677  $\mu\text{g Zn kg}^{-1}$ . The treatments at 50% of the soil WHC reached significantly lower available concentrations, both at 20 and 25 °C. Internal metal concentrations were related to the available metal levels in this soil, with higher bioaccumulation at 30% of the soil WHC. Metal uptake also was significantly higher when 30% of the soil WHC was combined with 25 °C with increases (from 20 °C+50% WHC to 25 °C+30% WHC) from 21.8 to 58.8  $\mu\text{g Cd g}^{-1}$ , from 2029 to 5382  $\mu\text{g Pb g}^{-1}$  and from 1671 to 4068  $\mu\text{g Zn g}^{-1}$ . The soils from the mine tailing and the forest also showed a decrease in the available metal concentrations, but without differences among the different climate conditions. Nevertheless, in the mine tailing soil, metal bioaccumulation was significantly higher when enchytraeids were exposed at 25 °C and 30% of the soil WHC with internal concentrations of 21.1  $\mu\text{g Cd kg}^{-1}$ , 3082  $\mu\text{g Pb kg}^{-1}$  and 2667  $\mu\text{g Zn kg}^{-1}$ . The forest soil showed a different behaviour in terms of metal bioaccumulation, without differences among the climate conditions tested. This study showed that metal uptake in enchytraeids was higher at low soil moisture content, which was mainly due to a higher metal availability in the soil. Metal bioavailability seemed further enhanced by high temperature.

### MO186

#### Metals contamination of marine sediments: how to assess bioavailability overcoming the granulometric bias.

S. Breda, Department of Molecular Science and Nanosystem; S. Chiesa, University of Aveiro & CESAM / Biology; R. Freitas, Biology; L. Gobbo, Ca' Foscari University of Venice / Molecular Sciences and Nanosystems Department; E. Figueira, CESAM University of Aveiro; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; E. Argeese, Ca' Foscari University of Venice Natural background and "granulometric bias" are among the most challenging topics about metals and metalloids pollution. Sediment bio-geochemistry is a key issue to be investigated, in order to identify the main drivers controlling contaminants exchanging into different chemical forms within an environmental matrix. Environmental legislation is still based on the measurement of total metal and metalloid content rather than on the amount of element available, that is strongly influenced by sediment physicochemical properties. In order to develop a multidisciplinary set of tools for a whole comprehension of metal and metalloid behaviour, an insight into bio-geochemical processes associated with sediment contamination must be conducted. In the present work, sediment samples were collected in four areas in the Ria de Aveiro lagoon (Portugal). For each area the redox potential, the grain size distribution and the total metal content were determined for sediments. In addition, sediment from each sampling area was dry sieved and each grain size class was subjected to the geochemical speciation protocol in order to determine the amount of the bioavailable metals (Cd, Cr, Cu, Fe, Mn, Ni, Pb and Zn) and As associated with each grain size class. The results obtained showed that different grain size fractions presented different element bounding behaviour: areas presenting higher amount of clay and silt fraction are less permeable to oxygen diffusion, present very negative redox potential values and have an higher percentage of elements that are potentially bioavailable. The present work further demonstrated the key role played by these two fine-grained fractions, which are the most polluted ones. In fact, the "metal scavengers" (Fe/Mn oxide/hydroxide, organic matter and sulphides) are bounded to these fractions and are strongly influenced by the redox potential changes, which can determine elements possible release. On the other hand, sandy fraction showed low level of contamination, mainly found in the residual fraction that is never bioavailable. This fraction is known as a good estimate of element natural background.

### MO187

#### Free Indium concentration determined with the technique AGNES

J. Galceran, Universitat de Lleida / Departament de Química; M. HeidarkhanTehrani, E. Companys, Universitat de Lleida / Department of Chemistry; J. Puy, Chemistry

Ecotoxicological paradigms such as the Free Ion Activity Model (FIAM) or the Biotic Ligand Model (BLM) attribute a key role to the free metal ion concentration (or activity). So, suitable analytical methods are needed. AGNES (Absence of Gradients and Nernstian Equilibrium Stripping) is an electroanalytical technique designed to determine free metal ion concentrations in solutions. Specific systems include seawaters [1, 2], river waters [3], dispersions of nanoparticles [4], extracts of soils [3], etc. The implementation of AGNES with mercury electrodes requires

amalgamating elements such as Zn, Cd or Pb. Indium is a critical element present in electronic devices, from which it can eventually move towards the environment. The large hydrolysis processes of Indium hinders the accurate study of its speciation with most conventional techniques and, so, there are many unresolved aspects of the behaviour of free Indium in many systems [5]. Given that Indium is also an amalgamating element with a negative standard redox potential, it can be tackled with AGNES and conventional electrodes. This contribution will report on the application of AGNES to Indium systems, while considering practical issues such as the computation of the deposition potential, the deposition time and the suitability of existing stability constants for complexes with nitrilotriacetic acid (NTA) and oxalate. ##### **Reduction of chromium toxicity to duckweed *Lemna minor* in presence of humic acid**

G. Kalcikova, A. Žgajnar Gotvajn, University of Ljubljana / Faculty of Chemistry and Chemical Technology

Humic acid is a major component of humic substances, which are ubiquitous organic matter in the aquatic environment. Humic acids have a great ability to form complexes with heavy metals; they can, under certain conditions, cause abiotic reduction of heavy metals and thereby potentially influence metals' toxicity. The aim of the present study was to investigate the combined effect of environmentally relevant concentration of humic acid (HA) and chromium (Cr) on toxicity to duckweed *Lemna minor* in terms of growth rate, chlorophylls and metal content evaluation. In treatment with chromium ( $Cr = 0.15 \text{ mg?L}^{-1}$ ) the growth rate, chlorophyll *a* and *b* content were reduced by 18%, 51% and 38%, respectively. On the contrary, in the presence of HA ( $TOC = 10 \text{ mg?L}^{-1}$ ) all of the investigated parameters stayed comparable to corresponding controls. In the absence of HA, duckweed accumulated almost twice more chromium in comparison to treatments with HA. Analyses of chromium species showed, that in the absence of HA, only hexavalent chromium is present in the medium. However, in the presence of HA most of the hexavalent chromium dissipated from the water phase being reduced to trivalent chromium. The differences in chromium toxicity and accumulation in presence or absence of HA could be explained by diverse mechanisms of both chromium species uptake. Uptake of hexavalent chromium is known to be metabolically driven and carried out by sulphate transporters while trivalent chromium is mainly retained by the cation exchange sites of the cell walls or precipitate on the surface of roots and thus not further transported. Since concentrations of humic acid as low as found in the aquatic environment so significantly altered toxicity and accumulation of chromium (and possibly other heavy metals) its content should be considered as an important factor related to heavy metals toxicity assessment.

#### MO189

##### **Bioaccessible Nickel in Various Particle Sizes of House Dust from Communities Close to Nickel Mining and Smelting Operations**

N. Dai, University of Guelph-SES / School of Environmental Sciences; L. Vasiluk, B.A. Hale, University of Guelph / School of Environmental Sciences; M. Dutton, Vale Inco Ltd.

Nickel accumulation in mammalian organs after ingestion of elevated levels of nickel from food, water, soil, and dust may be a significant source of exposure for communities close to nickel mining, smelting, and refining operations. Nickel accumulation can induce chronic inflammation in the liver and kidneys, promoting cancer development in these organs. Measuring sources of nickel exposure for the non-occupationally exposed population are therefore of interest, an example being dust ingestion. Indoor dust particles that settle on surfaces adhere upon contact to the hands of children and adults, who then ingest it through hand-to-mouth behaviours. Nickel exposure through dust ingestion needs to be considered as a separate exposure pathway from soil ingestion, due to higher organic carbon content in dust and its higher total and bioaccessible nickel concentrations. Bioaccessible nickel, the amount of nickel that becomes available for intestinal absorption as a result of digestion in the stomach, is likely a more accurate exposure measure compared to total nickel concentration present in house dust. Prior work at uncontaminated sites shows that smaller dust particles have higher total nickel concentrations than bulk particles do. For bioaccessible nickel, finer particles can have increased or decreased nickel depending on the site of origin. We are examining the relationship between particle size and nickel bioaccessibility in Port Colborne and Sudbury house dusts from Ontario, Canada. Samples are being

separated using plastic sieves into ranges of in vitro SBRC glycine digestion, which simulates stomach pH and churning via shaking the dust with extraction fluid in a water bath at body temperature. Samples will be analyzed using Flame Atomic Absorption Spectrometer. We hypothesize that there is a relationship between particle size and nickel bioaccessibility in house dust, but do not know whether to anticipate that nickel bioaccessibility will be higher or lower in fine particles compared to coarse particles. Study results will inform risk assessors on the contribution of indoor dust to total nickel exposure through ingestion, for populations close to nickel mining and smelting activities.

#### MO190

##### **Investigating the concentrations of lead in soil and water next to an abandoned mine in Azuaga (Spain).**

J. Gala Fernández, University of Extremadura / Unidad de Toxicología Departamento de Sanidad Animal; F. Soler, University of Extremadura / Faculty of Veterinary Medicine; A.O. Jiménez, Unidad de Toxicología Departamento de Sanidad Animal

Environmental pollution from active or abandoned mines can become an important source of metal contamination in soil and water. This study focuses on an abandoned lead (Pb) mine (Las Musas) located in Azuaga (Extremadura, Spain) surrounded by agricultural fields and one nucleus of population. The objectives of this research were to: (a) investigate the pollution distribution of Pb in soils and waters near the Pb mine; and (b) estimate the pollution degree in these environmental matrices on the basis of quality standards for soil and waters. Samples of top soils and waters were collected at different distances from the mine (southwest, southeast, northwest, and northeast of the mine for soils and upstream, stream that goes through the mine, and downstream for waters). Pb content was analyzed by anodic stripping voltammetry after acid digestion of the samples. The data showed that the total levels of Pb in soils are not considered of concern since in all sampling sites it concentration not exceeded the regulatory levels established by the regional legislation about reference values of heavy metals in soils from Extremadura for the protection of the human health and ecosystem. On the contrary, Pb concentrations in waters were higher than the regulatory levels established in the environmental quality standards in the field of inland surface waters policy.

#### MO191

##### **Understanding the chemical speciation of silver from the use of personal care products in aquatic freshwater systems**

A. Peters, Wca Environment Ltd.; G. Merrington, Environment Agency; S. Lofts, Centre for Ecology & Hydrology / Shore Section; S.D. Smith, Wilfrid Laurier University / Department of Chemistry; R. van Egmond; R. Nasir, Wilfrid Laurier University / Chemistry

The acute toxicity of silver to aquatic organisms has been extensively tested, and biotic ligand models have been developed for both fish and invertebrates. However when validated there were limitations to their performance. The chronic toxicity of silver has been much less well studied, and the factors modifying bioavailability (i.e. interactions with complexing ligands) are not sufficiently well understood to enable robust models to be developed. Silver is known to form strong complexes with both Dissolved Organic Matter (DOM, e.g. humic and fulvic acids), reduced sulfide ligands (e.g. free sulfide  $S^{2-}$ ), and also with thiol compounds (e.g. cysteine). Attempts to understand the speciation of silver in ecotoxicity tests have revealed significant limitations in our ability to predict silver speciation under different water chemistry conditions. The relative importance of the different strong silver-complexing ligand types, as well as uncertainties regarding their concentrations in natural systems, means that a meaningful interpretation of the existing chronic ecotoxicity data for silver in terms of biotic ligand model approaches is not currently possible. The reasons for these uncertainties, and the approaches which may be taken to address them, will be outlined. The key aims of this study are to determine silver speciation in a range of aqueous systems, from simple well defined systems with individual ligands to complex systems with multiple ligands. This information is being used to determine how well WHAM VII predicts Ag complexation in receiving waters in relation to variable DOM-sulfide and free sulfide concentrations. There are differences in the binding of silver by DOM from different sources which cannot currently be explained by WHAM, but appear to depend on the sulfur content of the DOM. This may require that sulfide ligands and their silver complexes are explicitly included in model calculations. Whilst it is clear that dissolved silver can be highly toxic to some aquatic organisms, a better understanding of the conditions which are likely to result in toxicity to organisms and ecosystems would lead to considerable advances in understanding the potential risks from silver in surface waters.

#### MO192

##### **A meta-analysis for assessing the relationship between metal toxicity and metal affinity for binding to the biotic ligands of soil and aquatic organisms**

M.M. Ardestani, Ecological Science; N.M. van Straalen, VU University Amsterdam / Department of Ecological Science; C.A. Van Gestel, Vrije Universiteit, Department of Animal Ecology

Biotic ligand models (BLMs) have been developed to predict the toxicity of different metals to different organisms. Most BLMs have been derived for aquatic organisms, while work on terrestrial organisms is still in progress. A BLM considers metal speciation in the medium and the interaction of metal species as

well as other organic and inorganic ligands, competing or making complexes with the free metal ions to bind to the biotic ligands. The main assumption of these models is that when an organism is exposed to metal in different media, only a fraction of the total metal load is bound to the site of action (biotic ligand) in the organism and as a consequence adverse effects occur. Each metal has a specific affinity for binding to the biotic ligands of an organism which is qualified by the conditional binding constants. In this study, the relationships between metal toxicity and metal affinities for binding to the biotic ligands of soil and aquatic organisms were investigated. We used data from the literature on terrestrial organisms such as plants, earthworms, and collembolans and on aquatic species such as fish and daphnids as well as other organisms like bacteria and fungi. We distinguished the conditional binding constants derived from toxicity or bioaccumulation tests. For all species and all metals, toxicity was well correlated with the conditional biotic ligand binding constants. Considering the effect of competing cations, major ions such as protons, calcium, and magnesium had the most significant effects on metal toxicity and as a consequence on the relationships between toxicity and strength of metals for binding to the biotic ligands. The correlations between toxicity and binding constants were obtained for single test species exposed to different metals and for all species together. Toxicity of Ag and Cu was highest for most test species. For almost all organisms, conditional binding constants for Ag, Cu, and Cd were higher than those for Zn and Ni. The values derived for aquatic systems seem to be equally valid for soil organisms, but in the case of soils, bioavailability from the soil solution is greatly influenced by the presence of the soil solid phase.

#### MO193

##### **An experimental system representative of groundwater hydraulic conditions to test the applicability of diffusive gradients in thin film (DGT) for groundwater monitoring**

C. Berho, BRGM / Laboratory Division; S. Robert, Suez Environnement / CIRSEE; J. ghestem, BRGM / Laboratory Division; T. Laurioux, L. Amalric, BRGM; A. Bruchet, CIRSEE Suez Environnement

**Key words:** diffusive gradients in thin film (DGT); groundwater, diffusive boundary layer (DBL), experimental system The validated common approach of groundwater monitoring is based on spot sampling after purging followed by laboratory analysis but has well known drawbacks (modification of contaminant distribution between the whole aquifer and groundwater sampled by pumping homogenization of the water column which can hide a potential stratification of contaminants ...). Passive sampling techniques present several advantages by comparison to the classical sampling approach (they neither need pumping, nor disturb the groundwater). However, few publications deal with the use of integrative passive samplers in groundwater. In this context, the aim of this work is to test the applicability of diffusive gradients in thin film (DGT) for metal monitoring in groundwater (Pb, Cd). Indeed, a diffusive boundary layer (DBL) forming on DGT surface especially in case of low flow conditions influences the uptake of metals. First of all, an experimental system representative of groundwater hydraulic conditions was developed. The system is composed of three open columns with an ascendant water circulation of a natural groundwater spiked with the targeted compounds (Cd, Pb). The flow is respectively in each column of 1, 2 and 4 m/day. DGT with several diffusive gels thicknesses were deployed in triplicates during 7, 14 and 21 days in each column. During the experiments, the concentration of metals in water and the uptake of compounds were followed to verify the linear accumulation with time. The DBL was estimated at 13 & 21 days of duration as well as the time weighted average concentrations (TWA). DBL values higher than those found in literature were found. By taking them into account, TWA concentrations were found closed to concentration of Pb and Cd measured in water samples. We acknowledge financial support from French National Research Agency (ANR ECOTECH 2011 ORIGAMI project 11 ECOT 003)

#### MO194

##### **Abandoned mine legacies: Determining the extent and impacts of pollution via a case study in the South West England**

S. Comber, Plymouth University / Environmental Science; S. Beane, Plymouth University; C.B. Braungardt, Plymouth University / School of Geography, Earth and Environmental Sciences; P. Long, Environment Agency

For parts of the UK and other European countries, contaminated land resulting from millennia of mining activities are contributing significantly to failures in water quality for a number of metals including lead, nickel, zinc, copper and cadmium under the Water Framework Directive. Practicalities such as land ownership, access, the diffuse nature of the contamination makes identifying and implementing remediation options complex and potentially costly. In order to successfully apply any measures, it is necessary to both fully understand the spatial extent of the contamination (including diffuse inputs from soil, spoil and mineral processing areas as well as obvious point sources from adits), the potential impact the metals are having on the receiving water chemistry in terms of speciation and hence potential negative ecological impacts. This paper reports on a specific case study in the SW of England (River Tavy catchment) where the extent of metal contamination around an abandoned mine site has been established in concert with assessment of metal bioavailability and impacts on receiving waters with the objective of supporting planning for future remediation.

#### MO195

##### **Dissolved Organic Carbon (DOC) Characteristics in Metal-rich Waters and Implications for Copper Aquatic Toxicity**

K.T. Dee, Geochemistry; J.F. Ranville, Colorado School of Mines / Chemistry and Geochemistry

Free copper ( $\text{Cu}^{2+}$ ) is a well-known contributor to heavy metal toxicity in aquatic systems. The concentration and bioavailability of  $\text{Cu}^{2+}$  is influenced by aqueous complexation, with humic and fulvic acids being especially important ligands. This research focused on examining changes in the binding affinity of fulvic acid (FA) that result from chemical fractionation occurring during the formation of hydrous iron and aluminum oxides (HFO and HAO) in AMD/ARD impacted streams. The, unfractionated DOC remaining in the water column was found to have less binding affinity than DOC in aquatic systems without the presence of HFO and HAO. Free copper concentrations were measured with a cupric ion specific electrode (ISE). FAs used in this study were collected from three alpine watersheds in Central Colorado that showed variability in spectroscopic properties of  $\text{SUVA}_{254}$  and fluorescence index (FI) to correlate with aromaticity and DOC source. The binding affinity of DOC is related to its inherited aromaticity and for which lower  $\text{SUVA}_{254}$  (lower aromaticity) suggest a lower binding capacity of DOC and a resulting higher concentration of  $\text{Cu}^{2+}$  in solution. This variation in DOC-Cu binding affinity is likely a significant factor in copper toxicity in aquatic systems and in toxicological modeling programs such as the Biotic Ligand Model (BLM).

#### MO196

##### **Accumulation of metals by *Ambystoma mexicanum* in an urban wetland: theoretical and experimental correlation with ambient metal content**

C. Ponce de Leon, Facultad de Ciencias; S. Rendón, G. Aldana, Universidad Nacional Autonoma de Mexico / Facultad de Ciencias; M. Hernandez, Facultad de Ciencias UNAM / Biology; C. Vanegas, UNAM, Mexico City / Ecology and Natural Resources

All organisms require a variety of essential metals for its metabolic functions whose concentrations are homeostatically regulated. At the same time, organisms possess regulatory mechanisms that prevent and control the accumulation and potential toxic effects of metals, essential and without known biological function. The bioaccumulation of metals depends greatly on the chemical metal specie in the environment interacting with the organism, whilst the bioavailable concentration of these chemical species depends on a variety of physicochemical parameters such as organic matter, clay content, pH, salinity, redox potential, etc., thus making it difficult to predict the organism's metal accumulation. In this study we assess the physicochemical parameters and metal concentration in sediments in a peri-urban wetland located south of Mexico City. *In situ* metal accumulation by juvenile *Ambystoma mexicanum* was assessed in selected sites from the above mentioned study and correlated with water and sediment metal concentrations as well as with theoretical bioavailable metal (Free metal) from water with an equilibrium speciation model for waters, the Windermere Humic Aqueous Model (WHAM7). The results showed that the highest concentrations detected in the axolotl liver were the essential metals. However, the concentration of several metals without known biological function (i.e. cadmium, lead) are similar or higher to those reported as critical levels for aquatic life. The free metal WHAM modeling simulating diffusion had limited correspondence with liver metal accumulation in the organisms, rather, sediment metal concentration more accurately reflected the metal accumulation in the organism, suggesting ingestion as the main route. Further WHAM simulations are offered as proposed by Stockdale et al. (2010) in Aquatic Toxicology. **Track and sessions:** "Metals in the environment: Fate, speciation and bioavailability in water, soil and sediment" in "Analysis, fate and behavior of contaminants". **(Co-)authors:** Claudia PONCE DE LEÓN HILL, Sherezada GONZÁLEZ RENDÓN, Manuel HERNÁNDEZ QUIROZ, Giovanni ALDANA and Cecilia VANEGAS PÉREZ. *Unidad de Análisis Ambiental, Facultad de Ciencias, UNAM, Mexico City.* **Key words:** metals, bioavailability, WHAM, *Ambystoma mexicanum* **Presentation preference:** Platform

##### **Comparison of four pore water sampling methods for metals and dissolved organic carbon**

B.G. Brumbaugh, US Geological Survey / Columbia Environmental Research Center; D. Cleveland, National Institute of Standards and Technology; J.M. Besser, USGS- Biological Resources Division / Columbia Environmental Research Center; D.D. MacDonald, MacDonald Environmental Sciences Ltd.

Toxicity of metals to aquatic invertebrates is most often attributed to bioavailable forms of dissolved metals in the interstitial (pore) water of sediments. Bioavailability for many toxic metals is known to depend greatly on certain water quality factors, especially hardness and dissolved organic carbon (DOC). Several pore water sampling methods have been investigated, but recommendations for individual methods vary. Importantly, there have been few, if any studies that compared sampling methods for both DOC and metals, and especially mixtures of metals. Our study compared four different methods for sampling pore water including: peepers, diffusion gradient in thin-film (DGT) probes, centrifugation and filtration, and push-point suction and filtration. Three field-collected sediments with elevated concentrations of metals representing different levels of organic matter, acid-volatile sulfide, and grain size were evaluated, both unspiked and

spiked. Spiking included cadmium, copper, nickel, lead, and zinc added at amounts in proportion to individual probable effect concentrations (PECs) and anticipated relative sediment binding capacities. Results of these comparisons will be presented and strengths and limitations of each of these methods will be discussed.

#### MO198

##### **Mechanisms of nickel toxicity in freshwater organisms: A practical approach for supporting mechanistic-based risk assessment tools**

K.V. Brix, University of British Columbia / Zoology; C.E. Schlekert, NiPERA; E.R. Garman, NiPERA / Ecotoxicologist

Assessment of ecological risk of nickel (Ni) uses mechanistic-based, albeit empirically derived, predictive tools such as Biotic Ligand Models (BLMs). Despite a number of detailed studies, the precise mechanism of chronic Ni toxicity to aquatic organisms remains elusive. A workshop was held in November 2014 to review currently available information on mechanisms of Ni toxicity to aquatic organisms. The goal of the workshop was to provide recommendations that can be used in future studies to build on existing mechanistic information. Freshwater aquatic organisms were the focus of discussion because of their sensitivities to Ni, the relatively abundant amount of mechanistic information available, and their importance in risk-based regulations like the Water Framework Directive and REACH. Evidence exists in the literature to support a number of possible mechanisms, including disruption of trace element homeostasis (e.g., Ca, Mg, and Fe), disruption of energy metabolism, and oxidative stress through the creation of reactive oxygen species. Workshop participants recommended using an adverse outcome pathway (AOP) framework to design a research program that explicitly links mechanisms of action at the protein level to responses that are relevant at the population level for specific sensitive freshwater taxa (*Lymnaea stagnalis*, *Lemna* sp., and daphnids), recognizing a specific common mechanism may not occur among different aquatic taxa. Participants also recommended using the AOP framework to evaluate a broader range of possible mechanisms of action, taking advantage of genomic/transcriptomic techniques and extant mechanistic knowledge from other environmental compartments (e.g., terrestrial plants) to identify potential mechanisms not previously considered in aquatic environments. The overarching goal of this research program is to develop a sufficiently robust mechanistic understanding of Ni toxicity to allow the application of predictive tools like the BLM to new species and a broader range of geochemical conditions.

#### MO199

##### **Stormwater Control Measures (SCMs) Decrease the Toxicity of Copper Roof Runoff**

W.J. LaBarre, Towson University; S.M. Lev, IDA Science and Technology Policy Institute / Urban Environmental Biogeochemistry Laboratory; D.R. Ownby, Towson University / Chemistry; R.L. Dwyer, International Copper Association / Health Environment and Sustainable Development Program; K.J. Rader, Mutch Associates, LLC; J.W. Gorsuch, Copper Development Association Inc.; R.E. Casey, Towson University / Chemistry

Concerns have been raised by regulators over diffuse and nonpoint sources of metals including releases from copper roofs during storm events. A copper roof runoff tool is in development for use by regulators and other stakeholders to quantify the potential ecological impacts of copper roof runoff in receiving waters. It considers three key components of copper runoff fate and transport: 1) copper emission from roofs during rain events; 2) copper attenuation in runoff prior to reaching receiving waters; and 3) copper bioavailability and fate in receiving waters. This study examined attenuation of copper from roof runoff and the factors influencing copper bioavailability and toxicity in a stormwater treatment system. Both laboratory bioassays and modeling with the biotic ligand model (BLM) were utilized. A 3 x 6 meter copper roof structure was built along with two biofiltration swales and two bioretention planters. Runoff samples were collected monthly from the roof downspouts and from the outlets of the swales and planter boxes. SCM copper removals were 82.6 – 99.2% (planters) and 93.3 – 99.3% (swales) by concentration. For a subset of storms, toxicity tests of stormwater were performed with *Daphnia magna* neonates. Stormwater toxicity testing can result in poor survival due to the low ionic strength of runoff that has not interacted substantially with soils or mixed with surface water. Utilizing cultures adapted to low hardness resulted in greater survival in reference stormwater. In toxicity tests using these adapted cultures, no survival was observed in copper roof runoff samples taken from the downspout (i.e., SCM influent). Survival from the planter box and swale outlets was ~86% and ~95%, respectively. Modeled *D. magna* LC50 values for the influent averaged 8 µg/L, while the swale and planter box outlets averaged 180 µg/L. This indicates a decrease in copper bioavailability and potential toxicity as water passed through the swale and planter boxes. Modeled toxicity was found to be strongly dependent on pH. This is critical since measured pH values in low ionic strength stormwater can vary based on the technique used. These results indicate that the swales and planter boxes can improve water quality prior to stormwater encountering biological receptors. These data, when integrated into the copper roof runoff tool, will allow more accurate assessment of potential impacts in receiving waters.

#### MO200

##### **Effects of wildfires on metals mobilisation in eucalypt and pine forests**

I. Campos, Universidade de Aveiro / Department of Environment; N. Abrantes,

University of Aveiro / CESAMDAO; C. Vale, IPMA Instituto Portugues do Mar e da Atmosfera; P. Pereira, Department of Biology and CESAM; J. Keizer, Department of Environment Centre for Environmental and Marine Studies CESAM University of Aveiro Aveiro Portugal

Forest fires are increasingly frequent and severe in Mediterranean region, mainly in Portugal, with huge environmental impacts. Among all the effects of fire on soil properties, deposition, mobilisation and fate of contaminants, with particular emphasis to trace metals, has been a relatively neglected issue. In fact, wildfires can release and deposited metals on soil surface, either directly by combustion of vegetation and soil organic matter mineralization or via re-availability from ashes-soil interactions. These contaminants are of major concern due to their high toxicology, environmental persistence and tendency to bioaccumulate in the food chain. Furthermore, these contaminants find their way into groundwater and surface sources via leaching and or into aquatic systems by overland flow (runoff) that promotes the inputs of ash and eroded particles of soil in water. The main objective of this study was to evaluate the input of metals (Mn, V, Co, Ni, Cu, Cd and Pb) in soils and ashes of eucalypt and pine forests (Ermida, North-centre of Portugal) associated with a wildfire and followed by rainfall events. This was accomplished by monitoring the temporal evolution (immediately after the fire, 4-, 8- and 15-months after the fire) of metals in soils and ashes. Concentrations of V, Mn, Co, Ni, Cu, As, Cd and Pb were analysed by inductively coupled plasma mass spectrometry (ICP-MS), after an acid digestion. The principal results obtained in this study were the following: (1) The levels of Mn, Pb, V, Ni and Cd were higher in the burnt soils compared with those in the non-burnt soil, while for As the opposite pattern was observed. As for Cu and Co no differences were found; (2) No temporal differences were found for metals concentrations in the non-burnt soils; (3) Metals levels in burnt soils differed for the four sampling occasions but not in straightforward manners; (4) Manganese, Pb, V, Cu, Ni, Co and Cd have peaked in ashes collected immediately after the fire, while the opposite was observed for As; (5) In general, metals levels (with the exception of As) declined sharply during the first 4 months and remained unchanged 8 and 15 months after the fire. Our results highlight that wildfires play a key role in the mobilisation of metals in the environment and underline the importance of further studies about the associated risks in terms of ecotoxicological effects, both in-situ and in downstream aquatic systems. Keywords: Wildfire; Metals; Soils; Ashes

#### MO201

##### **HEAVY METAL POLLUTION BY URBAN SUPERFICIAL RUNOFF: ACCUMULATED SEDIMENTS ON SOACHA-BOGOTÁ ROAD (COLOMBIA)**

N.A. Peña, IRTA; S. Alvarez, C.A. Zafra, Universidad Distrital Francisco José de Caldas / Facultad del Medio Ambiente y Recursos Naturales

Road sediments accumulated in dry weather carry metallic elements, which affects water resources when transported by runoff and deteriorates the air quality when suspended by wind and the turbulence induced by traffic. This study presents the results of a pollution assessment on heavy metal particles associated to road sediment from two particular areas (i.e. Zones 1 and 2) of the Bogotá-Soacha highway (Colombia). Road sediment was collected in each area by direct sweep over a surface of 0.25 m<sup>2</sup> and for a period of four months. The concentration of Mn, Fe, Cu, Zn, As, Cd, Ba and Pb was determined per size fraction (less than 250 µm from dry road sediment). These figures were obtained by means of flame atomic absorption spectrometry and also by using inductively coupled plasma mass spectrometry ICP-MS. The results suggest that the main origin of heavy metals were the mobile sources (i.e. the wear of tires, brake pads and automotive parts). In addition, it is shown that the concentration of Pb and Zn was higher than that allowed by current regulations (used as reference). With regard to urban soils, heavy metals that exceeded the permissible limits were as follows: Pb (21.7% and 87.0% of the time in Zones 1 and 2, respectively) and Zn (84.8% and 82.6% of the time in Zones 1 and 2, respectively).

#### MO202

##### **Modeling the Fate of Metal Concentrates Using the TICKET Unit World Model**

K.J. Rader, Mutch Associates, LLC; R.F. Carbonaro, Mutch Associates, LLC / Civil and Environmental Engineering; K. Delbeke, European Copper Institute; K.J. Farley, Manhattan College / Civil and Environmental Engineering

Among the key challenges associated with metal concentrates assessment and classification are their sparingly soluble nature and their long term fate following release. A concentrate's solubility affects its bioavailability. The environmental fate of a substance is in part described by its degradability. While metals do not "degrade" according to the classic definition typically applied to organics, their capacity to cause adverse effects in the environment is not without temporal limits. Assessment of metal "degradability" is not as straightforward as for organics where standardized test procedures are available. Nevertheless, the implications of the degradability criterion for metals are significant particularly when the concentrates are part of maritime cargoes subject to MARPOL Annex V requirements. Based on the Globally Harmonized System (GHS), guidance on the persistence or "degradability" of soluble metals was proposed in a 2011 European Union Classification, Labelling and Packaging (EU CLP) draft guidance document. In analogy to organic chemicals, "rapid degradation" for metals requires greater than 70% removal within 28 days. However, unlike organics, where removal from the

water column occurs via degradation, metal removal occurs through changes in speciation (partitioning and precipitation) followed by sedimentation which transfers metal to the sediment. Therefore, “rapid degradation” for metals requires one to demonstrate rapid and functionally irreversible loss from the water column. This entails 1) sorption of dissolved metal to suspended particles or direct precipitation, 2) transport of particulate metal to the sediment, and 3) functionally irreversible sequestration of metal in the sediment through precipitation and sorption. A unit world model for metals in lakes, TICKET-UWM, was applied to the assessment of concentrate bioavailability and degradability in a generalized water body. Model results indicate that settling of concentrates limits the direct impact dissolution had on water column metal concentrations. Continued dissolution of concentrates in the sediment resulted in some recycling of metal to the water column. However, the water column concentration resulting from this sediment flux was very low. The lack of significant remobilization indicated by the model is generally consistent with data from field and laboratory studies.

## MO203

### Sediment Cu bioavailability – the use of diffusive gradient thin films (DGT) and effects of chitosan amendment

T. Oksanen, University of Eastern Finland / Department of Biology; K.K. Vaananen, University of Eastern Finland / Biology; J. Akkanen, University of Eastern Finland / Department of Biology  
Mining industry often increases metal loading in surrounding environment. In water ecosystems, a part of the metals is stored in sediment compartment. When environmental conditions change, metals may be released back to water causing toxicity. Due to these fluctuations, risk assessment for metals is challenging, and widely used sediment quality guidelines are often inadequate for site-specific risk assessment. We used diffusive gradient thin films (DGT) a) to observe bioavailable fraction of Cu in sediment, b) to study metal bioavailability reducing effects of chitosan amendment in Cu-spiked natural sediment and c) did toxicity tests to reveal possible toxicity of copper and/or chitosan (*Lumbriculus variegatus*). Natural lake sediment (Parkkimajärvi) in Finland was chosen for this study. ICP-MS was used for metal concentration analysis. Possible toxicity was tested with 28-day reproduction and growth experiment using *L. variegatus*. Sediment was spiked with 25-410 mg/kg dw Cu and with 0; 0.5 and 5 % dw chitosan. In first experiment, DGT concentrations correlated with total copper concentrations. It indicates that in this sediment, DGT can be used for determining reactive concentrations of Cu. Chitosan adsorbed bioavailable copper (410 mg/kg dw) in chitosan concentrations of 0.5 (32 % reduction) and 5 % (87 % reduction). Chitosan had adverse effects on weight of *L. variegatus*, but not on reproduction. Higher Cu concentrations had adverse effects on total biomass, but no statistical difference was seen in reproduction or single worm weight at their own. Sediment ingestion is the main Cu-uptake route for *L. variegatus*, but the reduction of active Cu shown in DGT-experiment was not that clear according to toxicity test. DGT seems to be a promising tool for assessing metal bioavailability and risks in sediments. Chitosan was effective in binding copper in slightly acid sediment (pH 5-6). On the other hand, adverse effects of chitosan were seen in toxicity test. As a result, further studies should be concluded for the use of chitosan in remediation.

## MO204

### Risk assessment of the use of organic wastes as soil amendments: results from a field experiment

P. Alvarenga, Polytechnic Institute of Beja / Department of Technologies and Applied Sciences; P. Palma, Instituto Politécnico de Beja / Department of Technologies and Applied Sciences; M. Farto, C. Mourinha, J. Dores, M. Patanita, Polytechnic Institute of Beja; J. Renaud, Department of Life Sciences; T. Natal-da-Luz; J. Sousa, University of Coimbra / Department of Life Sciences  
The use of organic wastes as soil improvers seems an attractive option in soil amendment, because it would enable valuable components to be recycled (e.g. organic matter, N, P, K). However, this practice represents a potential risk to the environment, because of probable high heavy metal content of the wastes, a problem that may be aggravated if the metals are mobilized in the soil, available for plant uptake or transported in drainage waters. Taking this in account, a field experiment was established with different organic wastes: sewage sludge (SS), mixed municipal solid waste compost (MMSWC), and compost produced from agricultural wastes (CAW), at 6, 12 and 24 ton dry matter/ha, with *Lolium perenne* L., in order to assess the behaviour of metals in the soil/plant system and the effects of the amendments in soil chemical and biochemical properties. The SS application had a beneficial effect on plant production (chlorophyll, foliar area, biomass) and on soil properties (organic matter content, total nitrogen, available phosphorous, and nitrification potential), more pronounced than in the case of both composts application, without a significant increase in total heavy metals concentration, both in soil and in plants. Dehydrogenase activity was also positively affected by the amendments application. Accumulation factors for heavy metals in plants were low, and their concentrations in the plant were lower than the maximum tolerable level for cattle, used as an indicator of risk of entry of those metals into the human food chain. Two different heavy metal extractable fractions were determined: a mobile fraction, and a mobilizable fraction, which will allow a deeper discussion on the fate and behaviour of heavy metals in soils, and on the risk of the use of these organic wastes as soil amendments.

## MO205

### Contrasting abilities of metal bioaccumulation in Gammarus populations with different exposure histories

N. Urien, J.D. Lebrun, Irstea; A. Farfarana, Irstea Antony; a. chaumot, Irstea / UR MALY Laboratoire Ecotoxicologie; L.C. Fechner, Irstea Antony / UR HBAN; O. Geffard, Irstea / UR MALY Laboratoire Ecotoxicologie  
Gammarids are net accumulators of metals, hence considered as integrated indicators of metal bioavailability in freshwaters. However, aquatic organisms live in contrasted systems in terms of water chemistry and anthropic contaminations, including metals, to which they are acclimated. Indeed, chronic exposure may induce physiological mechanisms likely to modulate metal regulation (e.g. metallothioneins synthesis), thus bioaccumulation. So, differences in exposure histories of populations may lead to differences in accumulation patterns. In gammarids, tolerance to metal exposures is few documented and need to be evaluated conditioning the relevance of using gammarids to monitor water quality. The use of biodynamic modelling to describe metal bioaccumulation is now well established. Biodynamics assumes that bioaccumulation is the result of a balance between uptake and loss rates of contaminant, characterised by specific kinetics parameters for each metal. Here, we propose to use the comparison of kinetics parameters as approach to detect differences between populations and therefore to identify which of the physiological parameters is modulated (uptake and/or loss). In our previous studies, the between-population variation of kinetics parameters controlling bioaccumulation in several unexposed (control) populations of *Gammarus* has been defined and is proposed in this study as reference. The aim of this study was to investigate the metal bioaccumulation abilities of different populations of gammarids pre-exposed to metals in their natural environment and then to compare their kinetics parameters to values previously obtained with controls populations. To this end, three *Gammarus* populations, pre-exposed to Pb or Cd or Pb/Ni contamination, were collected and then exposed, in laboratory conditions, to various metal concentrations (Pb, Cd and Ni) for seven days immediately followed by a seven-day depuration period. The internal concentrations in gammarids were measured over time. Then, kinetics parameters of metal describing bioaccumulation were determined for each population. Finally, results will inform whether pre-exposure of populations may modulate their bioaccumulation capacities and the occurrence of potential tolerance mechanisms.

## MO206

### Comparison of in vitro estimates of bioaccessible Ni in field-contaminated soils and identification of mineralogy

L. Vasiluk, University of Guelph / School of Environmental Sciences; J. Wragg, M. Cave, British Geological Survey; M.D. Dutton, Vale INCO; B.A. Hale, University of Guelph / School of Environmental Sciences  
The bioaccessibility of a contaminant mixed with the soil matrix depends upon the soil properties, the contaminant and the manner by which the contaminant entered the soil. This study considers soil Ni contamination around smelting and refinery sites, such as the Vale complex in Sudbury (SUD) and Port Colborne (PC), ON, Canada. The objective was to determine if there was a relationship among particle size, mineralogy and trace element bioaccessibility. At each location, two naturally weathered soils were collected and separated into 2 fractions (150-250mm and < 70mm). Identifying the mineralogy was achieved with a non-specific sequential extraction with chemometric data processing (CISED), SEM-EDS and XANES. Once the predominant minerals in the soil associated with Ni were identified, its relative chemical “solubility” was compared to the *in vitro* assay (PBET). In the SUD soils, the smaller particle fraction had the greatest [Ni]; in one soil the difference was 8 fold while the other 3 fold. Total [Ni] in PC soils were not different between the fractions, but were much higher than in SUD. The comparison of bioaccessible Ni (PBET) and cumulative Ni extraction in the CISED sequence, showed that PC soils reached the PBET estimates at a lower nitric acid (up to 0.01M), while Ni from SUD soils required higher strength. Chemometric analysis identified a different number of physico-chemical soil components. The majority of Ni was co-eluted with the “carbonate” component, extracted mainly in 0.01-0.05 M HNO<sub>3</sub>, and was made up principally of Ca, Mg and Al. The high proportion of Ca suggests that these components could be carbonate material in a humic acid exchangeable fraction or clay-like matrix if Si is present. The mineralogy of the soil fractions from the same site was similar, but different between the two sites: PC soils were dominated by NiO whereas in the SUD soils were FeNiO. Neither of the mineral forms is very soluble. Bioaccessible Ni was low (< 15%), reflecting the large proportion of oxidic Ni in both soils. The CISED extracted more Ni from soils than PBET but at 0.01M of hydrogen ions the results were similar. In spite of the kinetic differences in methodologies the results are similar for the equivalent molarities of the two assays. The CISED identifies a very fine grained material, some of which is occluded into the less easily soluble components of the soil (e.g. Fe oxides). This fine grained material is the likely source of the bioaccessible fraction.

## MO207

### Developing New Tools for Assessing Legacy Pollutants and their Ecological Consequences in Lakes surrounding Mines Near Yellowknife (NT), Canada.

J.M. Blais, A. Houben, University of Ottawa; J. Korosi, A.J. Poulain, L. Kimpe, University of Ottawa / Biology

This project is to generate information on the extent and fate of environmental

contaminants in the Yellowknife area focusing on Giant Mine, which has left a legacy of contamination by arsenic and other metals, to inform future land and water management decisions. The objectives of this research are: (1) to characterize and determine the spatial extent of toxic metals and hydrocarbons produced by mines, and identify their toxicological effects on nearby lakes using paleoecotoxicological methods; and (2) to determine the mobility and bioaccessibility of arsenic species in the vicinity of Yellowknife and differentiate between the toxic arsenic trioxide derived mainly from stack emissions and the naturally occurring arsenopyrite, which is less toxic. Here we show evidence of elevated arsenic and antimony in all lake waters collected within a 15 km radius of Giant Mine, and we show that this contamination can only be attributed to the emissions from the roaster stacks. Radiometrically-dated lake sediment cores further confirm that the timing of arsenic and antimony contamination in these lakes may only be attributed to mining activities that began in 1934 and ended with the closure of the mines in 2004. We relate the enrichment of arsenic and antimony in these sediment cores to ecological responses by enumerating cladoceran assemblages and show that these zooplankton communities were markedly affected by the contaminants from these mines. This information is part of a growing database that will be critical for local decision makers who are responsible for managing the remediation of Giant Mine, as well as the Government of Northwest Territories and the City of Yellowknife, which are both responsible for managing lands still affected by these long abandoned mines.

## MO208

### Baseline data and initial impacts of the Mount Polley Tailings Pond breach on adjacent aquatic ecosystems - an update.

E. Petticrew, University of northern British Columbia / Geography; N. Gantner, Trent University / Ecosystem Science and Management; S. Albers, University of northern British Columbia / Quesnel River Research Centre; G.G. Pyle, University of Lethbridge / Biological Sciences; P.N. Owens, University of northern British Columbia

On August 4<sup>th</sup> 2014, the Mount Polley Tailings pond breach near Likely, B.C., released approximately 24 million cubic metres of tailings material into Polley Lake, Hazelton Creek and Quesnel Lake. The discharge scoured and eroded a swath of soil and sediment delivering an unknown amount of metals and sediment into this tributary ecosystem of the Fraser River. Subsequent efforts by the mine operator to remediate by pumping tailings water from Polley Lake into Hazelton Creek, which flows into Quesnel Lake, resulted in additional and continuous release of unknown volumes of contaminated water and sediments into the watershed. Heavy metals (e.g., selenium, copper, or mercury) reported as stored in the tailings pond entered the downstream aquatic environment and have been monitored in the water column of Quesnel Lake since August. These contaminants are likely particle-bound and thus subject to transport over long distances without appreciable degradation, resulting in the potential for chronic exposures and associated toxicological effects in exposed biota. While significant dilution is expected during aquatic transport, and the resulting concentrations in the water will likely be low, concentrations in exposed biota may become of concern over time. Metals such as mercury and selenium undergo bioaccumulation and biomagnification, once incorporated into the food chain/web. Thus, even small concentrations of such contaminants in water can lead to greater concentrations (~100fold) in top predators. Over time, our predictions are that food web transfer will lead to an increase in concentrations from water (1-2 years) → invertebrates (1-2 yrs) → fishes (2-5 yrs). Pacific salmon travel great distances in this watershed and may be exposed to contaminated water during their migrations. Resident species will be exposed to the contaminated waters and sediments in the study lakes year round. Little or no background/baseline data for metals in biota from Quesnel Lake exists. Notably, some of these fish provide food to recipients as diverse as aboriginal communities and large commercial markets embedded within a global marketplace. Moreover, metals can be accumulated in aquatic organisms, thus it is very important to understand its long-term biomagnification and potential health effects on organisms. We present an update on our findings from physical and chemical limnological early response-sampling and recommendations for future monitoring in the affected watershed.

## MO209

### Physiological response of wheat (*Triticum aestivum* L.) to elevated concentrations of cadmium and NaCl in the growth medium

M.S. Aleksić, B. Micić, Petnica Science Center / Department of Biology; T.D. Mišljenović, Faculty of Biology / Institute of Botany and Botanical garden Jevremovac

Effects of cadmium and sodium chloride were tested on wheat (*Triticum aestivum* L.). Concentrations of proline, total soluble proteins, cadmium uptake, and POD activity were measured. Plants were treated with different concentrations of NaCl (2000 i 4000 ppm) and CdSO<sub>4</sub> (0.4, 0.6, 0.8 and 1.6 ppm) for 14 days (12h photoperiod, 26-28 °C, 60 – 80% relative humidity). Level of proline in plants treated with moderate salt concentration (2000 ppm) increased with growing Cd concentrations in the medium. Higher concentrations of Cd in the growing medium lead to higher Cd uptake by plants. Cadmium shoots/roots concentration ratio was < 0.1. Presence of NaCl in the medium increased Cd uptake by plants, probably as a result of creation of Cd chlorocomplexes which are more easily absorbed by wheat. The activity of peroxidase (POD) was increased in plants treated with different

concentrations of NaCl. Increased POD activity might be a plant mechanism of alleviation of oxidative damage induced by salt. Different concentrations of Cd in the medium and a combination of Cd and NaCl had no statistically significant effect on POD activity. There was no statistically significant effect of cadmium, sodium chloride, or interaction of these factors on total protein concentration in the plant material.

## MO210

### Rainfall erosivity index EI<sub>30</sub> and losses of Cu-based fungicide in vines via throughfall

P.P. Rodríguez, Universidade de Vigo / Plant Biology and Soil Science; D.E. Gomez, The University of Exeter / College of Engineering Mathematics and Physical Sciences; M. Paradelo, J.L. Periago, University of Vigo / Plant Biology and Soil Science

Cu-based fungicides are widely applied in vineyards to fight against fungal diseases. Cu losses by rainfall may lead to an enrichment of Cu in soils becoming it an important soil pollutant and even may reach nearby basins. Rainfall energy may influence Cu losses although it has never been studied before in vineyards. The objectives of this study are: i) to quantify Cu losses under natural rainfall and ii) to examine the influence of rainfall erosivity index EI<sub>30</sub> (Wischmeier&Smith 1978) on Cu losses. Two nearby vineyards in Ribadavia (Galicia, Spain) were monitored during crop years 2009 and 2010. Collecting rainfall and throughfall up to 16 trays were placed under the vines to maximize the collection of the throughfall. Soluble-Cu fractions (CuS) in the water fraction < 0.45 micron ii) the Particulate-Cu fraction (CuP) were collected from trays after each rainfall episode. Additionally, daily EI<sub>30</sub> values (MJ ha<sup>-1</sup> mm h<sup>-1</sup>) for the same period were calculated from a tipping bucket pluviometer 5 min. Absolute frequency distributions of throughfall volume in collecting trays (mm) and throughfall/rainfall ratio are bimodal. Small rainfall episodes brought more less throughfall. Higher rainfall episodes gave more throughfall/rainfall ratio as expected. Throughfall average in all episodes was 14±17% of rainfall being 55% the maximum. That was 14.9±15.7 mm ranged between 0.3 and 44.4 mm. Concentration of CuS in throughfall in relation to accumulated EI<sub>30</sub> per sampling is higher at the beginning of the experiment, decreasing sharply with subsequent rainfall episodes. CuP is expressed as mg Cu per kg of total solids in throughfall samples. Solids result from the rainfall wash-off of anti-fungal sprays and natural dry deposition on leaves. CuP is about three orders of magnitude higher than CuS giving an average Solid/liquid distribution ratio about 1000 L/kg. The highest concentrations were also found in the first rainfall event although CuP and these data are fitted to a hyper-exponential model, which explains that CuP losses happened in two ways: one quickest than the other where bigger and/or stacked particles are detached first. Finally, Cu loss is dependent on amount of Cu stored on vine leaves and most of it are lost in the very first rainfall episodes. Wischmeier, W.H. y Smith, D.D. 1978. Predicting Rainfall Erosion Losses. Agriculture Handbook 537. United States Department of Agriculture. Science and Education Administration. 58 pp.

## MO211

### TOTAL CONTENT AND LEACHING BEHAVIOUR OF ARSENIC IN SOILS OF THE ANLL

D.M. Prieto, University of Santiago de Compostela / Soil Chemistry; D. Rubinos, J. Cancelo-González, University of Santiago de Compostela / Departamento de Edafología y Química Agrícola Facultad de Farmacia; F. Diaz-Fierros, University of Santiago de Compostela / edafologia y quimica agricola; M. Barral, University of Santiago de Compostela / Departamento de Edafología y Química Agrícola Facultad de Farmacia

Environmental arsenic (As) problems are commonly the result of mobilization under natural conditions, but human activities have contributed to an important additional impact. High As concentrations have been detected in Anllóns Basin (NW Spain) in superficial soils over arsenopyrite-rich materials, and in sediments downstream the mineralized area, with concentrations up to 4,000 and 264 ppm, respectively [1,2,3]. The main aim of this study is to determine the total contents and leaching behaviour of As in the soils of the Anllóns River Basin. With this purpose, 50 samples of C soil horizons were collected each square km covering the area adjacent to the river and selected to detect lithogenic As. This aspect could be of interest because the exploitation of the mineralized area is currently under study. Total native As concentration was determined by X-ray fluorescence spectrometry. Leaching behaviour of As was determined applying DIN 38414-S4 method with Milli-Q-water, employing a solid:liquid ratio (1:10) for 24 h with end-over-end agitation. Subsequently, samples were filtered by 0.45 µm and measured by ICP-MS. X-ray analysis revealed that total As concentration ranged between 2 and 498 ppm, with a mean value of 85 ppm, median value of 25 ppm and 5 and 344 ppm for 10<sup>th</sup> and 90<sup>th</sup> percentiles, respectively. The highest As concentrations were located at 8 hot spots matching the mineralized area. The reference As level in soils of Galicia was fixed at 50 mg kg<sup>-1</sup> (140 mg kg<sup>-1</sup> in soils onto slates with arsenopyrite) [4], which were exceeded for 21 and 9 soil samples, respectively. Leachable As ranged between 0.13 and 9.85 µg L<sup>-1</sup>. The percentage of As mobilized following these experimental conditions was low and ranged between 0.002 and 0.328 %. However, special attention must be paid to changes in environmental conditions, such as increased pH, salinity and liquid:solid ratio and changes in redox conditions and phosphate addition, which proved to have drastic effects on the As mobility in riverbed sediments containing As of geological origin in this area

### Toxic elements and element speciation in seafood samples from different contaminated sites in Europe

A. Maulvault, IPMA, I.P. / Division of Aquaculture and Seafood Upgrading; P. Anacleto, V. Barbosa, IPMA Portuguese Institute for the Sea and Atmosphere / Division of Aquaculture and Seafood Upgrading; J. Sloth, R. Rasmussen, K. Granby, DTU Technical University of Denmark; M. Fernandez, IRTA; A. Tediosi, AEI FORIA; F. Heuvel, Hortimare; M. Kotterman, IMARES / Fish; A.M. Marques, Portuguese Institute for the Sea and Atmosphere / Division of Aquaculture and Upgrading

Chemical pollution of aquatic ecosystems represents an ecological threat that has been receiving increased attention. In environmental monitoring, marine biota from different trophic levels (e.g. algae, bivalves and fish species) are commonly used to assess the levels of chemical contamination, accounting their propensity to accumulate certain contaminants. Coastal areas exposed to high environmental contamination by one or more pollutants from anthropogenic or natural sources are called "hotspots", being generally associated with highly urbanized and industrialized areas. Toxic elements (e.g. Hg, As, Cd and Pb) are widely present in the aquatic environment and may reach high levels in these hotspots. However, the elements' toxicity depends on the chemical form and oxidation status, which influences their bioavailability, transport, persistence and impact in the food chain. Thus, assessing the speciation of some compounds, such as Hg and As, is also highly relevant from an ecological and food safety point of view. In this context, the present study aims to evaluate the bioaccumulation of toxic chemical elements (Hg, As, Cd, Pb) and speciation (Hg and As) using different bio-indicators (*Mytilus galloprovincialis*, *Liza aurata*, *Chamelea gallina*, *Platichthys flesus*, *Laminaria digitata* and *Saccharina latissima*) collected in European hotspots (Tagus estuary, Ebro Delta, Po Delta, Scheldt estuary, and the vicinities of a Norwegian fish farm in Solund). Species exhibited different elemental profiles, most likely as a result of their ecological strategies, as well as elements' concentrations found at each hotspot (i.e. seawater and sediments). Higher levels of Cd and Pb were detected in bivalve species, particularly *M. galloprovincialis* from Ebro (Cd) and Po (Pb) deltas, whereas the highest content of Hg (mainly MeHg) was found in *P. flesus*. The levels of As were generally low in the analysed samples, except in *L. digitata* and *S. latissima* in which this element was mostly in its inorganic forms. Variations were encountered when comparing the present data with previous reports, which may be related to temporal and/or seasonal fluctuations in the environmental contamination of these hotspots. Hence, this work highlights that using ecologically distinct bio-indicators is a fundamental step in environmental monitoring, especially in coastal areas, enhancing the interpretation of species' biological responses towards chemical contamination.

## MO213

### Particle size of colloids in throughfall from vines sprayed with agro-chemicals

P.P. Rodríguez, Universidade de Vigo / Plant Biology and Soil Science; M. Paradelo, University of Vigo / Plant Biology and Soil Science; D.E. Gomez, The University of Exeter / College of Engineering Mathematics and Physical Sciences; I. De La Calle, University of Vigo / Analytical and Food Chemistry; J.L. Periago, University of Vigo / Plant Biology and Soil Science

Chemicals are applied to prevent fungal diseases in crops under humid climate (such as in vineyards in Galicia, NW Spain). Rainfall clearly contributes to detach chemical particles from leaves that reach soil via throughfall. Throughfall suspensions comprise soluble and particulate forms. The most of sprays are applied as suspensions that can be detached by rainfall wash-off from plant leaves. To identify the particle population in the throughfall is of paramount importance because the fate of contaminant particles in environment depends on the transport of suspended particles in water. Therefore, the objective of this work is to analyze the "soluble fraction" (< 0.45 µm) in aqueous suspensions of throughfall samples from vines by Dynamic light scattering (DLS). Two samples of throughfall (E1 and E3) obtained from sampling 1 and 3 under vines that were sprayed with Cu-based fungicide suspensions were filtered through a 0.45 µm pore size filter. After that, samples were performed by DLS using a Cordouan Technology VASCO-2 particle size analyzer (Pessac, France). Measurements were performed with a 65 mW laser (657 nm wavelength) at a temperature of 25 °C. Particle size of Copper oxychloride spray deposits were examined by SEM taken with an environmental scanning electron microscope ESEM FEI-Quanta (FEI Europe Co, Eindhoven, The Netherlands). Results obtained show that CO comprises polydisperse population noting that bigger particles are located on the top of the stack while smaller ones are in the bottom left by drying drop with several particles sizes ranged 20 to 2000 nm. Additionally, throughfall samples analyzed by DLS show that polydispersity index (PDI) calculated according to the Cumulants method was 0.454 for E1 and 0.350 for E3 according to obtained by SEM. Moreover, data of mean diameter obtained as well as size distribution of E1 and E3 suggest that bigger particles are detached first whereas smaller ones are washed after the third rainfall event. Finally, Cu substances, rain dry deposition and plant exudates as well as fungi, bacteria and

spores can be present in the throughfall.

## MO215

### Temporal trends of heavy metal concentrations in Arctic Char (*Salvelinus alpinus*) from an Austrian High Mountain Lake: effects of climate- induced changes in lake water chemistry

G. Köck, Institute for Interdisciplinary Mountain Studies; D.C. Muir, Environment Canada / Aquatic Contaminants Research Division; R. Lackner, R. Tessadri, University of Innsbruck; K. Koinig, Innsbruck University

Due to similar environmental characteristics (e.g. long ice-cover, oligotrophy) high-altitude and high-latitude lakes are very sensitive ecosystems where even slight environmental changes (e.g. input of pollutants, climate change) may substantially affect ecosystem function. The Austrian-Canadian research cooperation High-Arctic 1997-2014 is investigating the effects of short-term and long-term climate change on freshwater ecosystems in the Austrian Alps and in the Canadian High Arctic. Studies from the 1990s on Arctic char (*Salvelinus alpinus*) from Schwarzsee ob Sölden (SOS), the highest fish-bearing lake in the Alps (2792 m a.s.l., Ötztal Valley, Austria), revealed extremely metal contamination of this fish. Levels of cadmium (Cd) and lead (Pb) in liver and kidney tissues were comparable to those of fish from waters receiving metal-polluted industrial effluents. Since pH and alkalinity are important factors controlling bioavailability and toxicity of metals to fish, these findings were attributed to the very low pH and alkalinity values of the lake water. Char from SOS were re-examined in September 2010. Sizes of fish caught were similar to those sampled in this lake in the 1990s. A comparison between metal concentration in liver and kidney samples from 1992, 2007 and 2010 show remarkable differences between metal species. While tissue concentrations of Cu and Zn, both elements essential for many metabolic processes such as protein synthesis, remained relatively stable between 1992 and 2010, concentrations of Cd and Pb decreased considerably within this period of time. For instance, Cd and Pb concentrations in the kidney dropped by a factor of 2.6 from approx. 95 mg/kg Cd to 36 mg/kg Cd and by a factor of 5.4 from approx. 25 mg/kg Pb to 4.6 mg/kg Pb, respectively. The decrease of Cd and Pb tissue concentrations coincides with significant changes of lake water conditions over the past two decades. While concentrations of Cd and Pb in the water have dropped by a factor of 100, alkalinity has increased by a factor of 3 and pH increased almost by one unit to pH 6.33. The changes in water conditions could be attributed to climate change driven weathering processes and a shortening in the ice cover duration by several weeks. In consequence, the decrease of Cd and Pb concentrations in char tissues is to be attributed to a decreasing bioavailability of Cd and Pb for fish under more alkaline lake water conditions. \n

## MO216

### Biomonitoring potential of five sympatric Tillandsia species for evaluating urban metal pollution (Cd, Hg and Pb) in Asunción (Paraguay)

A. Sánchez-Chardi, Autonomous University of Barcelona / Microscopy Facility  
Chronic and acute exposure of inhaled pollutants at low concentrations can produce significant toxic effects in biological systems. Atmospheric emissions of metals in urban sites due to diverse anthropogenic activities such as domestic burning of wood or fossil combustibles, waste incineration, traffic or diverse industrial processes are a key scenario of this concern. In addition, in several developing countries, the progressive and unrestrained industrialisation and rapid urbanisation, together with insufficient emission control and shortcomings in environmental legislation, cause serious environmental problems. The present study identifies metal pollution sources in Asunción (Paraguay) using quantification of three non essential heavy metals highly toxic for biological systems (Pb, Hg and Cd) in five autochthonous epiphytic plants from *Tillandsia* genus (*T. recurvata*, *T. meridionalis*, *T. duratii*, *T. tricholepis*, *T. liliacea*) according to different traffic levels (reference, low, medium and high polluted sites). The three metals increased in polluted sites following Pb (till 62.99 ppm in *T. tricholepis*) > Cd (till 1.35 ppm in *T. recurvata*) > Hg (till 0.36 ppm in *T. recurvata*). Although the species showed similar bioaccumulation pattern (namely, higher levels of metals in polluted sites), enrichment factors reported *T. tricholepis* as the most relevant bioindicator due to its wide distribution, abundance, low metal content in control site and high metal contents in polluted sites, and significant correlations with traffic density. This study emphasizes the urgent necessity of biomonitoring air pollution in areas out of air monitoring control such as Asunción, where the high levels of metal pollution especially Pb, may represent an increment of risk for human populations of this urban area.

## MO217

### A proper Bivalve safety assessment using traditional and original Bioaccumulation Factors

S.-. Manente, Ca Foscari University of Venice / Department of Molecular Sciences and Nanosystems; A. Zuin, Ca Foscari University of Venice / Molecular Sciences and Nanosystems Department; G. Ravagnan, Ca Foscari University of Venice  
The first comprehensive approach to heavy metal (HM) ecotoxicology in marine environments is to find the bioavailable amount of HM. The aim is normally obtained using BAF (BioAccumulation Factor) determination referred to total HM into the sediment. Contrary we believe that it would be appropriate to replace BAF with a factor that takes into account the different chemical and physical forms in which HMs are found in the matrix. So, together to the traditional BAF, we also

considered a factor (BGPh-BAF) that takes into account only bioavailable (B) and potentially bioavailable metal's geochemical phases (GPhs) in the sediment of different areas of Venice Lagoon (Italy), obtained by sequential extraction. Despite the limitations (e.g. the lack of uniformity among operative protocols) HM's geochemical extraction/fractionation is useful for assessing the relative importance of the different geochemical forms. In particular, we measured 22 HM's levels both in sediments and in the Mollusc Bivalve *Venerupis philippinarum* (into soft tissues, hepatopancreas and shells), in order to evaluate a true bioaccumulation trend. In fact, since each HM's speciation form may have different bioavailability and toxicity, it seems rightly concerned about the exact quantification of the different forms of HM present in the aquatic environment. The measurement of total HM may not be able to provide information about the extent of pollution and its relevance on organisms; thus, the determination of different fractions, and particularly those bioavailable, assumes great importance to describe real phenomena of bioaccumulation and consequently biomagnifications in trophic chain. In this way, i.e. determining BGPh-BAF, we could obtain numeric (then comparable) values as index both of Bivalve specific uptake paths (metal bioaccessibility) and of pollutants bioavailability in sediments. In some cases, such as for the Co, it is detected and gives scientific evidence to a diversification in the ability to bioaccumulate some HM present in the BGPh in soft tissues and shells, which is not found in the comparison between the BAF calculated for the total sediment. This result highlights the complex phenomena that govern the processes of bioaccumulation pointing out both organism ability to take on the HM in bioavailable forms and, once the body is exposed, the physiological aspects otherwise undetectable.

## MO218

### Using a portable XRF analyzer for risk assessment of contaminants in soil at a recreational boatyard

M. Lagerström, Institute of Applied Environmental Science ITM; M. Norling, Stockholm University / Institute of Applied Environmental Science ITM; B. Eklund, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES

Recreational boatyards along the Swedish coast have been found to be heavily contaminated as a result of the use of anti-fouling paints on boat hulls. During boat maintenance, spent anti-fouling paint particles end up on the ground resulting in contamination of the soil. Concentrations well above the national guideline values for soil of, amongst others, Cu and Zn are commonly found. However, only 34 out of an estimated total of 2500 boatyards in Sweden have been investigated for soil contamination. During these investigations, an average of only five samples per site were collected, providing limited information on the contamination status of these areas. A method using a portable, handheld X-Ray Fluorescence (XRF) analyzer was tested at two recreational boatyards by lake Mälaren in Sweden to assess its potential in mapping metal contaminants in the surface soil at boatyards. The XRF analyzer is a quick way of measuring metals in soil (2 minutes per measurement) at a considerably lower cost compared to laboratory analysis. Around 50 measurements were carried out in each boatyard through systematic random sampling where the sampling points were randomly distributed in a 10x10m sampling grid. Sieved soil samples (< 2mm) were collected for confirmatory laboratory analysis through acid digestion and subsequent analysis on ICP-OES at no less than 10% of the sampling points at each site. The laboratory analyses showed linear correlations to the XRF measurements for Cu, Zn, Pb and Sn. The correlation slopes were close to 1, except for Sn for which the results showed that a correction factor was necessary to apply to the field measurements. Our study demonstrates that the XRF analyzer is a valuable screening tool that can provide a quick and high resolution overview of the contamination situation at a boatyard.

### Analysis of parabens by DLLME-HPLC-DAD during the four season on Mogi river Brazil-SP

C.A. Galinaro, Universidade de Sao Paulo / Chemistry; F.M. Pereira, University of São Paulo - USP / engineering of materials; E.M. Vieira, Sao Paulo University / Departamento de Química e Física Molecular

Parabens are preservatives extensively used to prevent microbial growth in many common care products. Most parabens are frequently found in river water at concentrations reaching from ng L<sup>-1</sup> to mg L<sup>-1</sup>, and their levels depend mainly on the extent of water dilution resulting from rainfall. Discharge of treated wastewater effluent into the river was found to be the main cause of water contamination with parabens. Dispersive liquid-liquid microextraction (DLLME) is an analytical technique, based in the dispersion of extraction solvent assisted with a disperser solvent within an aqueous solution that generates a very high contact area between the aqueous phase and the extraction solvent. The present study reports the application of a DLLME-HPLC-DAD for the simultaneous separation and determination of four paraben preservatives (methyl-, ethyl-, propyl-, and n-butyl-paraben) in surface water. The surface water samples were collected during the four seasons of a year period (december 2013, february 2014, may 2014, and august 2014), from Mogi river, on São Paulo state, Brazil. The DLLME-HPLC with

diodo array detection method shows a good chromatographic separation for the 4 parabens studied (methyl-, ethyl-, propyl-, and n-butyl). The method exhibit detection limits from 1.0µg L<sup>-1</sup> for methylparaben, 1.0µg L<sup>-1</sup> for ethylparaben (EP), 0.8µg L<sup>-1</sup> propylparaben (PP), and 1.0µg L<sup>-1</sup> butylparaben (BP). Good recovery index for the extraction procedure, from 30.3% (MP) to 68.0% (PP), and good reproducibility (> 95% RSD). Surface water samples collected from Mogi River, showed the average levels of parabens ranging from: < 1.0µg L<sup>-1</sup> (EP) to 21.83µg L<sup>-1</sup> (MP) during spring season, 1.10µg L<sup>-1</sup> (PP) to 27.50µg L<sup>-1</sup> (MP) during summer season, 1.64µg L<sup>-1</sup> (BP) to 4.80µg L<sup>-1</sup> (MP) during autumn season, and 0.88µg L<sup>-1</sup> (MP) to 6.76µg L<sup>-1</sup> (MP) during winter season. It is believed that these levels are associated with the greatest number of people, residences, and industries located in the river region, which has a higher consumption of products containing preservatives such as food, personal care products, pharmaceuticals hygiene, and others. **Acknowledgment:** This work was supported by CNPq (150540/2013-2).

## MO220

### SOLID PHASE EXTRACTION STRATEGIES FOR THE ENRICHMENT AND ISOLATION OF MICROPOLLUTANTS AND THEIR TRANSFORMATION PRODUCTS FROM DIFFERENT WATER MATRICES

A.A. Deeb, University of Duisburg-Essen / Instrumental Analytical Chemistry; T. Schmidt, University of Duisburg-Essen

The occurrence of a large spectrum of pharmaceuticals and personal care products in the environment clearly shows that conventional wastewater treatment plants are not capable of fully eliminating these compounds. Therefore, advanced treatment using ozonation is discussed intensively. A main drawback of ozonation is that it does not lead to a complete mineralization of organic compounds but to the formation of oxidation products (transformation products), which might be potentially toxic. For example, 2,6-dichloroaniline, a toxic and carcinogenic transformation product, has been shown to be formed during ozonation of diclofenac in an aqueous matrix. The need for proper sample preparation techniques is a challenging task. Up to date, there is no suitable sample preparation method available for isolation of transformation products produced during wastewater treatment. Sample preparation is a very important and essential step in environmental analysis. The basic concept of sample preparation methods is to convert a real matrix into a sample suitable for analysis. Even the best analytical techniques cannot rectify problems generated by sloppy sample pretreatment. The main goals of sample preparation include (a) removing of potential interferences, (b) increasing the concentration of target analytes in the meaning of enrichment, (c) producing a sample aliquot that will not damage the column or instrument and (d) providing a robust, reproducible method that is independent of variations in the sample matrix. Within this contribution, enhanced solid phase extraction (SPE) procedures that are highly effective for the simultaneous isolation and concentration of acidic, basic and neutral compounds (pharmaceuticals/personal care products and their transformation products following ozonation during water treatment) from different environmental water matrices have been developed. The best configuration for separation of cationic, anionic and neutral (hydrophilic and lipophilic) chosen compounds was developed using a tandem of mixed-mode strong anionic exchanger (Oasis® MAX) in combination with mixed-mode strong cationic exchanger (Oasis® MCX) sorbents without any need for pH adjustment, while mixed-mode strong anionic exchanger sorbent (Oasis® MAX) was used for the isolation of small chain polar acids. High recoveries were obtained in both procedures for all tested compounds. The SPE extraction efficiency of used procedures was examined based on developed and optimized analytical methods.

## MO221

### Simultaneous analysis of pharmaceuticals residues in water, soil and plants samples using ultrasonic extraction coupled with a solid phase extraction and their determination by HPLC-UV.

E. Perez-Carrera, University of York / Department of Environment; A. Boxall, University of York / Environment Department

An analytical method combining ultrasonic extraction and solid phase extraction (SPE) has been developed to extract and preconcentrate a wide range of nine pharmaceutical compounds including stimulants, antirheumatics, analgesics, anti-inflammatories, tranquilizers and veterinary medicines in soil, water and plants samples followed by their simultaneous determination using liquid chromatography with an UV detector. The extraction method was optimized and evaluated by testing the following variables: extraction solvents, solvent pH and time extraction. Applying 5 and 0.5 g of soil and plant samples and extracting with a mixture of methanol with citric acid (0.1 M) provided the highest recoveries, between 66-114% with relative standard deviations (RSDs) under 15% for all samples tested. Then, SPE was used to clean-up and preconcentrate the target analytes in the extract using HLB cartridges prior to the analysis through HPLC-UV. The limit of quantifications (LOQs) were between 0.2 and 2 ng.g<sup>-1</sup> and linearity higher than 0.98 for the majority of the selected pharmaceuticals. The method was successfully applied in several types of samples with different characteristics. The detection of 9 pharmaceuticals including ranitidine, verapamil, tylosin, losartan, diclofenac, ketoprofen, carbamazepine, trimethoprim and simvastatin was achieved at concentration levels of ng.g<sup>-1</sup>.

## MO222

## Chemical analysis and bioassays for the monitoring of wastewater: how many extractions are required for sample preparation?

R. Benoit, Chemical Engineering; Z. Baalbaki; A.R. Petosa, McGill University / Chemical Engineering; L. Taylor, McGill University; V.V. Yargeau, McGill University / Chemical Engineering

Contaminants such as pharmaceuticals, herbicides and hormones are of interest due to their known or expected impact on the aquatic environment. Their main entry point in the environment is through wastewater discharges. Our knowledge on contaminants of emerging concern is increasing every year but it is still a challenge to extract and analyse them since there is a wide range of compounds and these have different requirements for successful extraction due to their various chemical properties. Moreover, it is becoming increasingly important to consider that these extractions will also be used to prepare samples for diverse bioassays, which allow the analysis of wastewater quality or treatment efficiency not solely based on the removal of selected contaminants but also considering removal of toxicity. To tackle those challenges, various approaches were tried to develop a multi-residue method to extract diverse contaminants including a sweetener, hormones, pesticides, antibiotic and other pharmaceuticals and obtain representative toxicity data. Previous studies have recommended the use of multiple cartridge types and extraction protocols in order to recover a wide range of compounds that would be representative of the sample analyzed. With the objective of limiting cost and time associated with sample preparation for the monitoring of wastewater, we optimized a multi-residue method based on the use of only two different cartridges, OASIS MCX and OASIS MAX. Using this method, we were able to extract acidic, neutral and basic compounds as confirmed by analysis via liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS, Thermo Orbitrap XL). The use of labelled surrogates (one for each compound monitored) confirmed that recovery rates were acceptable for the list of target compounds (>75%). This suggests that the use of an OASIS HLB cartridge might not be required to extract the neutral compounds of interest. The multi-residue method developed was applied to the chemical analysis of influent and effluent samples collected at three different wastewater treatment plant over a period of 6 months (five different sampling campaigns). The same multi-residue method, without the addition of the labelled surrogates, is currently used for the preparation of the sample to be subjected to bioassays. From these it will be possible to confirm that the multi-residue based on two cartridges is adequate for both chemical analysis and toxicity testing.

## MO223

### Characterization of iodinated-disinfection byproducts formed during chlorination and chloramination of different source waters.

C. Postigo, IDAEA, CID-CSIC / Institute for Environmental Assessment and Water Research; S.D. Richardson, University of South Carolina; D. Barcelo, IIQAB-CSIC / Institute for Environmental Assessment and Water Research

**Iodinated DBPs** have been recently identified in drinking water. However, most iodo containing DBPs still belong to the unknown fraction of the halogenated material (~50% of the TOX) formed during water disinfection and hence, *remain unidentified*[1]. Identified iodinated DBPs have been found to be in some cases *more genotoxic and cytotoxic* than the corresponding brominated and chlorinated analogues<sup>[1,2]</sup>. In this context, the main goal of the present work was to investigate the formation of emerging iodinated DBPs in the production of drinking water from source waters with different iodide and bromide levels. *Chlorination and chloramination* reactions with two different reference aquatic natural organic matter (NOM) solutions, i.e., Suwanee River NOM and Nordic Reservoir NOM, and with different bromide/iodide content were performed at pH 7.5 and room temperature for 72 hours. Chlorination and chloramination reactions were also carried out with Llobregat River water. Source waters were characterized in terms of their total organic carbon, bromide and iodide concentrations, and SUVA, in order to relate these parameters to disinfection byproduct formation. Reacted waters were extracted onto purified XAD resins for identification and characterization of “unknown” iodinated disinfection byproducts by means of gas chromatography – mass spectrometry (GC-MS) detection. Furthermore, the formation potential of target iodo-trihalomethanes, iodo-haloacetic acids, and iodoacetaldehyde was evaluated. Determination of iodo containing trihalomethanes and haloacetic acids was performed by means of liquid-liquid extraction (LLE) with methyl tert-butyl ether (MTBE) and GC-MS analysis. Half of the extract was derivatized with diazomethane for iodo-haloacetic acid analysis. Target GC-MS analysis of iodoacetaldehyde required its derivatization with O-(2,3,4,5,6-pentafluorophenyl)methylhydroxylamine PFBHA and subsequent LLE with hexane. Overall, iodinated disinfection byproducts were formed to a larger extent after *chloramination* of waters containing *high iodide levels*.

### Optimization of molecularly imprinted solid phase extraction (MISPE) coupled with UHPLC-FD, for the determination of estrogens in wastewaters

R. Guedes-Alonso, Universidad de Las Palmas de Gran Canaria / Chemistry; S.

Santana-Viera, Universidad de Las Palmas de Gran Canaria / Departamento de Química; S. Montesdeoca-Esponda, Departamento de Química; Z. Sosa-Ferrera, J. Santana-Rodríguez, Universidad de Las Palmas de Gran Canaria / Departamento de Química

Endocrine disrupting compounds (EDCs) are an important group of contaminants, among emerging pollutants which have attracted the attention of the international community due to their capacity of altering the natural hormonal equilibrium, producing harmful effects in organisms. Female hormones, named estrogens, are considered EDCs because present estrogenic activity. Some authors have linked the concentrations of estrogens in environmental waters with changes observed in aquatic biota as for example changes in reproduction of fish [1]. The levels of EDCs in the environment are usually in the range of ng·L<sup>-1</sup> [2]. Therefore, it is necessary the develop of sensitive and selective methods that allow the determination of these compounds in complex matrices. Molecularly Imprinted Solid Phase Extraction (MISPE) is based in the use of a molecularly imprinted polymer as stationary phase of solid phase extraction which allows a selective extraction of a kind of compounds from a matrix. In this study, a molecularly imprinted solid phase extraction (MISPE) coupled to ultra-high performance liquid chromatography with fluorescence detection has been optimized to determine four estrogens (estriol, 17β-estradiol, 17α-ethynylestradiol and 17β-estradiol-3-methyl ether). Some parameters of the extraction process as pH of the sample and elution volume and the separation and detection process have been optimized. The method developed showed good recoveries (over 80%) and reproducibilities for the four estrogens in samples of wastewater treatment plants from Gran Canaria (Spain) which use different water treatment methods. **References:** [1] J.R. Colman, D. Baldwin, L.L. Johnson, N.L. Scholz, Effects of the synthetic estrogen, 17α-ethynylestradiol, on aggression and courtship behavior in male zebrafish (*Danio rerio*), *Aquat. ## MO225

### Molecularly imprinted polymer-based solid phase microextraction fibers for the selective separation and enrichment of the antiviral drug Abacavir from aqueous matrices

Z. Terzopoulou, M. Papageorgiou, G. Kyzas, D. Bikiaris, D. Lambropoulou, Aristotle University of Thessaloniki / Chemistry

The environmental release of antiviral drugs, like other active pharmaceutical ingredients, is of considerable concern due to potential ecosystem alterations and the development of viral resistances. Based on these concerns and the potential release of large amounts of anti-influenza drugs during pandemic outbreaks, there is a need for sensitive and reliable separation and enrichment methods. Solid phase microextraction (SPME) is currently among the most popular pre-treatment techniques for extracting and enriching analyte from environmental samples and thus development of new SPME sorbents has received considerable attention. Recently, the removal and enrichment of pharmaceuticals with selective adsorption onto molecularly imprinted polymers (MIPs) is characterized as one of the most promising techniques, since MIPs have specific binding sites with complementary size, shape, and functional groups to the template molecule and thus can recognize targets with high selectivity. In this light, novel MIP-based SPME fibers for the selective separation and enrichment of antiviral drugs from aqueous matrices were prepared. Abacavir, which is a HIV-1 reverse transcriptase inhibitor, was chosen as the model compound. The structure of the MIP fibers was characterized by FT-IR spectroscopy, SEM and X-ray Diffraction. The performance of the prepared SPME MIPs was evaluated by various parameters (i.e pH, contact time, temperature, initial compound concentration etc). The developed method by using LC-MS was thoroughly validated for its linearity, selectivity, precision and accuracy. Under the working extraction conditions, the proposed method showed good linearity in the range of 50-1000ng/L, repeatability of the extractions (RSD < 4.3%, n=3), and low limits of detection (< 5ng/L). This method combined the advantages of MIPs and SPME, and it could become an alternative tool for analyzing the residues of antiviral drugs in complex water matrices, such as wastewaters. **Acknowledgements** The support for this study was received from the Greek Ministry of Education and Religious Affairs through Operational Program “Education and Lifelong Learning” of the National Strategic Reference Framework(NSRF)-Research Funding Program “Excellence II(Aristeia II)” under the title “Advanced microextraction approaches based on novel nano- polymers to measure pharmaceuticals, personal care products and their transformation products in the aquatic environment”, which is gratefully appreciated.

## MO226

### Preparation of molecularly imprinted polymers for MISPE extraction endocrine disruptors, drug abuse and drugs in wastewater samples of the Greater ABC region, SP, Brazil

V.d. Bianchi, UFABC / CCNH; A.N. Soares, UFABC Universidade Federal do Grande ABC / Centro de Ciencias naturais e Humanas; E. de Lima, Universidade Federal do ABC / Centro de Ciencias naturais e Humanas

The sample preparation prior to instrumental analysis it is an indispensable prerequisite for the establishment of a chromatographic and / or electrophoretic sensitive and selective method for the trace analysis in complex matrices. New

trends in sample preparation for clinical and pharmaceutical analysis address the molecular recognition as the extraction based on immunoaffinity and molecular imprinting polymers (MIPs). From these materials it is possible to remove the analyte of interest in the sample eliminating most interfering compounds such as proteins, salts, acids, bases and other organic compounds with properties similar to analytes. The molecular imprinting materials are stable for long-term storage, are easy to prepare and economical. In our group we use the reaction processes for bulk and precipitation for the determination of estrogen hormones,  $\Delta^9$ -THC, cocaine, MDMA in effluents of the Greater ABC region which is in the metropolitan area of São Paulo. The results show that the polymers obtained through bulk pores have a size < 20µm and more uniform than the others obtained through precipitation. Factors that improve the retention of analytes of interest in these materials. The authors thank FAPESP Process 2013 / 12569-8 by the aid granted to carry out this work.

## MO227

### **An effective, easy and cheap way of monitoring widely used antibiotics in a catchment area**

E. Tzelepi, Lancaster University / Centre for Global EcoInnovation; C.J. Halsall, Lancaster University / Lancaster Environment Centre; K. Waterhouse, Bowland Analytical Support Ltd.

Over the last decade the potential impacts of pharmaceuticals in the environment have attracted increasing interest from the scientific community and the media. The main issue is that the occurrence of pharmaceuticals is closely related to the emergence and development of antibiotic-resistant bacteria. There is a growing need to monitor efficiently these analytes, using robust and quick screening methods in order to fully comprehend the extent of their influence in freshwater systems. This study involves monitoring the occurrence of widely used veterinary antibiotics in the area surrounding three high impact farms in a river catchment, using online SPE LC/MS. Conventional Solid Phase Extraction methods require at least 500mL of surface water and multiple steps until one sample is ready for analysis through an LC/MS system. This study utilises a regenerating online PLRP-S Solid Phase extraction cartridge for sample pre-treatment, with a required sample volume of 1.5mL. The sample is filtered through a 0.2µm syringe filter and then is loaded into the LC/MS system. Because of the high volume injection the LODs for this method are in the order of low ppt and in some cases sub-ppt levels with the total analysis time of 30 minutes. The classes of antibiotics included in the method are tetracyclines, b-lactams (penicillins, cephalosporins), sulphonamides, lincosamides, macrolides, fluoroquinolones, and aminoglycosides. Multiple sampling locations are examined across the river and streams to determine how these pharmaceuticals enter the aquatic environment.

## MO228

### **Organophosphate ester concentrations in Toronto tributaries, rain water, and waste water treatment plants**

J. Truong, University of Toronto / Chemical Engineering and Applied Chemistry; M.L. Diamond, University of Toronto / Department of Earth Sciences; L.M. Jantunen, Environment Canada; P.A. Helm, Ontario Ministry of the Environment & Climate Change / Environmental Monitoring and Reporting Branch

Organophosphate esters (OPE's) are commonly used as plasticizers, lubricants and as replacement flame retardants for the recently phased-out polybrominated diphenyl ethers (PBDEs). OPEs are a concern because of recent reports of high concentrations indoors and in surface water, their occurrence in herring gull eggs and fish, and their potential toxicity to aquatic biota and humans. As OPE's are typically employed as additives and are not chemically bonded, they are subject to release into the environment via volatilization, dissolution and abrasion. Since spring of 2014, surface water samples were collected monthly at three Toronto tributaries during high and low flow periods, three Toronto waste water treatment plants (WWTP), and bulk rain water. Results indicated that WWTPs have elevated levels from 4.9-6.1 µg/L of a total of 13 OPEs ( $\Sigma$ OPEs) that were dominated by TBEP followed by TCPP. Tributaries had lower concentrations of  $\Sigma$ OPEs ranging from 0.54-3.23 µg/L and were also dominated by TBEP followed by TCPP. Rain water had the lowest concentrations of  $\Sigma$ OPEs of 0.38-0.90 µg/L dominated by TBEP then TCEP. These trends are similar to those reported previously in Toronto urban tributaries by Jantunen (2013) which ranged from 0.010-1.6 µg/L and were also dominated by TBEP.

## MO229

### **SHORT-CHAIN CHLORINATED PARAFFINS (SCCPs) IN ENVIRONMENTAL WATERS**

A.R. Gamell, Aigues de Barcelona, Empresa Metropolitana de Gestio del Cicle Integral de l'Aigua; F. Santos, University of Barcelona / Analytical Chemistry; M. Boleda, Aigues de Barcelona; M. Galceran, University of Barcelona / Analytical Chemistry

Short chain chlorinated paraffins (SCCPs, C<sub>10-13</sub>) are persistent compounds of increasing concern because they bioaccumulate in wildlife and humans and they are persistent and transported globally in the environment. Moreover, these compounds are highly toxic to aquatic organisms at low concentrations. The demonstrated presence of SCCPs in environmental matrices underlines the need of a more permanent monitoring. SCCPs are included in the *priority hazardous substance* list of the Water Framework Directive 2000/60/EC [1], and a

concentration of 0.4 µg/L was set as environmental quality standard in waters [2]. For this reason, SCCPs levels in environmental waters must be monitored, which require reliable analytical methods. Two different methods for the determination of SCCPs in surface water and wastewater were developed and discussed: Gas chromatography (GC) with electron capture detection (ECD) and GC coupled to negative chemical ionization tandem mass spectrometry (NICI-MS/MS). Different MS techniques, such as EI-MS and NICI-MS have been used for the analysis of these compounds, but the tandem MS with NICI has not been performed till now [3]. One of the drawbacks of ECD is that a very efficient clean-up procedure is usually required to remove interferences in water matrices. For sample preconcentration, a liquid-liquid extraction (LLE) based on the method proposed by ISO 12010 and a clean-up with Florisil to remove interferences were used. Quality parameters for SCCPs in surface water and wastewaters according to ISO-17025 have been established. Recoveries were generally higher than 70% and method limits of quantification (LOQs) were in low µg/L levels for all matrices with intra-day and inter-day precisions reported as RSD lower than 15%. Samples from several WWTPs, around Barcelona Metropolitan area (Catalonia, NE Spain) were analyzed in order to evaluate the SCCPs presence in relation to the maximum levels set out in the Directive 2008/105/EC. SCCPs removals during these treatments were also calculated. Moreover, in order to evaluate the effect of the WWTPs effluents in the Llobregat river, 17 points were sampled along its basin. All these samples were analysed by both methods, and results are presented and discussed in this work. *D. 2000/60/EC*; Off. J. Eur.Com. **L 327/1**, 2000. *D. 2008/105/EC*; Off. J. Eur. ## MO230

### **WASTEFFECT: Life cycle effects of emerging contaminants in waste with focus on antimony (Sb)**

H.H. Arp, NGI / Environmental Engineering; G. Okkenhaug, Norwegian Geotechnical Institute; A.R. Almas, Norwegian University of Life Scienc; S.E. Hale, Norwegian Geotechnical Institute / Environmental Engineering; N.A. Morin, Environmental Engineering; M.M. Sparrevik; P.L. Andersson, Umea University / Chemistry Department; K. Breivik, Norwegian Inst. for Air Research; F. Wania, University of Toronto at Scarborough / Department of Physical and Environmental Sciences; G.D. Breedveld, Norwegian Geotechnical Institute / Department of Environmental Engineering

Waste treatment has become a dynamic sector, which in many countries is changing from traditional landfilling to recycling and incineration approaches that aim at material and energy re-capture. In addition to materials and energy, waste also contains a large variety of emerging contaminants, and yet how landfilling, incineration, and recycling can effect environmental emissions and exposures of such emerging contaminants remains largely overlooked. Antimony is an up and coming emerging contaminant, as it is increasingly used in diverse products as a flame retardant that can replace brominated flame retardants (BFRs). The effects of antimony in the environment, remain largely unknown. WASTEFFECT is a research project funded by the Norwegian Research Council where the main goal is to develop robust waste emission and exposure models for waste regulators and companies to anticipate and reduce risks from emerging contaminants. Therefore, one of the main part of this project is to determine how emerging contaminants behave in different waste streams, like landfilling, incineration and recycling. For priority contaminants used in consumer products, waste treatment will play a large role in the ultimate removal of these substances from the environment. As case studies, we have established a Norwegian waste emission inventory of legacy and new brominated flame retardants (BFRs), bisphenol A and antimony, in EE-waste, car waste, plastics, glass and combustible waste. Input parameters for these inventories have been obtained by sampling and analysing air, leachate and solid samples from various waste treatment methods, including incineration, recycling and landfilling, by considering the entire waste-life cycle. Antimony results will be used to establish a mass flow diagram and determine the percentage of antimony recycled, removed or emitted in to the Norwegian environment through waste handling like recycling, thermal treatment or landfilling. The data will be presented in the poster. These data (along the ones obtained for BFRs and bisphenol A) will be used to estimate the contribution of the waste sector to the net burden or exposure to the environment and humans. The main output of this research will help guide the waste management sector on which of the treatment methods provide the lowest risk in regards to emerging chemicals, and which processes can be optimized.

## MO231

### **Environmental monitoring of biocides - Cybutryne and azole fungicides in suspended particulate matter**

K. Pohl, Federal Environment Agency (UBA) / Section IV Biocides; K. Michaelis, Federal Environment Agency Germany; A. Koerner, Federal Environmental Agency Germany / Environmental Specimen Bank Germany; I. Noeh, Federal Environmental Agency Germany

Very few data for applied amounts and emission rates of biocidal active substances to the environment are available in Germany. Furthermore, data from environmental monitoring campaigns which could actually be attributed to biocidal uses only are limited. That means that Product authorisation in context of the Biocidal Product Regulation (EU) No. 528/2012 (BPR) has started without any

information of the actual situation of biocide emission into the environment. As regulatory authority we are interested if the consequences of the BPR are already observable (e.g. practicability of risk mitigation measures, exclusion and substitution of substances with very high concern). To improve our knowledge about the impact of biocides to the environment it was the aim of this case study to investigate the biocides cybutryne, propiconazole and tebuconazole retrospectively by analysing suspended particulate matter (SPM) samples of the German Environmental Specimen Bank. The active substance cybutryne was used as construction material preservative for façades and insulating material until it was banned for this use in 2011. An increase in use of other material preservative substances (e.g. tebuconazole, propiconazole) is therefore expected. Both active substances are probably endocrine disruptors and are persistent in the environment. The potential release of cybutryne, tebuconazole and propiconazole from material preservatives into surface water was examined in SPM samples from the years 2006 to 2012 from six different sampling areas (e.g. at the rivers Rhine and Elbe). All areas are assumed to be dominated by storm water and municipal waste water whereas the agricultural influence was rather secondarily. The results show that concentrations of all three substances are similar at nearly all locations. For cybutryne decreasing concentrations were detected at two the sampling sites. Comparable decreases were observed for propiconazole and tebuconazole at one sampling site of the river Rhine. But in most cases no significant trends are observed over time. We conclude that further investigations over a longer period are necessary to observe the effect of exclusion and substitution of substances. This study is part of a UBA research project with the question "Validation of a prioritisation concept for biocides and development of a monitoring program for biocides in Germany".

### MO232

#### PAHs in water and sediments of the Colombian Cauca River during heavy rain episodes and implications for risk assessment

W. Ocampo-Duque, R. Sarria, Pontificia Universidad Javeriana Cali / Industrial Engineering; M.I. Paez Melo, Universidad del Valle / Chemistry; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering

In this study, we report the presence of PAHs in the Cauca River (Colombia). Three sampling campaigns were carried out between May 2010 and June 2011, and the samples were collected at eight relevant sites. The period considered measuring before, during, and after a season of heavy rains which were influenced by the global atmospheric phenomenon which affects tropical countries with huge flooding called "La Niña". The highest mean  $\Sigma$ PAHs concentrations were 4476.5 ng/l and 1582.7 ng/g for water and sediments, respectively. The PAHs mostly detected were Benzo(b)fluoranthene, Benzo(k)fluoranthene, and Pyrene in sediments; and Fluorene, Acenaphthylene, and Anthracene in water. After the season of rains statistically significant higher PAHs concentrations were detected. The results of the study were compared to other rivers worldwide at both environmental compartments. In some sites, concentrations detected of PAHs were higher than screening benchmarks for ecological protection. Moreover, in the studied area, it was observed that people in poverty situation living close to the river could be more exposed to PAHs. Therefore, estimation of human health risks was carried out and the results suggest some likely carcinogenic effects due to PAHs presence especially in children exposed during current recreational swimming and adults working in low-technology sand extraction.

### MO233

#### Occurrence and spatial-temporal distribution of emerging contaminants in the Jundiá River Basin - SP, Brazil

D.N. de Sousa, Federal University of Sao Carlos UFSCar / Chemistry; A.A. Mozeto, Federal University of Sao Carlos / Chemistry; G.M. Grosseli, R.L. Carneiro, Federal University of Sao Carlos UFSCar / Chemistry; P.S. Fadini, UFSCar / Chemistry

The occurrence and spatio-temporal distribution of seven pharmaceuticals for human use, one personal care product and three hormones were evaluated in surface water, suspended particulate material (SPM) and sediment from rivers. Samples were collected in two water bodies in the Jundiá River Basin (Pirai Creek and Jundiá River), São Paulo State, Brazil, in the period of February 2012 to April 2013. The first one is a clean water stream and the second is a heavily polluted river. Compounds determinations were carried out using a liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS). Only the hormones 17- $\beta$ -estradiol and 17- $\alpha$ -ethinylestradiol were not found in any matrices analyzed. Atenolol, caffeine, propranolol and triclosan were detected in all samples of SPM and sediments in the Jundiá River. Caffeine was measured with highest concentrations in water, reaching up to 25  $\mu\text{g L}^{-1}$ , and a fraction in mass up to 6.8 % of the stream transported caffeine in the SPM. In the sediments, the maximum observed concentration value was 37.5 ng g<sup>-1</sup>. Results have shown that most compounds were measured in the dissolved phase, and the spatial distribution of contaminants along the river was mainly affected by higher concentrations resulting from discharges of wastewater from a sewage treatment plant, located a mile upstream of a sampling point in the Jundiá River. Seasonal variations were observed in the concentrations of analytes, mainly due to the dilution processes caused during periods of higher rainfall (February to April). Based on these results it is possible to notice the importance of evaluating the partition of these contaminants in aquatic ecosystems, in order to estimate more accurately their

transportation, fate, and to infer possible toxicological characteristics in the aquatic environment. Acknowledgement - The authors thanks to FAPESP, CNPq, CAPES and PETROBRAS

#### Partitioning of biocides between water and inorganic phases of render

M. Urbanczyk, Aarhus University Department of Environmental Science; U. Bollmann, Aarhus University; K. Bester, Aarhus University / Environmental Science

The use of biocides as additives for building materials has gained importance in recent years. These biocides are, e.g., applied to renders and paints to prevent them from microbial spoilage. However, these biocides can leach out into the environment. In order to better understand this leaching, the partitioning of biocides between water and inorganic phases of render was studied. In this study the partitioning constants of benzoisothiazolinone, carbendazim, dichlorooctylisothiazolinone, diuron, iodocarb, isoproturon, irgarol, mecoprop, methylisothiazolinone, octylisothiazolinone, terbutryn, and tebuconazole towards minerals were studied. A mixture of biocides listed above was used to estimate partitioning constants between water and five different minerals, commonly used as fillers in renders: barite, calcium carbonate, kaolinite, mica and talc. The resulting  $K_d$  values for all minerals analysed were compared. The partitioning constants for calcium carbonate varied between 0.1 (isoproturon) and 1.1 (iodocarb) and 84.6 (dichlorooctylisothiazolinone), respectively. The results for barite, kaolinite and mica were in a similar range and usually the compounds with high partitioning constants for one mineral also had high values for the other mineral. From all minerals investigated, only talc showed high partitioning for all studied biocides. Partitioning constants for talc vary from 2.2 (benzoisothiazolinone), 778.1 (carbendazim) and 435.6 (dichlorooctylisothiazolinone), respectively. The obtained partitioning constants were compared with render-water distribution constants, which showed that leaching of biocides, might be estimated based on partitioning constants for individual components of the render.

### MO235

#### An integrated experimental and computational approach for characterizing the kinetics and mechanism of triadimefon racemization

J.F. Kenneke, National Exposure Research Laboratory; Q. Cheng, Korea Institute for Advanced Study / School of Computational Science; Q. Teng, US EPA / National Exposure Research Lab; S.A. Marchitti, U.S. EPA / National Exposure Research Laboratory

Enantiomers of chiral molecules commonly exhibit different environmental fates, pharmacokinetics, and toxicities. Ignoring these differences can introduce significant uncertainty when modeling the physiological and environmental fate of chiral chemicals and evaluating their risk to human health and the environment. The stereoselective transformation of chiral compounds under biological and environmental conditions has been well studied, however, there is far less information on the biological and environmental racemization (and enantiomerization) of chiral compounds. Racemization is the macroscopic statistical process of the irreversible transformation of one enantiomer into the racemic mixture, while enantiomerization refers to the microscopic and molecular process of the reversible conversion of one enantiomer into the other. These processes have been shown to occur with environmental chemicals and pharmaceuticals and can have a profound impact on efficacy, toxicity, and sample preparation, storage, and analysis, particularly when they occur unknowingly. Triadimefon

[(RS)-1-(4-chlorophenoxy)-3,3-dimethyl-1-(1H-1,2,4-triazol-1-yl)butan-2-one] is a systemic broad spectrum 1,2,4-triazole fungicide that has been shown to undergo racemization in soils, water, and organic solvents. We utilized a series of NMR spectroscopic and GC/MS techniques to measure the rates of enantiomerization and racemization, deuterium isotope effect, and activation energies for triadimefon in H<sub>2</sub>O and D<sub>2</sub>O. From these results we were able to determine that the alpha-carbonyl carbon of triadimefon is the reaction site, cleavage of the C-H (C-D) bond is the rate determining step, the reaction is base-catalyzed, and the reaction likely involves a symmetrical intermediate. Computationally, we applied the B3LYP/6-311+G\*\* level of theory to compute optimized geometries, harmonic vibrational frequencies, nature population analysis, and intrinsic reaction coordinates for triadimefon in water and were able to hypothesize three racemization pathways. The experimental and computational results including the activation energies and the Gibbs free energies of the reaction agreed well with each other. This work provides an initial step in developing predictive, structure-based models that are needed to quickly identify both pharmaceutical and non-pharmaceutical compounds that may undergo racemization.

### MO236

#### Degradation of cytostatic drugs: hydrolysis, solar box, UV, UV-H2O2 and bioreactor

H. Franquet, Environmental Chemistry; A. Medina, C. Sans, Universitat de Barcelona / Department of Chemical Engineering; S. Lacorte, IDAEA-CSIC / Environmental Chemistry

Cytostatic drugs, used in chemotherapy, are partially excreted unchanged by urine and faeces. These compounds are directed to wastewater treatment plants (WWTPs), where some can be degraded while others are recalcitrant and

discharged to receiving waters by the WWTP effluents. Some authors studied their behaviour under different degradation processes [1-4], although degradation kinetics and pathways need further attention to determine their fate in the environment. The aim of this work was to evaluate the degradability of five treatments, namely hydrolysis, Solarbox, UV, UV-H<sub>2</sub>O<sub>2</sub> and biodegradation. To perform the experiments, sixteen cytostatic drugs were selected: those affecting the DNA, those most prescribed and those detected in hospital effluents. The bioreactor was filled with 1L of waste water spiked at 50 µg L<sup>-1</sup> and the other experiments were carried out using 2L of MilliQ water spiked at the same concentration. Samples were collected periodically and analyzed with liquid chromatography coupled to high resolution mass spectrometry (LC-HRMS) under positive electrospray ionisation (ESI) mode and a Luna C18 column. Some drugs were found to be unstable in water (vincristine, vinblastine); others were degraded under UV light (melphalan, etoposide) and some others were found to be stable using biodegradation or UV, making necessary the use of advanced oxidation processes (AOPs) such as UV-H<sub>2</sub>O<sub>2</sub> to eliminate them (ifosfamide, cyclophosphamide). Degradation constants were calculated in order to define the stability of this new family of contaminants under laboratory conditions. [1] Buerge IJ, Buser HR, Poiger T and Müller MD. 2006. ## MO237

### Photodecomposition of sulfamethoxazole under simulated sunlight irradiation: transformation products and residual antibacterial activity toward *Vibrio fischeri*

M. Gmurek, Lodz University of Technology / Faculty of Process and Environmental Engineering Department of Bioprocess Engineering; M. Majewsky, Karlsruhe Institute of Technology (KIT) / Engler Bunte Institut Chair of Water Chemistry and Water Technology; H. Horn, Karlsruhe Institute of Technology KIT / Chair of Water Chemistry and Water Technology  
Sulfamethoxazole (SMX) is a bacteriostatic antibiotic which is only partially metabolized during therapy. As a result, it reaches the aquatic environment in its unchanged biologically active form. Conventional wastewater treatment is not effective in removing SMX. Consequently, it has been detected in urban wastewaters and surface waters. Due to the genetic ability of environmental bacteria to transmit and acquire antibiotic resistance, the latter has become a global concern. Therefore, it is crucial to better understand photochemical processes occurring in natural water just as the formation of active transformation products (TPs). The main goal of the presented study was to investigate the TPs formed during SMX photolysis and to determine their antibacterial toxicity in mixture. To simulate natural conditions, a solar simulator was used as light source. TPs were identified by interpretation of product ion spectra using LC-MS/MS. Additionally, UHPLC/QToF hybrid mass spectrometer was used for the determination of accurate masses. *Vibrio fischeri* growth inhibition (GI; 24h) and luminescence inhibition (LI; 30 min; 24h) were used to determine the changes of antibiotic activity in mixture during simulated sunlight irradiation. During long-term SMX photolysis experiments (1 week, C<sub>SMX</sub>=100mg), nine TPs could be identified by reference standards. Moreover, three further TPs of photodecomposition of SMX were found. Some of the TPs (e.g. N<sup>4</sup>-acetyl-SMX) were observed to be formed during photolysis for the first time. Furthermore, a TP with m/z 270 was tentatively confirmed as dihydroxylated SMX. The kinetics of the TPs were determined and correlations between TPs were established. The DOC mass balance clearly showed that only around 5 to 10% were mineralized during the experiment emphasizing the need to elucidate the fate of TPs. The toxicity analysis confirmed that the mixture retains its toxicity toward luminescence (30min; 24h) and that there is no change over the treatment time on EC<sub>50</sub>. In contrast, growth inhibition activity was found to decrease over the irradiation time, however, this decrease was not proportional to the transformation of the parent compound SMX.

## MO238

### Householder contribution to glyphosate losses in urban storm drains

C. Ramwell; M. Kah, University of Vienna / Department of Environmental Geosciences; P. Johnson, Alabama Department of Conservation and Natural Resources / Alabama Aquatic Biodiversity Center  
Glyphosate has been detected at low levels in some water bodies and there is increasing interest in the contribution of urban areas. Glyphosate is widely used by both the amenity sector and by householders. In order to focus mitigation measures appropriately, it is necessary to ascertain the extent to which different sources contribute to any pollution. The extent to which glyphosate use in the home and garden sector may contribute to surface water contamination has not previously been quantified. The aim of this study was to quantify the widely-used herbicide, glyphosate, and its degradation product, aminomethylphosphonic acid (AMPA) in surface water drains (storm drains) that could be attributed to householder usage alone. Water samples were taken from a residential area in York, England where all

the surface water from the catchment drained to a single point. Samples were taken in June/July during one of the main application periods. Maximum glyphosate and AMPA concentrations in surface water drains were 8.99 and 1.15 µg/L respectively after the first rain event period, but concentrations rapidly declined to < 1.5 µg/L glyphosate and < 0.5 µg/L AMPA. The AMPA:glyphosate ratio was typically 0.35. Less than 1% of the applied glyphosate was recovered in drain water. Despite over-dosing occurring, glyphosate concentrations in drain flow were lower than concentrations reported elsewhere from professional use in urban areas.

## MO239

### The Inventory, Environmental Releases and Risk Assessment for Short-Chain PFASs in China

X. Hao, Peking University; Y. Cao; J. Wang, J. Liu, Peking University  
Since 3M Company voluntarily phased out of PFOS during 2000-2002, risk management of Per- and Polyfluoroalkyl substances (PFASs), represented by PFOS and PFOA as 8C PFASs, has already been one of the leading works in global chemicals management. For long-chain PFASs, due to the significant environment and health risks caused by the specific persistent, bioaccumulative and toxic characteristics, international communities have successively conducted risk assessment and management focusing on 8C-based long-chain PFASs, and devoted to developing short-chain PFASs as alternatives. Since being used on a global scale, concentrations of short-chain PFASs in the aquatic environment increased year by year and researches pointed out that short-chain PFASs might become the major PFASs in drinking water in the future. High concentrations of short-chain PFASs may endanger the ecological environment and living organisms, but current studies are insufficient, meanwhile, except for extremely high environment persistent, the notable bioaccumulation and toxicity still have lots of uncertainties and research gaps. Nowadays, with the industry transfer, China has been the main area for manufactures, process and use of PFASs. However, there is little inventory, release and risk assessment information available for short-chain PFAS. In this study, inventory of sources was established based on survey and analysis of the manufactures, process and use information for PFASs. Besides, emission amounts and factors were estimated to calculate environmental releases of short-chain PFASs. Furthermore, preliminary assessment of environment risk was conducted. Although the inventory and environmental releases may be coupled with uncertainties, this study provides sufficient information for follow-up scientific researches and risk management of short-chain PFASs. Keywords: PFASs, inventory, environmental releases, risk assessment

## MO240

### PERFLUOROALKYL SUBSTANCES (PFASs) IN TEXTILES

A. Dreier, Eurofins GfA GmbH; F. Neugebauer, Eurofins GfA Lab Service GmbH / RD; S. Selke, Eurofins GfA Lab Service GmbH; U. Kallée, BUND; M. Santen, In recent years, perfluorinated compounds (PFCs), particularly perfluorooctanoate (PFOA) and perfluorooctane sulfonate (PFOS) have been described as compounds of increasing environmental concern and numerous studies were conducted to investigate the environmental distribution and fate of these compounds. As result, various sources have been identified including emissions during the life-cycle (production, use, disposal) of products containing PFASs. This study aimed to investigate textiles as sources for volatile PFASs. For this purpose, more than 100 textile samples were analyzed for several PFASs (PFCA, PFSA, FTOH, FTA, FOSA, FOSE). All of the investigated textile samples contained PFASs. Concentrations varied strongly between the investigated materials and compounds. Concentrations of volatile PFASs were usually higher than concentrations of the perfluoroalkyl acids. Results presented on the poster will be evaluated on a statistical basis. Keywords: FTOH, PFOS, PFOA, textiles

## MO241

### Exposure and risk in indoor environment: VOCs analysis from unexpected microbiological sources

A. Micheluz, Ca Foscari University of Venice / Molecular Sciences and Nanosystems; M. Rovea, Agenzia Reg Prevenz Protez Ambientale Veneto AR / Dipartimento Prov Padova; G. Formenton, ARPAV; S.-. Manente, Ca Foscari University of Venice / Department of Molecular Sciences and Nanosystems; V. Prigione, University of Turin; V. Tigini, Univeristy of Turin; F. Pinzari, Consiglio per la Ricerca e la sperimentazione in AgricolturaAgricultural Research Council; G. Varese, University of Turin / Dept of Life sciences and systems biology; G. Ravagnan, Ca Foscari University of Venice  
In recent years, many studies were focused on volatile organic contaminants (VOCs) originating from biological sources and their relation to the air quality inside indoor environments, like archives, libraries, museums, schools, offices, etc.. In these climate controlled environments, particular fungal species are able grow, producing several volatile organic compounds that are suspended in the air or adsorbed on dust particles. The assessment of their nature is needed for a proper analysis of the indoor air quality, in order to understand the potential risk for the human health of workers and visitors and to propose fast remediation to avoid "sick building syndrome" phenomena. A rapid tool to understand fungal contamination in indoor environments could be air sampling followed by gas chromatography-mass spectrometry (GC-MS) analysis. For the broad speciation of unknown trace of VOCs we tested evacuated stainless steel canisters to sample the indoor air within a few seconds. The composition of the indoor air in a Ca' Foscari

University Library, furnished with the innovative closed metal cabinets called Compactus® and affected by an active mold infection was analyzed with the aim of detecting a specific chemical fingerprints of fungi. Six canisters were adopted in different areas of the deposit to collect VOCs and subsequent analyzed by GC-MS. Moreover, laboratory experiments were development to collect VOC productions directly from the dominant fungal species isolated from the library by previous sampling and identified by morphological and molecular analysis (*Eurotium halophilicum*, *E. chevalieri*, *Aspergillus penicillioides*, *A. creber*, *Penicillium chrysogenum*, *P. brevicompactum* and *Cladosporium cladosporioides*). All the samples were monitored for 1 month by weekly analysis of the emitted VOCs. For all the analysis, microscale purge & trap Entech 7100 was adopted as sampling and pre-concentration system directly connected with corresponding sampling devices (canisters and culture bottles) and GC-MS. Several volatile organic compounds, both known (*i.e.* 1,4-pentadiene and 2-butanone) and unknown emerging substances, that were detected by the direct analysis of indoor air were also found in the emissions of the dominant fungal species isolated from aerobiological sampling. The results suggest a close relationship between the fungal infections and the poor indoor air quality.

## MO242

### **Polychlorinated biphenyls and flame retardants in indoor and outdoor air: evaluation of seasonal variability and relationship with house characteristics**

**P. Bohlin Nizzetto**, NILU Norwegian Institute for Air Research; L. Melymuk, P. Kukucka, Masaryk University, Faculty of Science, RECETOX / RECETOX Research Centre for Toxic Compounds in the Environment; . Vojta, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; P. Cupr, Masaryk University, Faculty of Science, RECETOX / RECETOX Research centre for toxic compounds in the environment; J. Klanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment

Indoor air is affected by a wide range of pollutants arising from sources both inside and outside buildings. This study aimed to evaluate indoor air concentrations of semivolatile organic contaminants (SVOCs) across a range of residential environments with respect to house characteristics, indoor materials, and the ratios with outdoor concentrations. The targeted compounds were 7 polychlorinated biphenyls (PCBs), 4 polybrominated diphenyl ethers (PBDEs) and 12 novel halogenated flame retardants (NFRs). Air sampling was conducted in 17 homes in residential areas of Brno, Czech Republic using polyurethane foam passive air samplers (PUF-PAS). PUF-PAS were deployed concurrently inside and outside each home for 28 days, once during summer and once during winter. General sampling rates of 1.4 and 3.5 m<sup>3</sup>/day were used to obtain air concentrations indoors and outdoors, respectively. The selected houses had various characteristics (*i.e.* year of construction, renovation, type of house) and house contents (*e.g.* floor type, furniture, electronics etc). The range of indoor air concentrations of PCBs were 39-174 pg/m<sup>3</sup> (mean 78.8 pg/m<sup>3</sup>) in summer and 6.2-86 pg/m<sup>3</sup> (mean 52 pg/m<sup>3</sup>) in winter. Outdoor concentrations of PCBs were 17-65 pg/m<sup>3</sup> (mean 27 pg/m<sup>3</sup>) and 5.3-18 pg/m<sup>3</sup> (mean 12 pg/m<sup>3</sup>) in summer and winter, respectively. Indoor to outdoor ratios (I/O) of PCBs ranged from 1.2-6.4 (mean 3.1) in summer and 0.4-11 (mean 5.1) in winter. Indoor air concentrations of PBDE were 2.0-65 pg/m<sup>3</sup> (mean 14 pg/m<sup>3</sup>) in summer and 0.5-78 pg/m<sup>3</sup> (mean 13 pg/m<sup>3</sup>) in winter. PBDEs outdoors were 3.5-66 pg/m<sup>3</sup> (mean 12 pg/m<sup>3</sup>) and 1.1-6.2 pg/m<sup>3</sup> (mean 3.0 pg/m<sup>3</sup>) in summer and winter, respectively. The I/O ratios of PBDEs were 0.4-5.0 (mean 1.4) in summer, and 0.3-20 (mean 4.7) in winter. NFR indoor air concentrations were 15-2730 pg/m<sup>3</sup> (mean 222 pg/m<sup>3</sup>) in summer and 11-776 pg/m<sup>3</sup> (mean 102 pg/m<sup>3</sup>) in winter. NFR outdoors were 2.5-2340 pg/m<sup>3</sup> (mean 153 pg/m<sup>3</sup>) and 0.13-26 pg/m<sup>3</sup> (mean 3.7 pg/m<sup>3</sup>) in the summer and winter, respectively. For NFR, the summer I/O ratios were 0.7-33 (mean 5.6) while in winter I/O ratios were 3.2-1100 (mean 140). The indoor concentrations were significantly higher (*p* < 0.05) than outdoor concentrations for PCBs in summer and winter, PBDEs in winter, and NFR in winter. Higher concentrations indoors than outdoors were also found for PBDEs and NFRs in summer but differences were not significant.

## MO243

### **Emerging flame retardants in indoor environment: a multi-location study between the UK and Norway**

**K. Kademoglou**, University of Reading / geography and Environmental Sciences; C.D. Collins, Reading University / Soil Research Centre

Flame retardants (FRs) are man-made chemical compounds widely used in industry during the manufacturing of various commercial products such as computers, plastics, fabrics, textiles and polyurethane foam products in order to minimise or prevent fire. Worldwide phase-out campaigns and legislative restrictions on the use of polybrominated diphenylethers (PBDEs) have resulted in the production of new PBDE-replacement products, also known as emerging FRs (Stapleton et al., 2008). Sampling sites representing three different indoor environments (houses, stores and offices) were selected at the area of Reading (UK) and the area of Oslo (Norway) respectively. N=18 samples of indoor dust were collected from vacuum cleaner bags in houses, stores, offices and libraries in the area of Reading (UK) during August - December 2013. N=10 samples of indoor dust were collected during November 2013-April 2014 from vacuum cleaner bags in houses from the wider area of Oslo (Norway) as a part of a cohort study of N=60 people within the framework of the 'Advanced Tools for Exposure Assessment and Biomonitoring'

(A-TEAM) project, a Marie Curie Initial Training Network aiming to establish tools for human exposure biomonitoring of emerging FRs. In the present study the emerging FRs examined are: 1,2- bis(2,4,6-tribromophenoxy)ethane (BTBPE), 2-ethylhexyl-2,3,4,5-tetrabromobenzoate (EH-TBB) and bis(2-ethylhexyl)-3,4,5,6-tetrabromophthalate (BEH-TEBP). Prior to extraction, all samples were spiked with 13C-labelled TBB, TBPH and BTBPE used as internal standards. BDE-77 and BDE-128 were used as recovery standards for EH-TBB, BTBPE and BEH-TEBP respectively. A two-step Solid-phase extraction (SPE) using Florisil (step 1) and 44% acidified silica gel (step 2) was performed coupled with ultrasonication-assisted solvent extraction. The instrument analyses were conducted using a Thermo Scientific ITQ 1100 GC- Ion Trap MS on Electron Ionisation (EI) mode. We report levels of emerging FRs in British and Norwegian indoor environments where humans spend eight hours minimum on a daily basis. Preliminary results will be presented on how variability from diverse indoor dust sources such as houses, stores and offices can affect the levels of emerging FRs, as well as to compare the geographical trends of emerging FRs between Norway and the UK. This project is financially supported by the European Commission FP7 Marie Curie Initial Training Network "A-TEAM" grant number 316665.

## MO244

### **Rapid screening for oxidative characteristics of fine particle collected from the different regions in South Korea**

**I. Kim**, School of Environmental Science and Engineering; T. Jeong, Gwangju Institute of Science and Technology; J. Park, S. Kim, School of Environmental Science and Engineering

Many studies have demonstrated the association between particulate matter (PM) and adverse effects on human health including increased respiratory disease and lung cancer. It is well understood that PM<sub>2.5</sub> (diameter < 2.5µm) can reach the alveolar wall and generate oxidative stress. Oxidative stress is an important mechanism to the PM-induced health effect. Dichlorofluorescein (DCFH), glutathione (GSH), and dithiothreitol (DTT) assay are commonly used for assessing the oxidative stress of PM. Particularly, DTT assay is a cell-free assay, and can rapidly and quantitatively measure the oxidation capacity of PM. PM is heterogeneous, and its properties vary remarkably according to source areas. Therefore, the toxicity investigation of PM at the different regions is necessary. In this study, we collected the PM from various source areas (heavy traffic, industrial, urban, suburban etc.) and assessed its oxidative characteristics using the modified DTT assay and biological assay tools. DCFH and GSH for reactive oxygen species generation were measured to observe the cellular effect of PM using human alveolar epithelial cell (A549). The oxidative characteristics of PM showed the significant difference by sampling site. This result might be attributed to the various chemical composition of PM. Furthermore, a noteworthy relationship was observed between cellular ROS and modified DTT result. This study suggests that 1) the chemical composition of PM highly contribute to its toxicity, and 2) the modified DTT assay has the possibility to apply for measuring the quantitative oxidative effect of PM as good alternative assay.

## MO245

### **Organophosphorus flame retardants (OPFRs) in outdoor urban atmospheric particulate matter**

**D. Ramos García**, CSIC; S. Lacorte, IDAEA-CSIC / Environmental Chemistry; B.L. van Drooge,

This work presents an analytical procedure for the quantification of organophosphorus flame retardants (OPFRs) in atmospheric particulate matter (PM). The analytical method is based on Soxhlet extraction and a clean-up step with solid phase extraction (SPE). Detection and quantification was performed by gas chromatography-electron impact mass/mass (GC-EI-MS/MS). The validation included blank tests in order to see the background levels of these compounds and percentage of recoveries with spiked filters at two different levels. Ambient air PM samples were collected at an urban background site in Barcelona under contrasting meteorological conditions in order to study the influence of particle loads and meteorological conditions on the abundance of OPFRs. The presence of OPFRs has been determined and substantial correlations have been observed between the levels of certain OPFRs and particle loading of the atmosphere. The presence of individual compounds in ng/m<sup>3</sup> concentrations levels in the fine particle mode (PM<sub>1</sub>) at an urban background site, suggests a potential risk of these compounds to human health.

## MO246

### **Exploiting new technologies to monitor pollution in cities**

**A. Boxall**, University of York / Environment Department; E.E. Burns, University of York / Chemistry; E. Koutsoumpeli, University of York / Electronics; G. Makrai, University of York / Dept of Computer Science; K.E. Stevens, University of York / Environment Department; X. Fang, University of York / Dept of Computer Science; X. Gao, University of York / Environment Department; M. Kruza, York University / Environment; F. Medhat, M. Parmar, University of York / Electronics; R. Siyengwa, University of York / Department of Sociology; C. Wang, University of York / Chemistry; M. Depledge, European Centre for Environment and Human Health ECEHH; D.W. Kolpin, U.S. Geological Survey; F. Pilla, Trinity College Dublin / Department of Civil Structural and Environmental Engineering

With an increasing world population and subsequent urbanisation, the need to

address the resultant amplification of public health and environmental issues has become crucial, requiring cost-effective approaches to pollution monitoring, data management, and interpretation. Considering the increased complexity of urban pollution and the lack of monitoring schemes for emerging contaminants, it is imperative to enhance and update the currently used methods and employ faster and more efficient approaches for monitoring pollutants. In this paper, we present the conclusions from an expert workshop that aimed to develop a novel framework for understanding the exposure of city environments and citizens within cities. The poster will illustrate how state-of-the-art analytical techniques can be combined with innovative sampling technologies, such as citizen science, robotics and specimen banking to monitor air, water and soil within city environment. The poster will discuss how these methodologies meet the needs of end users and stakeholders, and how they could offer prompt and robust decision-making support. We recommend the development of a 'smart city' model for monitoring urban pollution which can potentially be tailored and adjusted to suit the needs and characteristics of cities of varying size and nature.

#### MO247

##### **Development and validation of a multi-residue analytical method for the simultaneous determination of antibiotics for monitoring of wastewater and seawater samples**

A. Margareto Mato, CSIC-IDAEA / Environmental Chemistry; S. Diaz-Cruz, IDAEA-CSIC / Environmental Chemistry; D. Barcelo, IIQAB-CSIC / Institute for Environmental Assessment and Water Research

**Keywords:** antibiotics, environmental analysis, wastewater, seawater Antibiotics are one of the pharmaceutical classes with higher usage worldwide. They are both used in human and veterinary medicine, mainly for treating or preventing bacterial infections. After administration most pharmaceuticals are not completely metabolized and thus they are excreted from the body via urine and faeces reaching the wastewater treatment plants via wastewater. Several reports have shown that many pharmaceuticals do not degrade during municipal conventional wastewater treatment being, therefore, discharged to environmental waters. One of the most notorious and significant negative effects attributed to the occurrence of antibiotics in the environment is the development of bacterial antibiotic resistance. While antibiotic-resistant bacteria are found in the natural environment, significantly higher number of these bacteria are present in wastewater or even in treated wastewater [1]. But not only continental water is affected, the use of antibiotics in aquaculture, thus their presence in seawater, has adverse effects on the marine environment as well. This work describes the development, validation and application of a fully automated analytical method for the determination of antibiotics from different therapeutic groups i.g. penicillins, tetracyclines, aminoglycosides, nitrofurans, cephalosporins, macrolides, quinolones, fluoroquinolones, sulfonamides and four of their acetylated metabolites, in wastewater and seawater. The method was based on automated on-line solid-phase extraction (SPE) followed by high-performance liquid chromatography coupled to quadrupole-linear ion trap-tandem mass spectrometry (HPLC-QqLIT-MS/MS). Quantification of target antibiotics was performed by the internal standard and matrix-matched calibration method, using isotopic labelled compounds for the different antibiotic groups. The performance of the method in terms of sensitivity, linear range and precision will be presented. To assess the applicability of the developed method, wastewater and seawater samples were analyzed. The results obtained will be discussed during the presentation. Acknowledgements This work was funded by the EU through the Project Sea on a Chip (Contract 614168) and by the Generalitat de Catalunya (Consolidated Research Group "2014 SGR 418 - Water and Soil Quality Unit")

#### MO248

##### **Fine particulate matters - PM10 in the Novi Sad's ambient air**

D. Lukic, Institute of Public Health of Vojvodina; M. Jovanovic, S. Bobic, L. Torovic, Institute of Public Health of Vojvodina / Department of Hygiene and Human Ecology; N. Dragic, University of Novi Sad Faculty of Medicine; S. Bijelovic, University of Novi Sad Faculty of Medicine / Department of Hygiene and Human Ecology

Results from the recent EEA Report from 5/2014 shows that Europe's air pollution problem is far from solved. One of the Europe's most problematic air pollutants, that clearly impact large parts of the urban population, is particulate matter (PM). The objective of this work was to investigate concentration of PM<sub>10</sub> in ambient air samples collected during one year in area of the City of Novi Sad. The sampling campaign was conducted by Institute of Public Health of Vojvodina, from January to December 2013, on two sampling sites denoted as *AD Holding Dnevnik* (traffic station) and *Nursery Liman III* (suburban station). Frequency of air sampling was defined by national law as indicative measurements throughout 8 weeks in 2013. Air samples were collected on fiberglass filters during 24 hours, using high volume sampler Sven Leckel LVS3. Meteorological parameters (wind speed and direction, relative humidity and ambient air temperature) were taken from the Republic Hydrometeorological Service of Serbia. After collection, filters were conditioned and weighted, according to the reference method EN 12341, describing sampling and measurement procedure. Laboratory method performance was characterized by limit of quantification of 1 µg/m<sup>3</sup> and measurement uncertainty of 8%. Sampling campaign resulted with 77 samples collected on *Nursery Liman III* and 87 samples

on *AD Holding Dnevnik* monitoring site. Measured PM<sub>10</sub> levels were in the range from 5 µg/m<sup>3</sup> (*Nursery Liman III*) to 75 µg/m<sup>3</sup> (*AD Holding Dnevnik*). The annual PM<sub>10</sub> average concentrations on *Nursery Liman III* and *AD Holding Dnevnik* monitoring sites were 27 and 33 µg/m<sup>3</sup>, respectively. On *Nursery Liman III* location, four samples (5.2%) exceeded 24-hour PM<sub>10</sub> limit value (50 µg/m<sup>3</sup>), and one sample (1.30%) exceeded tolerable 24-hour PM<sub>10</sub> limit value (65 µg/m<sup>3</sup>). On *AD Holding Dnevnik* location, aforementioned limits were exceeded in twelve (13.8%) and three samples (3.45%), respectively. The annual PM<sub>10</sub> average concentrations on both monitoring sites did not exceed the annual limit value for the protection of human health (40 µg PM<sub>10</sub>/m<sup>3</sup>). These results showed that Novi Sad as well as others European cities have problem with fine particulate matter PM<sub>10</sub> in ambient air, which implies the necessity of urban planning with new transportation models and heating system, as well as defining the source and impact on human health and environment.

#### MO249

##### **Assessment of the contamination from sampling materials and procedures for substances of urban/industrial origins: phthalates and perfluoroalkyl substances (PFAS)**

B. Lepot, INERIS; K. LeMenach, LPTCEPOC University of Bordeaux; c. ferret, E. Botta, INERIS; M. Dévier, LPTC-EPOC, University of Bordeaux / Oceanic and Continental Environments and Paleoenvironments; P. Labadie, H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC

The number of substances monitored in the environment is rapidly increasing in the last years. Among them, some substances such as the Bis(2-ethylhexyl) phthalate (DEHP) are already part of the first priority substances list to be monitored in the European Water Framework Directive (No. 2477/2001/EC). In addition to these substances, since August 2013 new substances have been included in this list (Directive 2013/39/EU), such as the perfluorooctane sulfonic acid and its derivatives (PFOS). Moreover, other phthalates, perfluorooctanoic acid (PFOA) and PFOS compounds were recently largely investigated in national screening studies in surface and groundwater (France, 2011 and 2012). Due to their properties, these compounds are often part of composition of many plastics that are used in tubing material for surface water or wastewater sampling operations. Nowadays, it is generally accepted that the uncertainty of a chemical measurement is a crucial parameter for enabling the reliable interpretation of a measurement result for any purpose. It is also widely agreed that the measurement process begins at the time when a primary sample is taken, rather than when a delivered sample arrives at the analytical laboratory. Water sampling within environmental monitoring programs often require operations that involve more or less prolonged contact between water sample and different materials such as pumping tubes. AQUAREF (National reference laboratory for water and the aquatic environment) technical guidances suggested the use of Teflon® material as a component of the sampling equipment for the monitoring of the micropollutants. However, these guidances were established taking in account studies essentially performed on inorganic (metals) or organic (pesticides or PAHs) compounds. The results obtained on phthalates join the findings observed in the tests conducted by the BRGM for groundwater in 2012 and may partly explain the high frequency of quantification found during the 2012 screening study (see presentation Botta et al., SETAC 2015). From the point of view of technical instructions for WFD monitoring programs, these results do not lead to a categorical choice of material for tubing to improve the quality of results on phthalates. Only possible research or monitoring of the substance DEP/ DiBP may lead to pay attention to the material used for sampling or the sampling duration. We conclude that field blank must become of routine in monitoring.

#### MO250

##### **Presence of PBDEs and alkylphenols in different water environments. Hints for pressures and impact analysis**

S. Carrer, THETIS SpA / Environment and Territory; c. carrer, THETIS SpA; C. Nasci, Thetis Ltd / European Union and RD

The occurrence of PBDEs in biota, sediment, humans, milk, food and dust was extensively monitored during recent years whereas little information is available on their concentrations in water on the other hand the occurrence of alkylphenols in rivers and transition waters is sometimes causing failures of achievement of environmental quality standards for water bodies according to WFD 2000/60. The monitoring of emerging contaminants in different environments such as stormwater runoff, WWTP effluents, dewatering plants, surface waters as well as the integrated analysis of data deriving from manifold studies give important hints for the pressures and impact analysis of the water bodies. The possibility to compare chemicals' concentrations in different type of samples helps to go back to sources of contamination, allowing to plan appropriate measures aiming at the achievement of chemical and ecological objectives. The present work represents an elaboration of data derived from a collection of recent studies and monitoring activities conducted in the lagoon of Venice and its drainage basin. Six PBDEs congeners were considered, whereas 4-nonylphenol and octylphenol were considered for alkylphenols. After data collection, a database of 598 samples was constructed and elaborated. PBDEs were very rarely found above the detection limit of 50 pg/l in lagoon water where as in Venice canals only BDE-47 showed an average concentration slightly above 50 pg/l. On the other hand stormwater runoff samples and the dewatering plant serving an urban area showed relevant concentrations of

PBDEs. Alkylphenols were surveyed in lagoon waters and in dewatering plants. In this case, 4-nonylphenol in lagoon water showed some peaks very close to MAC-EQS. Again, both 4-nonylphenol and octylphenol showed higher concentrations in “mainly urban” dewatering plants than “mainly rural” dewatering plants with some exceptions especially for octylphenol. Integrated analysis of different types of water samples helps understanding sources and fate of contaminants of emerging concern, especially those which are very difficultly detected in water, which shows sudden and sharp peaks and which are characterized by manifold anthropic uses, leading in some occasion to exceed EQS and impair chemical status of water bodies. Both PBDEs and alkylphenols seem characterized by urban origin and maybe found more frequently in stormwater runoff discharges than in industrial and WWTP effluents.

## MO251

### **Loads of parabens, triclosan and triclocarban in greywater: are PCPs the main source of pollution?**

S. zedek, LEESU laboratoire eaux environnement et systèmes urbains; A. Bressy, S. Deshayes, Paris-Est Université / Leesu; V. Eudes, Laboratoire Central de la Préfecture de Police; E. Caupos, Université ParisEst LEESU UMRMA UPEC ENPC AgroParisTech UPEMLV / Leesu; R. Moilleron, Paris-Est University / Leesu

Parabens (PBs), triclosan (TCS) and triclocarban (TCC) are known to be pollutants released by the use of personal care products (PCPs) leading to the contamination of aquatic environment by wastewater discharges. These chemicals are used as conservative and biocide in various other applications as food, clothes or pharmaceuticals. Occurrence of these compounds in aquatic environment and urban water are known but their sources in greywater have been few investigated until now. In this context, our goals were: i) to assess the level of impregnation for these compounds for different kinds of greywater ii) to compare the different kinds of greywater in order to evaluate the main source; and iii) to evaluate the contribution of greywater to the wastewater contamination. Four types of greywater were sampled: manual dishwashing, washing machine, showers and washbasin. Eight compounds were analyzed: methylparaben (MeP), ethylparaben (EtP), propylparaben (PrP), benzylparaben (BzP), butylparaben (BuP), isobutylparaben (IsobuP), TCS and TCC by liquid chromatography coupled with tandem mass spectrometry. Concentrations and loads in µg/inhabitants/day were assessed. For MeP, the most concentrated compounds, concentrations vary from 40 ng.L<sup>-1</sup> to 2.1 mg.L<sup>-1</sup> leading to a median flux of 500 µg/inhabitant/day that represents around 16 % of the loads carried by wastewater. The key lessons highlighted by this study are that greywater strongly contributes to the contamination of wastewater. However PCPs are not the only source of parabens and triclosan in wastewater: dishwashing and washing machine waters appeared as concentrated as shower water. Moreover measured concentrations were highly variable depending on the consumption practices. This latter finding indicates the need to link environmental sciences with social sciences; this is our outlook for a future research in the frame of the Cosmet’eau project. New samplings of wastewater will be carried out in 2015 to evaluate the evolution of concentrations in wastewater in relation to potential consumption changes (i.e. paraben free products or organic cosmetics). **Keywords:** *Greywater, loads, personal care products, paraben, triclosan.* √

## MO252

### **Impact of road de-icing salt on foliage of ornamental lime trees (*Tilia x vulgaris* H.) in the city of Riga (Latvia)**

G. Cekstere, Swiss Federal Research Institute for Forest, Snow and Landscape Research; A. Osvalde, Institute of Biology of the University of Latvia / Laboratory of Plant Mineral Nutrition; P. Vollenweider, WSL / Forest Dynamics Ornamental lime trees (*Tilia x vulgaris* H.) in Latvia, provide city inhabitants with different sorts of ecosystem services. De-icing salt, spread on roadways during winter, accumulates in tree foliage during vegetation seasons causing leaf injury and tree decline. Moreover, salt uptake can significantly interfere with mineral nutrition and symptoms found in foliage may partly relate to nutrient imbalances. However, injury and tolerance mechanisms in response to salt accumulation in *Tilia* spp. are still poorly understood. Objectives were to compare levels of de-icing salt (NaCl) contamination in street tree leaves with the concentration of nutrients and macro-/micromorphological changes. In September 2014, foliage was collected at 8 typical street sites lined with lime trees in the centre of Riga and one control site in the National Botanical Garden (NBD). After evaluating the percentage of necrotic leaf area, leaf samples were prepared for chemical and microscopic analysis. Leaf concentration of Ca, Mg, Fe, Cu, Zn and Mn was determined by AAS, that of N, P, Mo, B by colorimetry, S by turbidimetry using a spectrophotometer, K and Na by flame photometer and Cl by AgNO<sub>3</sub> titration. The microlocalisation of and structural injury by salt were analysed using several methods in diascopic light, fluorescence light and transmitted electron microscopy. In comparison to lime trees from the NBD, asymptomatic healthy street tree leaves contained higher concentration of Na, Cl, P, Ca, Mg, Fe, Mn, Zn, Cu and Mo No nutrient deficiency was observed in asymptomatic healthy foliage. However, amounts of K, Ca, Mg and Mn tended to decrease with higher levels of leaf necrosis. In severely damaged leaves, the concentration of K and Mn was close to the deficiency limit. In street trees, the intensity of leaf necrosis was positively correlated to leaf concentration of Na, Cl, Zn, and Mo, but negatively to that of K. Given the chemical composition of de-icing salt, positive correlations between Na and Cl on one hand and Zn, and Mo

on the other could indicate simultaneous uptake of salt and other environmental contaminants. Negative correlation between salt and Ca, B and Mg concentration may relate to injury in mesophyll cells caused by NaCl accumulation. Given the sensitivity of lime trees to road de-icing salt, accumulation of NaCl at sensitive - e.g. mesophyll – sites, where they may severely affect cell physiology and cause structural injury, is expected.

## MO253

### **Biomonitoring of Dioxins/dl-PCBs in the north of the Netherlands: eggs of backyard chickens, cow and goat milk and soil as indicators of pollution**

A. Arkenbout, Toxicowatch Foundation

In the region of Harlingen in the north of the Netherlands people have recently been very concerned about adverse health effects related to possible emissions of dioxins and other POPs by a recently installed waste incinerator. To evaluate these effects the local authorities make use of a very limited monitoring program. Using eggs of backyard chickens, cow and goat milk and soil as indicators we however set up a more adequate monitoring program. Because the Dutch authorities do not routinely check the eggs from small farms (or households) – with less than 200 chickens per farm – the risk of pollution with dioxins and dl-PCBs is underestimated. After finding several egg samples that did not comply with the Dutch regulation IKB for the commercial use of eggs (in case the level exceeds 1.75 pg BEQ / g fat one is compelled to take further action) we started a more extended monitoring program. This study shows that eggs of backyard chickens are sensitive biomonitoring parameters for dioxin/PCB contamination in the vicinity of potential sources (harbour activity, waste incinerator, landfill). By using cost-efficient screening analysis tools (such as DR CALUX<sup>®</sup>) that are also affordable by private households, areas of public concern can be monitored in a rapid and efficient way. The correlation between DR CALUX<sup>®</sup> and GC/HRMS proved to be very satisfactory; there were no false positive or false negative results. The results of this study point to at least two types of source of dioxin emission near Harlingen. The fact that the levels of dioxins and dioxin-like PCBs are increasing with decreasing distance to the harbour urgently calls for closer investigation in order to find the sources of the dioxin/PCB pollutions, and to prevent adverse health impacts for domestic animals, wildlife and human beings.

## **POPs and Pseudo-POPs: Environmental occurrence and exposure (P)**

## MO254

### **Scientific rationale for the evolution of PBT and POP criteria and cut-off values in international regulatory tools**

M. Matthies, University of Osnabrueck / Institute of Environmental Research; K.R. Solomon, University of Guelph / School of Environmental Sciences; M. Vighi, University of Milano / Earth and Environmental Sciences; A. Gylman, Sustainable Solutions International; J. Tarazona, EFSA

The concepts of PBT and POP assessment are extremely important for regulatory purposes because they allow identifying and classifying substances that require particular attention for the control of chemicals on the market (e.g. PBTs or vPvB in REACH) or that need to be banned or strictly controlled at global level due to their potential for long range transport (L) and to become global pollutants (e.g. POPs in the Stockholm Convention). In spite of this internationally recognised relevance for regulators and policy makers, these concepts are not fully consistent in international regulatory tools and their meaning may be changing. In particular, the origin of the criteria and the evolution of their cut-off values and the specific testing requirements often do not have a clear and identifiable scientific rationale. An overview is given on the different definitions used to identify these kinds of chemicals. Most national regulations and international agreements derived cut-off values from substances with known PBT/vPvB or POP properties (“dirty dozen”) by using them as reference chemicals. In particular, differences in the cut-off values for P, B, T and L concepts are highlighted and the consequences of these differences (e.g. the different classification and the different number of chemicals requiring strict control measures) are discussed. The need for using sound science-based criteria or precautionary-based values required for management-policy reasons is also accounted for. The possibility of rationalization of approaches is discussed in connection with the different protection aims of the various regulatory frameworks.

## MO255

### **A pilot study on the exposure of individuals to chemical pollutants, via ritualistic consumption of Ganges River Water, during the Maha Kumbh Mela (2013).**

B.C. Lemanski, Department of Biology; S. Gullapalli, Colgate University / Department of Economics; S.P. Connor, Wadsworth Center New York State Department of Health / Department of Analytical Chemistry

The Maha Kumbh Mela is one of the most important religious pilgrimages in Hinduism, taking place along the banks of the Ganges River (India) every 144 years. As part of these pilgrimages, millions of individuals ritualistically consume the water of the Ganges River. However, increasing utilization of the river in the past 60 years for both domestic and industrial uses (latter emphasis) has negatively impacted the water quality of the river. This may potentially affect the exposure of religious practitioners to chemical pollutants. In this pilot study, we examined and

collected whole water samples (water and suspended sediments) at six sites of religious significance spanning the length of the river - Devprayag, Rishikesh, Haridwar, Allahabad, Varanasi, and Gangasagar - from December 2012 to February 2013. These samples were subsequently analyzed for select polychlorinated biphenyls (PCBs), organochlorinated pesticides (OCPs), and polycyclic aromatic hydrocarbons (PAHs), through micro-electron capture or mass spectrometric methods, where applicable. Results suggest that while previous studies may have found high levels of pollutants, the levels of surveyed chemical pollutants were relatively low at all sites surveyed.

## MO256

### Occurrence and exposure assessment of organophosphate flame retardants (OPFRs) associated with the consumption of drinking water in Korea

W. Jeong, S. Lee, Hanyang University; S. Lee, Hanyang University / College of Science and Technology; y. jeong, Hanyang University; H. Moon, Hanyang University / Marine Sciences and Convergent Technology  
Organophosphate flame retardants (OPFRs) have been widely used in a variety of commercial products such as plastics, foams, paints, textiles, and furniture. Due to high consumption of OPFRs in surrounding environments, some studies showed the occurrence of these contaminants in environmental compartments such as air, water and biota worldwide. However, despite the evidences of adverse health effects for OPFRs in laboratory animals, a comprehensive survey on human exposure to OPFRs was not conducted in Korea. In this study, we analyzed ten OPFRs (TEP, TBP, TCEP, TCPP, TDCPP, TBEP, TPP, EHDPP, TEHP and TCP) in three types of drinking water samples ( $n=75$ ; tap water, bottled water and filtered water) collected from representative cities in Korea, including Seoul, Busan, Incheon, Daegu, Ulsan, Daejeon, Gwangju and Ansan, to investigate the occurrence and contamination patterns of OPFRs in the samples. Total concentrations of OPFRs in tap water, bottled water and filtered water ranged from 0.17 to 295 (mean: 30) ng/L, from 6.0 to 229 (mean: 82) ng/L, and from < LOQ to 826 (mean: 134) ng/L. The highest concentrations of OPFRs were found for filtered water samples, which were contaminated by the components (crush seal O-rings) used in water purifier system. The major compounds of OPFRs in all of the samples were TCPP, TBEP and TCEP, which collectively accounted for 90% to the total concentrations of OPFRs. We found different composition patterns of OPFRs in tap water samples among cities surveyed, suggesting the different contamination sources or consumption patterns of OPFRs within cities in Korea. Considering the consumption of drinking water (L/day) and body weight (kg) for Korean populations, the estimated daily intakes (EDI) of total OPFRs were 2.23, 2.22, and 2.22 ng/kg body weight/day for male, female and average populations. The EDIs in the present study were  $10^4$ – $10^6$  times lower than the reference doses for selected OPFRs such as TCPP, TPP and TCP. However, we confirmed that the consumption of drinking water is an important exposure pathway of OPFRs to Korean populations. Further studies are required to assess the multiple exposure sources (dust, inhalation, and diet) of OPFRs, for more accurate exposure assessment.  
Keywords OPFRs, Tap water, TCPP, TCEP, Drinking water

### Monitoring of trihalomethanes in drinking water distribution system in Novi Sad, Serbia

L. Torovic, Institute of Public Health of Vojvodina / Department of Hygiene and Human Ecology; S. Bijelovic, University of Novi Sad Faculty of Medicine / Department of Hygiene and Human Ecology; S. Bobic, M. Jovanovic, E. Zivadinovic, Institute of Public Health of Vojvodina / Department of Hygiene and Human Ecology  
Drinking water disinfection is a very significant public health advance, providing protection against waterborne pathogens. However, disinfecting agents react with natural organic matter and form a range of chemicals collectively called disinfection by-products (DBPs). Trihalomethanes (THMs) are one of the most abundant and important classes of DBPs, due to their potential adverse health effects on humans. In the Novi Sad municipality, one water treatment plant supplies the City of Novi Sad and 14 surrounding settlements with 130 000 m<sup>3</sup> of drinking water in a day, through 1100 km distribution network. The plant uses ground water as its water source, and chlorine is applied as disinfectant. THMs are regularly monitored by the Institute of Public Health of Vojvodina, in the following way: 18 water samples are collected weekly, on the same day, 10 of them on sampling points in Novi Sad city (supplied directly by the treatment plant), and 8 towards system extremities (influenced by rechlorination facilities and reservoir storage within distribution system). Samples were analyzed by gas chromatograph coupled to headspace sampler and mass spectrometry detector. Based on 3753 samples collected from 2010-2013, concentration of THM4 (sum of CHCl<sub>3</sub>, CHCl<sub>2</sub>Br, CHClBr<sub>2</sub> and CHBr<sub>3</sub>) ranged from 4.9 to 71.5 µg/L (mean 30.1 µg/L). Annual THM4 mean level showed increase of 42% in the second year, and then stayed relatively constant. Calculation of proportions of the individual THMs, relative to the surrogate measure (THM4), showed that chloroform was predominant specie (overall mean 18.5 µg/L), while bromoform was not detected (LOQ 1 µg/L). Data were averaged to obtain monthly THM concentration across the study period, but no obvious pattern was found in this ground water supplied system. With regard to spatial variations, as expected, a substantial increase of average THM4 concentrations between finished water leaving the plant and the distribution system extremities was observed (1.4 to 2.5-fold). When Novi Sad city

distribution network is considered, this ratio remained fairly constant (1.3-1.4) over the examined period. Maximum contaminant levels for drinking water in the Republic of Serbia include 100 µg/L for THM4 - evaluation of regulatory compliance showed no exceedance. However, THM exposure of nearly 400 thousand inhabitants of Novi Sad municipality differs, depending on residence location.

## MO258

### Polychlorinated Biphenyls Monitoring in Surface Water

A. Aleksandryan, Hazardous Substances & Waste Policy Division / Head of Division; A. Khachatryan, Waste Research Center; B. Gabrielyan, Scientific Center of Zoology and Hydroecology NAS RA; Y. Bunyatyan, Waste Research Center  
Among major sources of environmental pollution are power transformers, condensers, turbines and other types of equipment filled with polychlorinated biphenyls (PCBs)-containing liquids, as the mentioned equipment is functioning in the industry, power engineering and other branches of National Economy in a considerable quantity. The daily risk of PCB-related affections in big groups of population in the course of professional activity of humans is extremely great. The greatest danger to environment and people originates from incompetent handling of these compounds, ignorance among owners of PCB and PCB-filled equipment about the hazards of the given substances, as well as contact to soils, foodstuff and other objects polluted by PCBs. Monitoring of PCBs was performed on samples of water from Sevan Lake and rivers of its basin, biomedica of the lake and rivers of its basin, bottom sediments, soil near the former pesticides shops and storages, as well as arable soil in the vicinity of these shops and storages, area formerly known by pesticides intense application In 2002-2003, relatively high amounts of PCBs were revealed in samples from rivers flowing near major settlements: in Gavaraget River – 0.751 mcg/L, in Martuni River – 1.577 mcg/L (Table 3.1.4). In these rivers besides the impact of agricultural runoffs, residential, household-related pollution is added. In 2012 Samples of surface water from Sevan Lake and rivers of its basin, benthos, silt and other type of soil from Sevan and rivers of its basin, as well as soil samples from different regions were taken. The average water samples were studied using Gas-Chromatography. Totally 46 samples were analyzed for PCB and 596 findings were obtained. Average PCBs content in water from Sevan Lake made 0.727 mcg/L, while the maximum level was 6.831 mcg/L. In biomedica the average level of PCBs was 0.530 mcg/g and the maximum content was 0.743 mcg/g. Upon investigation of the mentioned environmental media a typical picture of technogenic pollution by PCBs due to application of transformer oils of “Arochlor” type was observed. To this latter signifies the content of PCB revealed congeners. Furthermore, attention should be paid to the presence of great amounts of congeners No.87 and No.95 among all the revealed PCB congeners; this also confirms the fact that transformer oils are the source of pollution. The research outcomes demonstrated that, generally, PCBs content did not exceed the hygienic standard.

## MO259

### Input of neonicotinoids into the aquatic environment after application as seed treatment

F.E. Wettstein, Institute for Sustainability Sciences ISS; M.F. Garcia Delgado, Agroscope / Institute for Sustainability Sciences ISS; I. Hanke, Plant Protection Chemistry; S. Huntscha, Agroscope / Plant Protection Chemistry; R. Kasteel, T. Poiger, Agroscope; T.D. Bucheli, Agroscope ART / Analytical Chemistry Natural Resources  
Environmental Protection in Agriculture  
Today, modern agriculture is not feasible without the use of plant protection products. Since 1997, the use of neonicotinoids (NNT) as insecticides was permitted in Switzerland. Over the past years, the compound class of the NNT received particular attention, because of their toxicity to bees and bumblebees. Therefore, the spray application on blossoms and the use as seed treatment on annual flowering plants (e.g. canola, corn, ...) was banned in the European Union and Switzerland for two years starting from December 1<sup>st</sup>, 2013. Simultaneously, authorities called for more data about the occurrence of Clothianidin (Clo), Imidacloprid (Imi) and Thiamethoxam (Tim) in different environmental compartments to provide a basis for future decisions. Concerning the aquatic environment, the occurrence of Tim in five Swiss rivers in concentrations up to 47 ng/L was reported by Moschet et al. 2014 [1]. The authors mentioned spray application onto fields and seed treatment as possible sources. To test whether seed treatment could be a significant source of NNTs in surface waters, we cultivated sugar beet seeds impregnated with NNT on a test field [2] and monitored the temporal development of NNT residues in plant, as well as in drainage water. To encompass the entire growing season of sugar beets, drainage water was collected from mid-March to November, 2014. The two applied NNT Imi and Tim as well as Clo, one of the metabolites of Tim, were regularly detected over the entire investigation period. Concentration dynamics and an overall mass balance of NNTs will be presented and discussed. References: [1] C. Moschet, I. Wittmer, J. Simovic, M. Jungmans, A. Piazzoli, H. Singer, C. Stamm, C. ## MO260

### Multi-stressor modeling - assessment of D5 (decamethylcyclopentasiloxane)

#### behavior in the Baltic Sea using the next generation multimedia fate and transport model BALTSEM-POP

E. Undeman, Stockholm University / Dept of Applied Environmental Sc; B. Gustafsson, Stockholm University / Baltic Nest Institute Baltic Sea Centre; C. Humborg, Stockholm University / Department of Applied Environmental Science ITM Baltic Sea Centre; M.S. McLachlan, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES

Organic contaminants constitute one of many stressors that deteriorate the ecological status of the Baltic Sea. When managing environmental problems in this marine environment it may be necessary to consider the interactions between various stressors to ensure that averting one problem does not exacerbate another. A novel modeling tool, BALTSEM-POP, is presented here that simulates interactions between climate forcing, hydrodynamic conditions and water exchange, biogeochemical cycling and organic contaminant transport and fate in the Baltic Sea. We discuss opportunities to use the model to support different aspects of chemicals management. We exemplify these opportunities with a case study where two emission reduction strategies for a chemical used in personal care products (decamethylcyclopentasiloxane) are evaluated, and where the confounding influence of future climate change and eutrophication on the impact of the emission reduction strategies are assessed.

#### MO261

##### Spatio-temporal pattern of pesticide residues in the Turia and Júcar Rivers (Eastern Mediterranean Area of Spain)

A.D. Ccancapa, University of Valencia / Medicine Preventive; a.m. reyes; V. Andreu, CIDCE CSIC UV GV; Y. Pico, University of Valencia / Medicine Preventive

The Júcar and Turia rivers, with a length of 512 and 280 km respectively, are the most important of the Júcar hydrographic demarcation (East of Spain). The main fluvial network has a markedly Mediterranean water contribution regime, characterized by more dry periods in the summer and by growth of circulating flow in the fall. The average annual rainfall is 500 mm; however, there is large spatial variability with values of 300 mm in the southern regions, whereas in other areas reached values are greater than 750 mm. The Júcar hydrographic demarcation contains large crop areas in which pesticides are applied widely to protect plants from disease, weeds and insects. This work presents the results of analyzing 50 commonly-used pesticides by liquid chromatography of 81 water and sediment samples taken from both rivers and in consecutive periods of time as follows: 30 samples from the Júcar river in the period 2010-2011, and 51 samples from the Turia river in the period 2012-2012. The study also presents the results of correlating pesticide concentration and physical-chemical characteristics of the water and sediment matrices. In the two river basins, pesticides were detected primarily in water (Júcar 58% and Turia 92%), whereas their presence in sediments was more intermittent. Those at high concentrations in water were the azole (imazalil up to 6750 ng L<sup>-1</sup>), the organophosphorus (chlorpyrifos in 100% of the samples), and the Benzimidazole (carbendazim up to 382 ng L<sup>-1</sup>). However, this pattern differed in sediments, which were contaminated primarily with organophosphorus (higher Kow) (chlorpyrifos 100 % of sediments in 2010-2011 and 64% in 2012-2013 up to 141 ng g<sup>-1</sup>). According to the results of this study, pesticide residues in the Júcar and Turia basins do not seem to represent a high risk to sediments. Nevertheless, the monitoring program can be very useful to control the contamination of the river basin. *Acknowledgement* –The authors thank the Spanish Ministry of Economy and Competitiveness for the financial support through the projects Consolider-Ingenio 2010 CSD2009, and CGL2011-29703-C02-02

#### MO262

##### Spatio-temporal patterns of selected organic pollutants in sediments from western Svalbard fjords

K. Pazdro; A. Pouch, Institute of Oceanology Polish Academy of Sciences-Centre for Polar Studies; A. Zaborska, Institute of Oceanology Polish Academy of Sciences; g. siedlewicz, IO PAN / Marine Chemistry and Biochemistry Department The knowledge of biogeochemical cycling of organic contaminants in polar marine ecosystems is still incomplete. Meanwhile, knowledge of migration routes of these contaminants and factors determining their distribution in a given ecosystem is essential to the reliable determination of ecological and ecotoxicological risks arising from the presence of these compounds in the ecosystem. Moreover, polar ecosystems are considered to be particularly sensitive to changes in environmental factors related to climate change. Global warming may cause changes in pollution load to the Arctic seas as well as affect the transfer of contaminants between biotope and biocenosis. Marine sediments in accumulation areas can be regarded the final sink for important portion of organic pollutants entering the Arctic, thus can be used as a useful tool in reconstruction of pollution history. In the present study we examine the contaminant record in two Svalbard fjords – Hornsund and Kongsfjorden using sediment cores dated by <sup>210</sup>Pb geochronology. Sediments cores were collected during r/v “Oceania” Arx campaigns. Composition and levels of persistent organic contaminants (Σ 12PAHs, Σ7PCB, HCB) in sediments layers were investigated. Selected samples were analysed for the presence of pharmaceutical residues. Potential POPs sources were identified based on interpretation of the congener proportions and overall sediment concentrations of the studied compounds. The study also provides an opportunity to discuss the

influence of burial and post-depositional sediment reworking processes on the interpretation of persistent organic contaminants detected in marine sediments. Finally the obtained results provide good basis to predict future changes in organic pollutants cycling in changing Arctic environment. The presented study was partly realised in the frame of Centre for Polar Studies (Leading National Research Centre)¶

##### Depositional history of polychlorinated biphenyls (PCBs) in two South Atlantic subtropical estuarine systems

T. Combi, University of Bologna / Environmental Sciences; S. Taniguchi, University of São Paulo / Physical Oceanography department; C.d. Martins, Universidade Federal do Paraná / Centro de Estudos do Mar

The environmental patterns and fate of persistent organic pollutants (POPs) are of global concern because of their high persistence in the environment, liposolubility, capacity of biomagnification and endocrine disrupter and carcinogenic characteristics. Considering several factors, such as chemical stability and extensive global usage, polychlorinated biphenyls (PCBs) are often used to assess the environmental behavior of POPs. To assess the spatial and temporal distribution of PCBs, sediment cores and surface sediments from two South Atlantic subtropical estuarine systems (Guaratuba and Paranaguá Bays) were analysed. The study area is located in the Southeastern Brazilian coast and is surrounded by one of the last preserved Atlantic Rainforests of South America. While Guaratuba Bay represents a well-preserved environment and has been selected by the Nature Conservancy's Coastal and Marine Conservation Program as a priority site for biodiversity conservation in Brazil, Paranaguá Bay is surrounded by urban and industrial areas and shelters the largest grain exporter port in Latin America. The historical input of PCBs in the area was elucidated through the integrated analysis of the vertical profile and sedimentation rates. Since PCBs were not produced in Brazil, historical trends show a late usage in comparison with industrialized areas from Northern Hemisphere. PCBs were not detected before the decade of 1960 and the first peak of relative high concentration occurred around 1965. The next decades were characterized by increasing concentrations of PCBs, reaching the highest values between the late 1980's and beginning of 1990's, which corresponds to the period of increased human occupation around the region. Concentrations decreased in recent years, reflecting the prohibition of the use, production and importation of PCBs since 1981. Distribution of PCBs in Paranaguá Bay showed the anthropogenic activities (port, industries and urbanization) on the margins of the bay are the major responsible for the contamination in the area. In contrast, the main source of PCBs in Guaratuba Bay was located outside the estuary, with PCBs coming through the rivers that flow into the bay. Notwithstanding the early ban on PCB usage and production worldwide, emissions are predicted to continue for the next decades, highlighting the importance of understanding the sources and distribution of these compounds worldwide.

#### MO264

##### Historical sediment record and distribution of polychlorinated biphenyls (PCBs) in sediments from the Adriatic Sea (Italy)

T. Combi, University of Bologna / Environmental Sciences; S. Miserocchi, L. Langone, CNR Institute of Marine Science ISMAR; R. Guerra, University of Bologna / Department of Physics

PERSEUS EU FP7 Project (Policy-oriented marine Environmental research in the Southern European Seas) aims to identify the interacting patterns of natural and human-derived pressures on the Mediterranean and Black Seas, to assess their impact on marine ecosystems in the framework of the Marine Strategy Framework Directive (MSFD). In the context of the 'ADREX: Adriatic and Ionian Seas Experiment' within the PERSEUS project, a monitoring survey has been conducted in order to investigate spatial and temporal patterns of polychlorinated biphenyls (PCBs) in sediments from the Adriatic Sea (Italy). To this end, surface sediment along transversal-to-the-coast transects and undisturbed sediment cores were collected at four coastal areas: the prodelta Po River, Ancona, Gargano Promontory and Bari. The spatial distribution of total PCB concentrations in surface sediments varied between 4.1 µg kg<sup>-1</sup> and 0.84 µg kg<sup>-1</sup>, and revealed a decreasing pattern from the northern to the southern Adriatic Sea. The maximum concentration of total PCBs was detected in the Po River Prodelta area, and the lowest concentrations in the Bari coastal area. The historical trends of PCBs showed a common pattern, with increasing concentrations from the lower horizons to the middle sections of sediment cores, followed by a decreasing trend upwards in the surface layers deposited in recent years. Historical data on PCBs show that production and emissions increased sharply from the mid 1960's to 1980's in Italy; the trend reversed at the end of 1980s continuing to decrease in the following decades. Concentrations found in middle sections of sediment cores probably recorded periods of higher production and emission of PCBs, while the lower concentrations found in the upper layers most likely reflected ban/restriction on PCB production and use in Italy due to incoming European regulations. Despite the low levels of total PCBs found in surface and middle sections of sediments when compared to highly urbanized coastal areas in the World, concentrations have declined with distance from the Po River Prodelta southward, suggesting the Po River outflow to be a major contributor of PCBs to sediments in the Adriatic Sea. In addition, the presence of PCBs in areas far from the direct source of input and the congeners pattern suggest that PCBs in the sediments from the Adriatic Sea may also come

from discharges of local sources, as well as atmospheric deposition.

## MO265

### **Sources and of Polychlorinated Biphenyls (PCBs) in Admiralty Bay, King George Island, Antarctica**

T. Combi, University of Bologna / Environmental Sciences; C.d. Martins, Universidade Federal do Paraná / Centro de Estudos do Mar; S. Taniguchi, University of São Paulo / Physical Oceanography department; J. Leonel, Universidade Federal do Rio Grande / Instituto Oceanográfico; R.A. Lourenço, PUCRio; R.C. Montone, Instituto Oceanográfico - Universidade de São Paulo / Departamento de Oceanografia Física Química e Geológica

Long-range transport of persistent organic pollutants (POPs) to polar regions is one of the most important issues in the actual global environmental scenario. Even though the Antarctic continent is the most remote and protected area on the planet, recent studies suggest that it is no longer a pristine environment, being subject to both direct impacts due to increasing tourism and research activities and indirect impacts through atmospheric transport. Sediment cores were analysed for temporal patterns and sources of polychlorinated biphenyls (PCBs) in Admiralty Bay, King George Island. The samples were taken at nine sites: Ferraz Station; Ulmann Point; Botany Point; Stenhouse Point; Refuge II; Crepin Point; Arctowski Station; Barrel Point; Thomas Point. Total PCB concentrations were slightly higher in comparison with other remote and well-preserved areas, ranging from 1dry weight. In a general way, the historical distribution of PCBs presented relative high values around the middle of the decade of 1980, coinciding with the installation of research stations and increased tourism activities in the study area. However, this trend was not verified for all studied locations and some of the sediment cores registered non-negligible PCB concentrations in surface sediments, corresponding to the period after the year 2000. The detectable levels in recent sediments and the lack of a clear decreasing trend on PCB concentrations in the majority of the sediment cores can be a result of several factors, such as emissions from current sources and late cessation of production/usage of PCBs in some countries. In addition, previous studies have shown that the dynamics of changes of the glacier barriers can affect the concentrations and represent a source of organochlorine contaminants to polar marine ecosystems. The similar congener composition and the prevalence of low-chlorinated PCBs indicate same source of PCBs and confirms long-range transport is the most likely source of PCBs to the Antarctic environment. In addition, the presence of some high-chlorinated PCBs points out to a minor influence of local input sources, especially in the sediment core collected close to the Brazilian Station Comandante Ferraz. This study provides valuable information concerning the contamination status of the Antarctic continent, confirming the increasing impact of anthropic pressures and long-range transport of pollutants in remote environments.

## MO266

### **Influence of soil organic matter on the PAHs accumulation in the top layer of agricultural land of different anthropopressure**

A. Klimkowicz-Pawlas, Institute of Soil Science and Plant Cultivation - State Research Institute / Department of Soil Science Erosion and Land Protection; B. Smreczak, Institute of Soil Science and Plant Cultivation / Department of Soil Science Erosion and Land Conservation; B. Maliszewska-Kordybach, Institute of Soil Science and Plant Cultivation - State Research Institute; A. Ukalska-Jaruga, Institute of Soil Science and Plant Cultivation - State Research Institute / Department of Soil Science Erosion and Land Protection

Information on the level of persistent organic pollutants (POPs) accumulation in soils, their inputs/outputs and fate is unsatisfactory. One of the most important POPs group includes polycyclic aromatic hydrocarbons (PAHs). PAHs incorporated into terrestrial environment may undergo many physicochemical and biological processes. The PAHs properties (the low water solubility and high sorption affinity to soil organic matter) may result in sequestration and ageing processes, which fosters their high persistence in the terrestrial environment. PAHs transformations are strongly linked to soil properties – particularly those relevant in the sorption/desorption processes. The literature data on the relationships between specific soil parameters and levels of PAHs are incoherent. The factor, which is generally considered to have significant impact on PAHs concentrations is soil organic matter (SOM) content. The aim of the study was to evaluate the links between the content and the quality of SOM and the levels of PAHs accumulation in agricultural soils as affected by different level of anthropopressure. The concentrations of 16PAHs were determined in the top layer of soils from two agriculture regions of similar soil types and different anthropopressure (long-term high exposure *versus* low exposure). Characteristic of organic matter covered determinations of different carbon forms (total carbon, organic carbon, black carbon and dissolved carbon) as the most active components critical for accumulation of those contaminants in soils. In the region of low anthropopressure the relationships between PAHs concentrations and the content of different forms of SOM were not observed. This may suggest different sources of pollution. For the contrary, in the region of high anthropopressure the concentrations of PAHs were significantly related to both the type and content of SOM. The strongest links were observed between high molecular weight PAHs and the black carbon content. The level of anthropopressure was very important factor affected PAHs/OM relationships. *The financial support from the National Science Centre grant No UMO-2011/03/B/ST10/05015 is kindly acknowledged.*

## MO267

### **Biodegradation of pesticides in soil under different environmental conditions**

A. Muskus, UFZ Center for Environmental Research / Department Umweltbiotechnologie; K.M. Nowak, RWTH Aachen University / Institute for Environmental Research Biology V; U. Hamer, WWU - University of Münster / Institute of Landscape Ecology; M. Kästner, Helmholtz centre for environmental research - UFZ / Department of Environmental Biotechnology

Anthropogenic organic chemicals like pesticides (2,4-Dichlorophenoxyacetic acid and Glyphosate) are deliberately released in major amounts to nearly all compartments of the environment. Soil as a complex matrix provide a wide variety of binding sites and are the major sinks for these compounds. Xenobiotics entering these complex systems may undergo various turnover processes. They can be degraded chemically (e.g. photolysis), biologically by microorganisms, volatilised leached to the groundwater, taken up by living organisms or immobilised. The biological degradation of organic contaminants in soil generally results in the formation of metabolites, microbial biomass, CO<sub>2</sub> and “bound” residues (non-available form). The extraction of these metabolites from soil allows the estimation of microbial activity; however, this activity could be modified thought the variation of physical, chemical or biological factors. Many studies have shown that parameters like the temperature, the organic matter content and the acidity of the soil are key factors to determinate the degradation rate of some organic contaminants and the way in which they are released into the environment. Nowadays, enhanced transformation of contaminants into “bound” residues (non-extractable form) has been proposed as an alternative remediation method for polluted soils. Nevertheless, this kind of residues may pose a potential risk for environment due to their chemical structure and possible remobilization under different conditions. Some part of these residues may be “biogenic” because microorganisms use the carbon and nitrogen from the pollutant to form their biomass components (fatty acids, amino acids) what can result in the overestimation of the risk of “bound” residues in soil.

## MO268

### **Comparing spatial variability of PCBs, PCDDs/Fs and metals in heavily contaminated farm soils in Brescia (Italy)**

A. Di Guardo, University of Insubria / Department of Science and High Technology; G. Raspa, La Sapienza University / Department of Chemical Engineering Materials and Environment; S. Borin, University of Milan / DeFENS; E. Zanardini, C. Morosini, University of Insubria / DSAT; S. Armiraglio, Municipality of Brescia / Museum of Natural Sciences; V. Sale, S. Anelli, P. Nastasio, ERSAF

The SIN Brescia Caffaro is a national priority polluted site located in Brescia, a city of about 200,000 inhabitants in northern Italy. The site originated from the activities of the former Caffaro s.p.a. chemical factory, the largest former PCB producer in Europe, which produced such chemicals for more than 50 years up to mid 80'. About 100 Ha of agricultural soils in the SIN Brescia Caffaro present a mixed contamination of halogenated Persistent Organic Pollutants (POPs, mostly - polychlorinated biphenyls, dioxins, furans) and heavy metals (Hg, As) in variable concentrations, often exceeding the safety values. Contamination by Polychlorinated biphenyls (PCBs) is of particular relevance, since they were classified as carcinogenic, are extremely persistent in the environment and bioaccumulate and biomagnify in the food web. The clean-up of this site is therefore a priority for local (Lombardy Region, Brescia municipality) and national authorities. Among the actions planned, a specific research program started in 2014, to test pilot bioremediation processes to be later applied to the entire agricultural area. Given the extension of the contaminated site the application of biologically-mediated techniques is among the sustainable choices available. The use of plants to extract and modify the pollutants (phytoremediation) together with root associated microbes to i) degrade organic pollutants or modify the heavy metals (rhizoremediation), or ii) stimulate plant growth (plant growth promotion, PGP) is a promising activity for the SIN Brescia Caffaro bioremediation. However, the field-scale application for POP bioremediation has nevertheless few preceding studies and in particular needs a multidisciplinary approach for the characterisation of remediation potential, and monitoring and modelling of the process. In this part of the research, the activities to characterize the patterns of historical contamination by atmospheric deposition as well as surface water transport and subsequent redistribution in space are reported with the aim to guide the following bioremediation. A three phase analytical campaign was started to identify the contaminants, basing on the historical factory production inventory in order to evaluate the spatial distribution (both horizontal and vertical) in three different areas and plan future actions. **Acknowledgements:** The project is funded by Lombardy Region, within the remediation activities of the SIN Brescia Caffaro.

## MO269

### **Impact of Diurnal Temperature Fluctuations on Soil-Atmosphere Exchange of POps**

Z. Bao, Department of Geosciences; C. Haberer, University of Tübingen / Department of Geosciences; U. Maier, Helmholtz Center for Environmental Research - UFZ / Department of Hydrogeology; P. Grathwohl, Uni Tübingen / Center of Applied Geosciences

p margin-bottom: 0.1in; direction: ltr; line-height: 120%; text-align: left; widows:

2; orphans: 2; In the long term soils generally act as sinks for airborne persistent organic pollutants (POPs), which were released into the environment by natural sources and anthropogenic activities. Diurnal temperature changes, however, may vary the source-sink function of soils for atmospheric pollutants. As a result, POPs cycle between soils and the atmosphere. In this study, we applied an extended version of the multicomponent reactive transport code MIN3P to model the short-term concentration evolution of gaseous pollutants in soils and the atmosphere over a time period of three days. Phenanthrene was chosen as representative chemical for many semi-volatile POPs. We assumed two systems: a closed system that neglects mass exchange of gaseous phenanthrene with the upper atmosphere, and an open system that allows mass exchange with the upper atmosphere. For each system, we modelled the concentration evolution of gaseous phenanthrene depending on temperature (day/night cycle, soil depth) and with respect to different heights of the atmospheric boundary layer. Phenanthrene was affected by photo-degradation in the atmosphere during daytime, and by biodegradation in the soil compartment at all times. We found that diurnal temperature changes in the topsoil cause concentration fluctuations of POPs in the atmosphere. Due to strong retardation of POPs in the soil compartment, the magnitude in concentration evolution in the soil depends on temperature change, regardless of the prevailing atmospheric conditions and the height of the atmospheric boundary layer. In contrast, in the atmosphere, the magnitude in concentration evolution is determined by the atmospheric conditions and the height of the atmospheric boundary layer. Moreover, a phase shift in peak concentration in the atmosphere with respect to the atmospheric temperature evolution was observed. Generally, diurnal temperature changes lead to a non-equilibrium state between soil and the atmosphere. The concentration gradient forming in the atmosphere can be taken as an index to identify the source-sink function of soils for airborne pollutants. Our model results can be applied to interpret the diurnal pattern for the concentration evolution of atmospheric pollutants. Also, the long-term environmental fate of POPs between soil and the atmosphere can be evaluated.

## MO270

### Past vs. recent sources of PCBs in Italy: an analysis of soil and air concentrations in four transects from a large remediation site

E. Terzaghi, University of Insubria (Como) / Departement of Science and High Technology; T. Mercurio, University of Insubria Como / Department of Science and High Technology; G. Raspa, La Sapienza University / Department of Chemical Engineering Materials and Environment; A. Di Guardo, University of Insubria / Department of Science and High Technology

PCBs are a family of 209 compounds (congeners) widely produced and used in many countries for many decades until their production was banned. PCBs, being highly persistent in the environment, tend to accumulate in the food chain, posing adverse effects to the human health and the environment. Even if measures were taken to reduce their release to the environment and their environmental levels experienced a substantial decrease, these compounds are still present in the environment and can be released from reservoir compartment or secondary sources, such as contaminated sites. The area of Brescia, a highly industrialized city in the Lombardy Region (Northern Italy) is characterized by the presence of a Site of National Interest (SIN) for remediation (SIN Brescia-Caffaro). Here, an industrial plant (Caffaro S.p.a.) produced PCBs for about 50 years (1930-1984) and its surrounding areas were found to be heavily contaminated with high concentrations in air, irrigation water and soils at mg/kg levels. The aim of the present study was to investigate the potential of the contaminated area in driving the PCB contamination in the surrounding areas and the current effects on air concentrations. Different sampling campaigns were organized to collect samples of soil and leaves along four  $\approx 100$  km transects that ran in NW, NE, SW and SE directions considering the production plant as starting point. 16 samples were collected for each transect at about 7 km distance. In each sample the following PCB congeners were determined employing GC-ECD: tri-PCB 28; tetra-PCB 52; penta-PCB 101, hexa-PCB 153, 138; hepta-PCB 180; Deca-PCB 209. The results of each transects were compared in order to evaluate the presence of a contamination gradient, that decrease with increasing distance from the point source. Moreover the fingerprints of the soil and leaf samples were compared to profiles of soils from the contaminated site in order to understand if the concentrations found in the transect samples could be attributed to the Brescia site. Geostatistics techniques were also employed to analyze the data produced in order to evaluate the gradients, also considering weathering phenomena which could have occurred in time altering the original PCB congener profiles. A number of simulations were also performed using a dynamic air-vegetation-soil model (SoilPlusVeg) in order to interpret the actual soil and leaf concentrations and predict the order of magnitude of fluxes.

## MO271

### Evaluation of models for gas-particle partitioning of polycyclic aromatic hydrocarbons in background air in central Europe

P. Shahpoury, Max Planck Institute for Chemistry / Multiphase Chemistry; G. Lammel, Masaryk University; A. Holubová Šmejkalová, Czech Hydrometeorological Institute; J. Klanová, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; L. Landlová, P. Pribylová, Masaryk University; M. Váňa, Czech Hydrometeorological Institute Gas-particle partitioning is an important mechanism, which affects the transport and fate of semi-volatile organic compounds (SOCs). The preferential partitioning

of SOCs in the atmosphere depends on parameters such as the compound's molecular structure as well as particulate matter (PM) physical and chemical properties, and can be explained by various empirical and theoretical models. These include, but not limited to, Junge-Pankow (JP), Harner-Bidleman (HB), Lohmann-Lammel (LL), and poly-parameter linear free energy relationship (ppLFER) models. To explain the SOC partitioning, each model considers one or more of the compound's physico-chemical properties or PM characteristics. Despite the past efforts in determining the most appropriate model, discrepancies remain, as each model neglects certain intermolecular interactions. The aim of the present research was to determine what model better predicts the gas-particle partitioning behavior of polycyclic aromatic hydrocarbons (PAHs) in non-urban environments. To this end, 162 air samples (gas and particulate phase) were collected from Košetice observatory, a background site located in central Europe.  $\Sigma$  PAH concentrations in gas and particulate phase ranged from 0.6 to 138.6 (mean  $\pm$  standard deviation:  $11.3 \pm 15.7$  ng m<sup>-3</sup> and 0.1 to 189.3 ( $9.3 \pm 21.2$ ) ng m<sup>-3</sup>, respectively. Median particulate mass fractions for individual PAHs ranged from 0.01 to 0.99. Significant negative correlation was found between the particulate mass fractions and near-ground temperature at the site, highlighting the effect of temperature on SOC partitioning behavior. Initial results showed that HB and LL models are overall better in predicting PAH gas-particle partitioning; however, ppLFER could do a more accurate prediction for some individual congeners.

**Keywords:** semi-volatile organic compounds, polycyclic aromatic hydrocarbons.

## MO272

### Musk fragrances, among other organic molecular tracer compounds, in urban in- and outdoor atmospheric particulate matter.

B.L. van Drooge; J.O. Grimalt, Environmental Chemistry

This work presents the analysis of musk fragrances, among other organic molecular tracer compounds in atmospheric particulate matter (PM) samples collected at indoor and outdoor site in the urban area of Barcelona, including bars, subway platform, class rooms, playgrounds, road sites and urban parks. PM samples were collected on quartz microfiber filters by means of a high volume sampler and analysed following a described procedure. Galaxolide, tonalide and methyl-dihydrojasmonate were detected in the samples, among other organic compounds, including toxic compounds, such as PAH, but also source-specific compounds, such as those from traffic, tobacco smoke, wood burning, plastics and dust. Indoor environments exhibit highest concentrations of musk fragrances (in ng/m<sup>3</sup> to  $\mu$ g/m<sup>3</sup> range), and were often correlated with other 'urban-life-style' compounds, such as nicotine, from cigarette smoke, hopanes from traffic, or plasticizers from furniture and building material. Outdoor levels were two orders of magnitude lower in urban background sites, such as urban parks and playgrounds, while similar-to-indoor levels were detected in outdoor air busy street site in the urban center.

## MO273

### Presence of persistent organic pollutants in urban air: gas-particle partitioning

B. Barbas, CIEMAT; A. de la Torre, Environmental; P. Sanz, I. Navarro, M. Martínez, B. Artíñano, CIEMAT

Persistent Organic Pollutants (POPs), and emerging pollutants as flame retardants, are some of the wide extent of dangerous chemicals which can be found in the ambient air. They are present in the gas phase and also adsorbed on the suspended particulate matter, depending on ambient temperature and the physico-chemical properties of the pollutant. Due to their toxic, bio-accumulative and persistent characteristics these chemicals are matter of great concern for human health and natural ecosystems. However there are several data gaps related to their fractionation in ambient air. Therefore improving our knowledge of POPs in this matrix remains a challenge. The aim of this study was to evaluate the presence of several POPs in ambient air samples from the city of Madrid (Spain). Gas phase and airborne particulate matter were studied separately. Levels and fractionation of the following analytes were evaluated: polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs: the 2,3,7,8-substituted congeners), polychlorinated biphenyls (PCBs: dioxin-like PCBs and indicator PCBs), polybrominated diphenyl ethers (PBDEs: tri to deca-BDE) and Dechloranes (Dec 602, Dec 603, Dec 604, Dechlorane Plus (DP), Chlordane Plus (CP) and Mirex). Results revealed i-PCBs indicators as the major pollutants, followed in decreasing order by dl-PCBs, PBDEs, DP and finally by PCDD/Fs. PCBs were mainly related to gas phase, while PCDD/Fs, DP and PBDEs were associated with particulate matter. Mirex and Dec 602 were only occasionally detected, while Dec 603, Dec 604 and CP were not detected in any of the analyzed samples. The data obtained in this study concerning the partitioning and concentration profiles of the various analytes evaluated, represent an important advance in the study of the behaviour of these pollutants, resulting very interesting for research on human exposure to POPs.

## MO274

### Assessment of external routes for human exposure to phthalate plasticizers in indoor environment. A case study based on a Norwegian cohort of 61 adults in Oslo area.

G. Giovanoulis, IVL Swedish Environmental Research Institute Ltd / IVL Swedish Environmental Institute; J. Magner, A. Palm Cousins, IVL Swedish Environmental Research Institute Ltd; C.A. de Wit, Stockholm University / Applied

The extensive use of phthalate esters (PEs) as plastic additives in a wide range of consumer products has caused these contaminants to be ubiquitous in environments relevant for human exposure, and as a result also in human tissues. The main purpose of this study was to investigate the most relevant exposure pathways for human body burdens to phthalate plasticizers. The targeted substances were measured indoors in samples from 61 households and their inhabitants in the Oslo area. All participants within the cohort were adults and provided hand-wipe samples in order to establish potential dermal exposure of phthalates. Personal and stationary air samples (24h) were collected and analyzed to estimate the human exposure through inhalation. Oral exposure via ingestion of food was assessed by taking liquid and solid food samples from a 24h duplicate diet. Dust samples from elevated surfaces, floor dust and sieved dust from the vacuum cleaner bags were analyzed to monitor the exposure through skin contact, dust ingestion, ophthalmic and pulmonary phthalate exposure. Analyses were carried out on a gas chromatography/triple quadrupole mass spectrometry (GC/MS/MS) in multiple reaction monitoring (MRM) mode. Validated extraction methods for selective and sensitive determination of phthalates esters, minimizing the sample cross-contamination will be presented, together with the measured concentrations, as well as a comparison of the estimated body burdens of phthalate concentrations with defined acceptable tolerable daily intake values (TDI) for children and adults. This research is part of the 'Advanced Tools for Exposure Assessment and Biomonitoring' (A-TEAM) project within a Marie Curie Initial Training Network.

## MO275

### PAH in settled house dust in selected European countries

Y. Ma, School of Geography Earth Environmental Sciences; S.J. Harrad, Polycyclic aromatic hydrocarbons (PAH), a group of pollutants with reported adverse health impacts including cancer, are emitted from a wide range of combustion activities in indoor environments (e.g. cooking, heating, etc.). While human exposure to these chemicals via the diet and inhalation of indoor air has been widely studied, very little is known about exposure via contact with indoor dust present on surfaces such as floors, soft furnishings and tables etc. Thus, our study (by investigating around 400 samples from 40 UK homes plus 20 homes each from Finland, Czech Republic, Spain, and Greece) provides a valuable baseline evaluation of the range of exposure of European citizens to PAH via ingestion of indoor dust. We also examined potential putative sources of contamination with PAH in indoor dust. Our findings improve understanding of the PAH sources in settled house dust and inform strategies to reduce such contamination.

## MO276

### Dynamics of emerging and legacy contaminants in a tidal urban river

R. Lohmann, University of Rhode Island / Graduate School of Oceanography; M. Khairy, URI; M. Weinstein, New Jersey Institute of Technology  
The transfer of hydrophobic organic contaminants (HOCs) from sediments into aquatic biota is of global concern especially where human activities have resulted in highly elevated concentrations of pollutants in the ecosystem. We investigated the trophic transfer and biomagnification of HOCs in the oligohaline-fresh portion of the tidal Passaic River estuary, a tributary of the Hudson River Harbor complex, extending from the Dundee Dam (river km 29) to its entrance at Newark Bay, New Jersey, USA (river km 0). We deployed passive samplers in the overlying water column and used them to derive porewater concentrations and profiles of sedimentary HOCs. The following compound groups were targeted: polycyclic aromatic hydrocarbons (PAHs), organochlorine pesticides (OCPs), polybrominated diphenylethers (PBDEs), polychlorinated biphenyls (PCBs), polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs), as well as the currently used pyrethroids. Results for PAHs, PCBs and PCDD/Fs were recently published (Khairy et al., 2014). For PBDEs, only five PBDE congeners (BDE-30, BDE-47, BDE-100, BDE-154 and BDE-153) showed a significant biomagnification along the food web. For these congeners, concentrations significantly increased with the increase in the trophic level ( $p < 0.05$ ). Trophic magnification factors (TMFs) for the congeners with statistical significant relationship ranged from 2 (BDE-153) to 3.30 (BDE-47). For all the other congeners, the relation was statistically insignificant ( $p > 0.05$ ), and the TMF ranged from 1 (BDE-15 to 2 (BDE-99).

## MO277

### Use of macroinvertebrates and fish to determine priority substances concentrations in Walloon Rivers: biota monitoring and caging techniques.

D. Leroy, ISSeP / Ecotoxicology; P. Libert, Service Public de Wallonie SPW; A. Galloy, A. Joris, I. Hardy, ISSeP; Y. Marneffe, Inst. Scientific de Service Public / Ecotoxicology Department  
The European Water Framework Directive (WFD) aims to achieve and ensure a good quality status of water in each Member State by 2015. Most of the Environmental Quality Standards (EQSS) are defined for water itself. However standards have also been set in biota for some substances (Directive 2008/105/EC). This is the case of mercury, hexachlorobenzene (HCB) and hexachlorobutadiene (HCBd). Moreover the recent Directive 2013/39/EC adds other substances to that list, including PAHs (benzo-a-pyrene and fluoranthene). To answer these recommendations we developed methods to measure the concentration of these pollutants in freshwater biota sampled in Walloon Rivers. Four fish species (*Leuciscus cephalus*, *Abramis brama*, *Cottus gobio* and *Barbatula barbatula*) were

chosen for their interest as sentinel species. These fish were analyzed for mercury, HCB and HCBd. Moreover, benthic macroinvertebrates (crustaceans and/or molluscs) were sampled and analyzed for PAHs. Thirty four sites distributed in 3 hydrographic districts and corresponding to sites of the surveillance monitoring network defined for the WFD were sampled for these organisms in 2013-2014. Differences in contamination between the studied sites and between the different fish species are discussed. When possible, comparisons with precedent results obtained during the study made in 2010-2012 in the same rivers are made. In addition to these thirty-four sites, fifteen others were visited without finding the sentinel species and no results could be obtained. To overcome this problem, a caging technique with the crustacean *Gammarus pulex* is currently being developed. A preliminary experiment was conducted. Gammarids coming from a clean site were acclimatized for two weeks in the laboratory and caged in one reference site and one polluted site. The experiment lasted one or two weeks to establish the time to equilibrium. Benzo-a-pyrene and fluoranthene were searched in these organisms after caging. Results are discussed.

## MO278

### Very low levels of POPs in tern eggs from a remote island in the Indian Ocean

H. Bouwman, North-West University / Environmental Sciences and Development; R. Choong Kwet Iyve, University of Mauritius / Chemistry; H. Kylin, Linköping University / Department of Thematic Studies Environmental Change; A. Polder, The Norwegian School of Veterinary Sciences

The Indian Ocean is the world's third largest and relatively unknown regarding POPs in biota. Previously, we reported on POPs in tern eggs from Rodrigues 450 km east of Mauritius, an island populated by about 35 000 people. The levels were very low. We have now analysed eggs from terns on another Mascarene island, St Brandon's Rock (SBR), located 400 km north of Mauritius, and with a transient population of about 25 fishermen. Ten eggs each of the Fairy Tern (FT, *Gygis alba*, also known as White Tern), Sooty Tern (ST; *Sterna fuscata*), and the Common Noddy, also known as the Brown Noddy (CN; *Anous stolidus*) were collected from SBR. Here, we report on the initial analyses of four eggs from each species in ng/g wet mass (wm). FT eggs were not collected on Rodrigues, as they occurred in low numbers. Mean  $\Sigma$ PCBs was 1.0 (FT), 1.1 (ST) and 1.0 (CN) ng/g wm. This is half the concentrations measured in ST and CN from Rodrigues (2.6 and 2.2 ng/g wm) respectively. For  $\Sigma$ DDT, the egg concentrations were 0.75 (FT), 0.95 (ST), and 1.0 (CN) ng/g wm, compared with 3.1 (ST) and 1.9 (CN) ng/g wm from Rodrigues, also half. The concentrations for HCB were 0.75 (FT), 0.33 (ST) and 0.52 (CN) ng/g wm, compared to slightly lower concentrations in eggs from Rodrigues; 0.41 (ST) and 0.39 (CN) ng/g wm, respectively. Mirex concentrations were 0.73 (FT), 0.43 (ST), and 0.65 (CN) ng/g wm in eggs from SBR, while ST and CN from Rodrigues had 0.69 and 0.96 ng/g wm, respectively. For  $\Sigma$ chlordanes,  $\Sigma$ toxaphenes and BFRs, the concentrations were also low, and comparable between the tern species and the islands, with Rodrigues eggs slightly higher in most respects. One ST egg from SBR had HBCD at 0.61 ng/g wm (the other eggs were below detection limit), possibly indicating ingestion of plastic. Provisionally, it can be concluded that although there were minor differences in concentrations between the species, the analyses of eggs from only one species and one island will provide enough information for regular monitoring in this region. It should be kept in mind that even though the contaminant levels were in all respects low, industrialisation, conflict, development on the periphery, commercial exploitation of the coasts and oceans, and long-range transport of pollutants, including facilitation by marine debris, is likely to add to chemical pressure in this region. Monitoring the changes in contamination from a background site will be informative.

## MO279

### Accumulation of the polyfluorinated ether sulfonate F53-B in food items from two provinces in China

R. Vestergren, Stockholm University / Analytical Environmental Chemistry; H. Zhang, Research Center for EcoEnvironmental Sciences Chinese Academy of Sciences; T. Wang, MTM Research Center; D. Herzke, NILU - Norwegian Institute for Air Research / MILK; G. Jiang, Perfluoroalkyl substances (PFASs) have received considerable attention from scientists and regulators over the past decade due to their persistence, bioaccumulation potential and toxicity. The concerns regarding adverse environmental and human health effects related to PFASs have initiated a transition to replace long-chain PFASs with short-chain alternatives and replacements with ether bonds in the perfluoroalkyl chain. The rationale for favoring these replacements is based on the decreasing bioaccumulation factor or reduced environmental persistence. Yet, our understanding of PFAS replacements remain rather limited due to the lack of empirical data. In this study, we analyzed market food items from the Hubei province (n=124) and the Zhejiang province (n=104) for the polyfluorinated ether sulfonate (F53-B) which have been used as replacement for perfluorooctanoic sulfonic acid (PFOS) in China. An analytical method employing HPLC-MS/MS was developed to quantify F53-B in food items that previously have been analyzed for perfluoroalkyl acids. Overall, F53-B displayed a similar distribution as PFOS with the highest concentrations being observed food samples of animal origin and particularly in liver samples from pig and duck (ranging up to 2.3 ng/g w wt). Collectively, these findings corroborate *in silico* estimations suggesting that F53-B is a highly persistent and bioaccumulative substance and underscores the need for human biomonitoring studies.

## MO280

### Risk assessment of dermal exposure to chemicals through direct contact with clothing

J. Rovira, Departament d'Enginyeria Química; M. Nadal, University Rovira i Virgili / Laboratory of Toxicology and Environmental Health; M. Mallen, CSIC Spanish National Research Council / Institute of Environmental Assessment and Water Research; E. Eljarrat, IDAEA-CSIC / Department of Environmental Chemistry; D. Barcelo, IQAB-CSIC / Institute for Environmental Assessment and Water Research; J. Domingo, Universitat Rovira i Virgili / Laboratory of Toxicology and Environmental Health

The current textile market is full of products made by using a number of fabric materials, such as cotton, silk, wool polyester, viscose, spandex or polyamide, among other. In addition, some of these products also contain chemical additives, which are mainly incorporated in the finishing processes. Typical chemical additives are flame retardants, dyes and mordants, antimicrobials, softeners, ultraviolet protectors, water or oil repellents, insect resist, and mite protection finishers. This high amount and variety of chemicals contained in clothing might lead to a potential risk for the human health, especially for those clothes in direct contact with skin. It is well known that some metals, such as cobalt (Co), chromium (Cr), copper (Cu), and nickel (Ni), are skin sensitizers. In addition, other elements (e.g. arsenic, cadmium, mercury and lead) are highly toxic, exhibiting adverse health effects following a chronic exposure. Other organic pollutants, such as polybrominated diphenyl ethers (PBDE), are easily absorbed through the skin, reaching rapidly the bloodstream. This study was aimed at evaluating the human exposure to chemical pollutants through dermal contact to clothes in direct contact with skin (T-shirts, blouses, baby pyjamas, and bodies). Thirty-one individual clothing items were randomly purchased in four stores types (sport stores, chain stores, brand stores, and hypermarkets) in Catalonia (Spain). Clothes were made of different materials (cotton, polyamide, polyester, spandex, and viscose), colours (coloured and white), and brands. It is noteworthy the high levels of Cr in a polyamide dark clothes (605 mg/kg), Sb in polyester materials (up to 52-204 mg/kg), and Cu in some green cotton fabrics (280 mg/kg). The concentrations of substances found in textiles were used to calculate the exposure and human health risks for three groups of population: men, women, and one-year-old children. The dermal exposure to each one of those chemicals was compared with the intake through other routes.

## MO281

### Assessing the implications of export of waste electrical and electronic equipment (WEEE) towards developing regions: PCBs as a case study

K. Breivik, Norwegian Inst. for Air Research; J.M. Armitage, University of Toronto - Scarborough / Department of Physical and Environmental Sciences; F. Wania, University of Toronto at Scarborough / Department of Physical and Environmental Sciences; T.H. Nøst; A.J. Sweetman, K.C. Jones, Lancaster University / Lancaster Environment Centre

Densely populated areas (i.e., urban centres) are largely responsible for the generation of waste electrical and electronic equipment (WEEE/e-waste) in both industrialized and developing nations. The potential emission of both emerging and legacy contaminants present in WEEE (e.g., organic chemicals, metals) during handling and disposal of these products is a concern with impacts at local to global scale. Over the last decade, a number of studies have reported surprisingly high levels of polychlorinated biphenyls (PCBs) within or outside developing regions in Asia and West Africa. As PCBs were never extensively produced nor used in these regions, this previously led us to hypothesize that there might be a potential shift in global source regions, attributed to exports of wastes containing PCBs towards developing regions. If true, it follows that global emissions, transport and exposures can neither be completely estimated, nor fully rationalized, without considering emissions caused by the global flows of relevant wastes. In this study, we have therefore updated an existing global historical PCB emission inventory to account for exports of wastes, using global flows of e-waste as a proxy for wastes containing PCBs. Our revised emission scenarios indicate that (i) global emissions may significantly increase as result of exports of wastes in comparison to reference scenario (i.e. no exports) and (ii) different long-term temporal trends in emissions within former production and use regions versus developing regions implicated as importers of wastes are expected. The second goal of this study is to simulate the global fate and transport of PCBs using emission scenarios that include potential contributions linked to the export of e-waste and compare model output to the baseline scenario (no export). To accomplish this task, we use the BETR Global 2.0 model, a publicly available fate/transport model, which represents the globe as 288 interconnected, multi-compartment zones at a spatial resolution of 15 x 15 degrees. Simulations are conducted for the period 1930–2100 and output from various locations and time periods are interpreted in the context of available monitoring data. Model output is also used to assess the potential implications of transboundary movement of wastes containing PCBs for human exposure in developing regions. However, significant uncertainties in these global emission scenarios still persist.

## MO282

### Polychlorinated biphenyls (PCBs) in transformer oils: Environmental Risk Assessment Challenges in Colombia

W. Ocampo-Duque, R. Sarria, Pontificia Universidad Javeriana Cali / Industrial

Engineering; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering

Polychlorinated biphenyls (PCBs) are widely used in a variety of applications mainly including dielectric fluids in transformers. These substances have been recognized by the scientific community as a threat to the environment and human health. In Colombia, according to very recent environmental regulations these substances must be eliminated from the electrical sector. Consequently, a project funded by UNEP is being carried to promote best technologies in the country for PCBs management. Therefore, some environmental research laboratories, as ours, are developing analytical methods for PCBs detection in diverse local environmental matrices. The final aim is to study the human health and environmental risks posed by these substances in the Colombian environment. PCBs were analyzed by GC/ECD from samples of transformer oils collected in cities from Colombia. A chromatograph Shimadzu GC-2010 Plus, donated by Spanish Government, equipped with a <sup>63</sup>Ni ECD was used for analytical measurements. A column HP-5MS was used and samples were injected in split mode. Injection and ECD temperatures were set to 250 and 320 °C. The oven temperatures were conveniently programmed. Ar-CH<sub>4</sub> was used as carrier gas at 1.23 mL/min. Calibration curves from 0.01 to 1 ppm were built to mix of Aroclors. The validation method was carried out following ISO 17025 methodology for QA/QC and Accreditation purposes. Practical quantification limits, and mean recoveries (>66%) were set up. Specificity, linearity, accuracy, repeatability and precision were good evaluated to the method. The analytical results showed that PCBs in the transformer oils may be identified for Aroclors 1242, 1254 and 1260. Real samples were analyzed and PCBs concentrations in transformer oils were between not detected and 328.25 ppm. PCBs concentrations of some samples exceed the 50 ppm national accepted limit. The analytical survey results suggested the presence of PCBs in the Colombian environment, and further research is required to estimate environmental risks due to the presence of such pollutants in Colombian cities.

### Aquatic Nanotoxicology: from Freshwater to Seawater - overcoming the difficulties of standard toxicity tests and the implications for higher tier toxicity testing (P)

## MO283

### Size-dependent toxicity of silver nanospheres and nanowires to *Glyptotendipes tokunagai*

J. Jung, Korea University / Environmental Science and Ecological Engineering; S. Choi; T. Shim, Korea University / Environmental Science and Ecological Engineering; J. Park, Korea Institute of Toxicology / Center for Environmental Biotechnology

Toxicity of silver nanomaterials (Ag NMs) is largely influenced by coating material, surface charge, size and shape. This study comparatively evaluated physicochemical properties of spherical silver nanoparticles (Ag NSs; diameter = 50, 100, 150 nm) and cylindrical silver nanowires (Ag NWs; length = 10, 20 μm) coated with polyvinylpyrrolidone (PVP) and their acute toxicity and bioconcentration to *Glyptotendipes tokunagai*. The aggregation and dissolution of the Ag NMs increased with increasing exposure time, which was more significant for Ag NWs compared with Ag NSs. In all experimental conditions, however, the dissolved concentrations of Ag ions from Ag NMs was lower than LC<sub>50</sub> value for AgNO<sub>3</sub> (3.51 mg L<sup>-1</sup>). This indicates that the toxicity of Ag NMs to *G. tokunagai* does not result from dissolved ions. Acute toxicity (48 h) of Ag NPs was the highest for the smallest particles (50 m Ag NSs), whereas bioaccumulation (48 h) was the highest in the largest particles (150 m Ag NSs). According to the result of bioaccumulation of Ag NSs as a function of time, bigger particles were found to be more quickly excreted. This indicates that smaller Ag NSs stay longer in the body of *G. tokunagai*, resulting in higher toxicity than larger Ag NPs. On the other hand, both acute toxicity and bioaccumulation of Ag NWs appeared higher with increasing length. The uptake of Ag NWs continuously increased within 48 h and the longer Ag NWs were absorbed more rapidly. In addition, acute toxicity of Ag NWs to *G. tokunagai* (20 μm, LC<sub>50</sub> = 81.646 mg L<sup>-1</sup>) was found to be higher than that of Ag NPs (50 nm, LC<sub>50</sub> = 101.181 mg L<sup>-1</sup>). This study suggests that the shape and size of Ag NMs have a significant effect on their acute toxicity to *G. tokunagai*. Considering that *G. tokunagai*, deposit feeder, recognizes larger particles as food more easily and eats them, this should be further studied relating to bioaccumulation and toxicity of Ag NMs.

## MO284

### Does Silver Nanocolloid Disturb Medaka's Defense to Pathogenic Bacteria?

C. Kataoka, Toyo University / Life Sciences; S. Izumi, Tokai University; M. Fujita, Toyo University; S. Kashiwada, Toyo University / Department of Life Sciences

Silver nanomaterials including silver nanocolloid (SNC) have been utilized mainly as antibacterial products. Ecological risks posed by silver nanomaterials has been internationally concerned because the amount of production and usage of nanomaterials are increasing. However, there are little information of the specific toxic mechanisms. From microarray data using embryos and post-hatch larvae of medaka exposed to SNC, immune-relative genes were significantly responded. Hence, we have a hypothesis that disturbed immune responses may lead to reducing of biological defense to pathogenic bacteria in medaka. To investigate exposure

effects of SNC on medaka immune system, medaka embryos (developmental stages 11, 21, and 30) were exposed to 0.05 mg/L of SNC until hatching. Post-hatched larvae (stage 40) were also exposed for 7 days. Exposed eggs and larvae were subjected to qRT-PCR analyses of immune relative genes, such as nuclear factor kappa B (NFκB) p105 and NFκB p100, and tumor necrosis factor  $\alpha$  (TNF $\alpha$ ). In case of exposure from stage 11, NFκB p105 was suppressed, NFκB p100 and TNF $\alpha$  were enhanced compared with control. In exposure from stage 21, the three gene expressions were all enhanced. From stage 30 and 40, the three gene expressions were all suppressed. Eggs exposed from stage 21 were subjected to whole mount *in situ* hybridization on day 3. Enhanced NFκB p105, NFκB p100, and TNF $\alpha$  genes were detected in pectoral fins and head; in liver and intestinal tract; and in ducts of Cuvier and heart, respectively. On the other hand, suppressed gene expressions of NFκB p105 were measured in exposure from stage 11. Activities of p50, a metabolite of NFκB p105, and was decreased slightly by SNC exposure. It is well known that toll-like receptors (TLRs) signalings regulate these three factors and TLRs detect pathogen-associated molecular pattern. These findings strongly suggest that SNC can disturb immune responses and damage biological defenses to pathogenic bacteria in medaka.

## MO285

### Effects of different sizes of silver nanoparticles on *Gammarus fossarum* (Crustacea, Amphipoda): Link between physiological and behavioural responses.

K. Mehennaoui, Luxembourg Institute of Science and Technology / Environment Research and Innovation; A. Georgantzopoulou, Environment and AgroBiotechnologies; S. Cambier, Centre de Recherche Public Gabriel Lippmann / Environment and AgroBiotechnologies; M. Garaud, Laboratory LIEC - CNRS UMR 7360 - UdL / CNRS UMR; J. Andrei, CNRS UMR 7360 / LIEC CNRS UMR; V. Felten, LIEC; T. Serchi, S. Contal, J. Ziebel, Luxembourgish Institute of Science and Technology; C. Guignard, Centre de recherche public Gabriel Lippmann; Y.L. Balachandran, Bharathiar University; S. Pain-Devin, Université de Lorraine - UL / LIEC CNRS UMR; L. Giembérini, Laboratoire Interdisciplinaire des Environnements Continentaux; A.C. Gutleb, Luxembourgish Institute of Science and Technology / Environment and AgroBiotechnologies

Silver nanoparticles (AgNPs) are widely used in daily life products for their antibacterial properties. Their increased and non-regulated use will lead to their release in aquatic environments. The aim of this study was to investigate the toxic effects of different sizes of “conventionally synthesized” (AgNPs 20 and 200) and “green synthesized” (AgNPs 23 and 27) particles on survival, physiological and behaviour responses of *Gammarus fossarum*. *G. fossarum* was selected for its wide distribution, ease of sampling and identification, sensitivity to many pollutants in addition to its major functional role in freshwater ecosystems. A first experiment aimed at determining the toxicity of AgNPs and Ag<sup>+</sup>, and to compare the sensitivity of two different populations of *G. fossarum* (*Gf1* and *Gf2*). The results showed that, after 72h exposure, Ag<sup>+</sup> was the most toxic form for both populations, followed by AgNPs 23, AgNPs 27 and AgNPs 20. No mortality was recorded for animals exposed to AgNPs 200. *Gf2* appeared to be the most sensitive population and was selected for the second experiment. Thus, *Gf2* individuals were exposed during 72h to 1 and 3 μg.L<sup>-1</sup> of Ag<sup>+</sup>, AgNPs 20, AgNPs 23 and AgNPs 27. The selected concentrations represented the EC5 and EC20 of AgNPs 23. Effects on survival, osmoregulation, antioxidant responses, defence mechanisms, cellular damage, energy reserves and behaviour were investigated. Ag<sup>+</sup> and AgNPs 23 led to a significant decrease in survival rates, osmoregulation and locomotor activity. The other targeted responses were not impacted. AgNPs 20 and AgNPs 27 had no effects on any of the studied responses. Soluble Ag from AgNPs in exposure medium were assessed using ICP-MS. The amount of soluble Ag was under the limit of quantification. The results showed that Ag<sup>+</sup> and AgNPs 23 altered osmoregulation which appeared to be an effective marker as it indicates the physiological health status of *G. fossarum*. Locomotor activity, which was the most impacted response, reflects the potential effects of AgNPs 23 at the population level. In addition to highlighting the potential of *G. fossarum* as a model organism in nanotoxicology, this study illustrates that Ag<sup>+</sup> and AgNPs 23 act at very low concentrations and their toxicity is highly dependent on their physico-chemical properties. Indeed, in addition to the size, this study demonstrated the importance of the methods of synthesis in nano-ecotoxicology.

## MO286

### Toxicity of silver nanoparticles in *Chironomus riparius* cultured in field contaminated sediments

s. Lee, S. Choi, University of Seoul; J. Choi, School of Environmental Engineering Graduate School of Energy and Environmental system Engineering

Sediments are complex and heterogeneous media and a potential sink of contaminants in aquatic environment. Therefore, to understand fate and toxicity of aquatic contaminants in a real aquatic system, it is important to understand the interaction between contaminants and sediment and their role in sediment dwelling organisms. In this study, to understand fate and toxicity of silver nanoparticles (AgNPs) in a real aquatic environment, we evaluated toxicity of AgNPs in a sediment dwelling organism, *Chironomus riparius* in contaminated field sediments which were sampled from surface stream with industrial as well as natural contaminants. Ecophysiological response of *Chironomus* cultured in polluted field sediments were first compared with those cultured in sand, a media commonly used

for *Chironomus* lab culture. AgNPs were then exposed to *Chironomus* cultured in field contaminated sediment, as well as to those cultured in lab sand and their acute and chronic ecotoxicity were compared. The results showed how natural organic matters, as well as, contaminants present in the field sediments, affect toxicity of AgNPs to *C. riparius*, which will contribute to understand the toxicity of AgNPs in a real aquatic environment. This study will also enlarge our understanding on species adaptation process in natural environment. Acknowledgement : This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education, Science and Technology (2012R1A1A2041679).

## MO287

### Determination of silver in hemolymph of the marine amphipod (*Parhyale hawaiiensis*) as a tool to understand silver nanoparticles diet exposure

M. Vannuci-Silva, UNICAMP; M.C. Artal, University of Sao Paulo - USP / Toxicology and Toxicology analysis; G.d. Pessoa, S. Oliveira, M.A. Arruda, S. Cadore, State University of Campinas - UNICAMP; G.d. Umbuzeiro, FACULTY OF TECHNOLOGY - UNICAMP / LEAL

Silver has been largely incorporated in the nanomaterials and its release into the environment is becoming an environmental concern. The evaluation of silver nanoparticles (AgNP) exposure in organisms via diet is interesting because they tend to agglomerate and sink in the aquatic environment. Therefore, for bottom feeding organisms, like the marine amphipod *Parhyale hawaiiensis*, diet will be the most important route of exposure. The aim of this work was to evaluate a method to understand the exposure of AgNP through feeding in *P. hawaiiensis*. We will provide food with AgNP for adult organisms (0.5-1 mm). Determination of the internal dose of total Ag in the organism, as an exposure measure, will be used and hemolymph analysis was chosen for this purpose. Preliminary experiments were performed, aiming to develop methods for total Ag determination in hemolymph of adult animals that were exposed to different concentrations of AgNO<sub>3</sub> in seawater. After 24h-exposure, hemolymph was collected and pooled samples of 10 organisms were made. Two analytical techniques were used for total Ag determination: Inductively Coupled Plasma Optical Emission Spectrometry (ICP OES) and Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Copper concentration in the hemolymph was also determined and used as an internal standard for method validation because this metal can be found on hemocyanin of amphipods and its concentration is not expected to vary. Limits of detection for Ag using ICP OES and ICP-MS were 0.41 and 0.0034 μg L<sup>-1</sup>, respectively. Ag concentration in hemolymph ranged from 4.26 to 94.4 and from 1.30 to 71.6 by ICP OES and ICP-MS determinations, respectively. Using both techniques, Ag concentrations in the hemolymph increased with the increase of Ag concentration in the water. However, ICP-MS showed more satisfactory results than the ICP-OES for our purpose, due to the higher sensitivity of the first technique, especially for Ag determinations. ICP-MS also seems to show a better stability for the determination of copper concentrations. Thus, determinations by ICP-MS will be used to determine Ag and Cu concentrations in hemolymph of *P. hawaiiensis* exposed to AgNP through feeding as a next step. We anticipate that measurement of metals in hemolymph of such small organisms can be an interesting tool both in laboratory as well as field studies to better determine the real exposure of those contaminants in the aquatic environment.

## MO288

### Ecotoxicity of silver nanoparticles to marine planktonic communities at environmentally relevant concentrations: A microcosm and mesocosm approach

I. Kalantzi, Hellenic Centre for Marine Research / Institute of Oceanography; A. Tsiola, Institute of Oceanography; C. Tsangaris, A. Callol Junyer, M. Kagiorgi, Hellenic Centre for Marine Research / Institute of Oceanography; K. Knauer, Federal Office for Agriculture / Section Plant Protection Products; C. Toncelli, HCMR / Institute of Oceanography; K. Mylona, Hellenic Centre for Marine Research / Institute of Oceanography; S. Pergantis, University of Crete / Department of Chemistry; V. Pitta, Hellenic Centre for Marine Research / Institute of Oceanography; M. Tsapakis, Institute of Oceanography

Silver nanoparticles are frequently used in many consumer products because of their antibacterial and antifungal properties. The inevitable release of nanosilver products can result in the contamination of aquatic ecosystems. Planktonic communities are of great environmental importance because they produce and transfer energy in the food web and they play a key role in nutrient recycling (e.g. via grazing and release of organic material). Planktonic organisms such as bacteria interact strongly with their ambient environment and are expected to be affected by exposure to silver nanoparticles, thereby potentially constituting the most endangered organisms in the aquatic environment. Silver nanoparticles may cause toxicity via multiple mechanisms such as inhibition of respiratory enzymes and induction of oxidative stress upon generation of reactive oxygen species (ROS) as well as inhibition of photosynthesis due to the accumulation of nanoparticles on the surface of photosynthetic organisms. The behavior of silver nanoparticles in the environment is complex and can differ from the respective behavior under standardized laboratory conditions, in terms of both abiotic and biotic factors and interactions with the surrounding environment. To date, most of the eco-toxicity studies with silver nanoparticles have been carried out mainly in freshwater systems, at much higher concentrations and over much shorter time periods than

would ever be expected to occur in the future in a natural aquatic ecosystem. In this study, microcosm and mesocosm nanotoxicology studies in the marine environment were conducted focusing on realistic exposure conditions in the ng/L range. An aqueous suspension of branched poly(ethylenimine) capped silver nanoparticles (AgNPs) of 60 nm size was used for this AgNPs exposure study. Preliminary analysis revealed that, in the presence of silver nanoparticles, there was a decrease in enzymatic antioxidant activity, photosynthetic activity and chlorophyll concentration and an increase in intracellular ROS formation and lipids peroxidation in planktonic communities which indicate that the organisms possibly underwent oxidative stress.

## MO289

### Size of agglomerates like a major contribution to silver nanoparticles aquatic toxicity

J. Oprsal, University of Pardubice / Institute of Environmental and Chemical Engineering; M. Pouzar, University of Pardubice / Environmental and Chemical Engineering; P. Knotek, University of Pardubice; L. Blaha, Masaryk University, Faculty of Science / Faculty of Science RECETOX; P. Plodikova, Research Institute of Organic Synthesis

One of the general problems in aquatic toxicity testing of nanoparticles is their fast agglomeration and subsequent sedimentation, which limits the use of "standardized" protocols in the assessment of particle toxicity. The present work suggests an original approach enabling to control the maximal average size of nanoparticle agglomerates during the aquatic toxicity test. The modification is based on the variable frequency of exposure media exchange, i.e. frequent exchanges of the tested colloid depending on the nanoparticle concentration levels. The method was applied for the short-term toxicity test with the embryo and sac-fry stages of common carp (*Cyprinus carpio*). Toxicity of silver nanoparticles (AgNPs) with initial average hydrodynamic diameter ( $D_H$ ) of 40 nm was tested at four concentrations (5; 10; 25 and 50 mM). Based on the chemistry and behavior of AgNPs in the culture medium, two levels of maximal average sizes of agglomerates (200 and 400 nm) were selected, and exchanges of media were employed to control for formation of these types of agglomerates. The comparisons with the semi-static fish embryotoxicity test, where the formation of agglomerates had not been controlled, indicate that different sizes of agglomerates influence different stages of embryo development. Interestingly, larger agglomerates rather than original nanoparticle colloids were responsible for the most severe effects, which could be mechanistically explained by other observations during the study. Details on the novel testing approach and its advantages and limitations will be discussed.

## MO290

### Effect of silver nanowires on embryonic development of *Daphnia galeata*

C. Rongxue, Konkuk University; Y. An, Konkuk University / Department of Environmental Science

Silver nanomaterials were widely used in various nanoproducts. This study investigated the effect of silver nanowires (AgNWs) using water flea *Daphnia galeata* embryo. Two types of AgNWs tested were 10  $\mu$ m- and 20  $\mu$ m- AgNWs having different length. Stage two embryos were harvested from adult *Daphnia galeata* female which completed third reproductions, and the embryos were exposed to AgNWs for 72h. The development stage and mortality were measured every 24 hours for 72h. The developmental abnormalities measured were antennae, eye, rostrum, heart, carapace, post abdominal claw, malpighian tube, sensory bristles, and tail spine. The results show that the antennae and tail spin were the most sensitive to *D. galeata* embryonic organogenesis. The effect of effect on embryonic development with different lengths of AgNWs were negligible in the study.

## MO291

### Responses of antioxidant enzymes to nanoparticulate and ionic silver in aquatic microbes

D. Barros, Universidade do Minho / Centre of Molecular and Environmental Biology Department of Biology; A. Pradhan, University of Minho / Department of Biology; P.M. Santos, Universidade do Minho / Centre of Molecular and Environmental Biology CBMA Department of Biology; C. Pascoal, F. Cassio, University of Minho / Centre of Molecular and Environmental Biology (CBMA), Department of Biology

Silver nanoparticles (AgNPs) are among the most used nanoparticles and are likely to be released in significant amounts to aquatic environments. Due to their antimicrobial properties, it is relevant to examine whether AgNPs can pose a risk to aquatic microbes in natural ecosystems. Here, we investigated the effects of AgNPs (citrate-coated; 20 nm) on the growth and activity of antioxidant enzymes in i) two aquatic fungal strains of *Articulospora tetracladia*, one isolated from a non-polluted stream (AT72) and the other from a metal-polluted stream (AT61), and ii) the bacterial strain *Pseudomonas* sp. M1 (PsM1) isolated from a sediment sample in a metal-polluted stream. The activities of glutathione peroxidase (GPx), glutathione S-transferase (GST) and superoxide dismutase (SOD) were analyzed at AgNP concentrations inhibiting biomass production in 10% ( $EC_{10}$ ) and 20% ( $EC_{20}$ ) and the results were compared with those of ionic precursor ( $Ag^+$  in  $AgNO_3$ ). AT72 was the most sensitive strain to AgNPs, whereas PsM1 was the most tolerant one ( $EC_{20}$ : 7.5, 158.9 and 300  $\mu$ g  $L^{-1}$  for AT72, AT61 and PsM1, respectively). The activity of all tested enzymes increased after exposure to AgNPs and  $Ag^+$  in all

microorganisms. However, at similar stress level, the increase in all enzyme activities was higher in AT72 than in AT61 indicating higher oxidative stress in the strain from the non-polluted stream. The exposure to both stressors led to higher stimulation of GPx and SOD in PsM1, whereas SOD and GST responses were more pronounced in fungi. This suggests that the enzymatic defense mechanisms against both forms of silver might differ between bacteria and fungi.

\nFEDER-POFC-COMPETE and the Portuguese Foundation for Science and Technology supported this work (PIDDAC-Pest-OE/BIA/UI4050/2014, PTDC/AAC-AMB/121650/2010) and D. Barros (SFRH/BD/80407/2011).

## MO292

### Impacts of environmentally realistic silver nanoparticle exposure on *Gammarus roeseli* (Crustacea Amphipoda) from individual to functional levels.

J. Andrej, CNRS UMR 7360 / LIEC CNRS UMR; J. bouquerel, Université de Lorraine; S. Pain-Devin, Université de Lorraine - UL / LIEC CNRS UMR; L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIEC CNRS UMR; F. Guernold, Université de Lorraine / Laboratoire Interdisciplinaire des Environnements Continentaux

By means of some antibacterial properties, silver nanoparticles (nAg) are used in current consumer products and released into aquatic environment. One of the main priorities is now to address an appropriate risk assessment by using environmentally realistic exposure concentrations and media. Because they are good integrators of environmental perturbations, the gammarids are currently used as model organisms in ecotoxicology. They play a major role in ecosystem functioning by their capacity to breakdown leaf-litter and release fine particulate organic matter (FPOM) in the aquatic ecosystem. The objective of this study was to evaluate the impact of low concentrations of nAg in gammarids on both the locomotion behavior and the respiratory response. Ventilation of gills provides oxygen for cellular bioenergetics ensuring sufficient ATP levels to perform maintenance, reproduction and growth. On the opposite, the locomotion behavior is an ATP-dependent process that may be primarily impaired when energy lacks. Thus monitoring these parameters could provide integrative information about nanoparticles effects. In this context, the effects of low concentrations (0.5, 2.5 and 5  $\mu$ g  $L^{-1}$ ) of nAg of different sizes (10, 20, 40, 60 and 100nm in diameter) with the same shape and coating were assessed on the *G. roeseli* species after 36 and 72h of exposure. The locomotor activity was monitored in a group of 8 gammarids. After that, we measured individually and on the same organism the nAg impacts on: the oxygen consumption, the ventilatory activity and the electron transport system (ETS). Concurrently, measures at the functional level such as the organism's consumption and the FPOM production were performed. Realistic nAg concentrations did not induce mortality of gammarids despite a metal bioaccumulation. The first results showed an impact of the nAg on the gammarid oxygen consumption dependent of the nanoparticle size and concentration. The exposure to decreasing nAg sizes induced a proportional increase of the oxygen consumption by gammarids. For the 10nm nAg contamination condition, the highest concentrations induced also an increase of gammarid respiration. For environmentally realistic concentrations, nAg contamination has direct effects on organism's respiratory behavior. These impacts are dependent of the nanoparticle size and concentration. Some potential effects on the energy metabolism of *G. roeseli* could affect the aquatic ecosystem functioning.

## MO293

### The influence of pH and media composition on suspension stability of Ag, ZnO, and TiO<sub>2</sub> nanoparticles and immobilization of *Daphnia magna* under guideline testing conditions.

D. Cupi, DTU (Technical University of Denmark) / Department of Environmental Engineering; N.B. Hartmann, Technical University of Denmark (DTU) / DTU Environment; A. Baun, DTU Environment / Department of Environmental Engineering

In aquatic toxicity testing of engineered nanoparticles (ENPs) the process of agglomeration is very important as it may alter the bioavailability of the ENPs and hence their toxicity. In this study we evaluated test conditions that are more favorable in maintaining a stable and low agglomerate size profile of ENPs in aquatic media applicable in OECD guideline. In this study we focus on controlling stability (as point of zero charge) by employing changes in pH to media of different ionic strength (M7, and Very Soft EPA medium) and documenting the influence of these parameters on acute immobilization of *Daphnia magna*. Despite being sterically stabilized, test suspensions of Ag NPs were found to consist of large agglomerate sizes (close to  $\mu$ m range) for both VS EPA and M7 media. The toxicity of the AgNPs was found to be higher in VS EPA medium than in M7 medium caused by an increased dissolution in VS EPA medium. Maintaining a constant pH throughout the testing period of 48 hrs proved to be challenging. Especially for ZnO NPs a constant and stable pH is crucial since a large degree of dissolution was observed below pH 6.5. Pzc for ZnO ENPs was observed at pH ~8. Increased dissolution of ZnO NPs tested in VS EPA medium (at pH 7) rendered them more toxic compared to M7 medium. TiO<sub>2</sub> ENPs revealed a pzc at pH values between 7-8 and were present in relatively low-size agglomerates (~200 nm) in VS EPA medium (pH 7), whereas the agglomerate size in M7 medium reached  $\mu$ m range. While various studies have classified TiO<sub>2</sub> ENPs non-toxic, we saw that the low-size stable agglomerates caused immobilization to *D. magna* revealing  $EC_{50}$

of 13.7 mg L<sup>-1</sup>. Aquatic toxicity studies used for regulatory purposes should ideally comprise a set of testing parameters under which the lowest size of ENPs can be maintained. This could be achieved by employing a medium of low ionic strength and measuring the point zero charge of the specific suspension, in order to test for toxicity related to nano-size properties.

#### MO294

##### **MultiXenobiotic Resistance (MXR) vs Nanoparticles: is MXR a good biomarker of exposure? A study with zebra mussels and gammarids exposed to silver and titanium dioxide nanoparticles**

M. Potet; J. Andreï, CNRS UMR 7360 / LIEC CNRS UMR; B. Marchal, Université de Lorraine; M. Garaud, Laboratory LIEC - CNRS UMR 7360 - UdL / CNRS UMR; S. Devin, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR; V. Felten, LIEC; L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIEC CNRS UMR; F. Guerold, Université de Lorraine / Laboratoire Interdisciplinaire des Environnements Continentaux; S. Pain-Devin, Université de Lorraine - UL / LIEC CNRS UMR

MultiXenobiotic Resistance (MXR) is a membrane efflux system involving ABC-transporters. Because MXR limits the cellular accumulation of a wide diversity of chemicals including environmental pollutants, it was shown to be protective against chemical injuries and was thus proposed to be used as a biomarker for the assessment of organism health. Numerous studies have shown that MXR is an effective defense against organic and metallic contaminants and it could also be involved in protection against nanoparticles. Since it becomes critical to worry about their environmental release and their potential effects on biota, we wonder whether MXR could reveal the exposure of organisms to this new class of environmental pollutants. The present study addresses this question by monitoring the response of MXR in two freshwater invertebrates from different habitats, trophic levels and functional roles. While zebra mussels (*Dreissena polymorpha*) is a filter-feeding bivalve responsible for clearing waters and for organic matter deposition, gammarids (*Gammarus roeseli*) are shredders involved in the flux and redistribution of matter and energy. The poster presents an overview of the results from both short-term (72h in microcosm) and long-term exposures (up to 21 days in mesocosm) of mussels and gammarids to different types and concentrations of silver (PVP-coated plates 35nm, citrate coated spheres 10, 20 and 60nm – from 0.5 µg/L to 50µg.L<sup>-1</sup>) and titanium dioxide (Rod-shaped and cubic anatase, rutile – from 20µg.L<sup>-1</sup> to 1mg.L<sup>-1</sup>) nanoparticles (NP). MXR was assessed by measuring the accumulation of fluorescent dye in gill tissues with or without inhibitors of efflux transporters. The Cohen *d* effect-size between inhibited and non inhibited conditions gives a picture of MXR activity. The results showed differential responses of MXR depending on the invertebrate species, the NP type, the exposure concentration and the duration of the exposure. Briefly, silver NP induced MXR activity in mussels. In gammarids, concentrations as low as 0.5µg/L caused the most pronounced response when compared to higher concentrations and to ionic silver. Titanium dioxide NP caused high, early and transient inductions of MXR especially at lower concentrations. Though there is a lack of knowledge on the mode of interaction of NP with MXR, this biomarker seems to be a promising tool for NP exposure assessment.

#### MO295

##### **Effect of salinity and DOC gradients on the stability of TiO<sub>2</sub> nanoparticle agglomerates and their effects towards plankton from Lagoon of Venice (Italy)**

V.I. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences; C. Pestrinaux, University of Geneva / Institute Forel Earth and Environmental Sciences; S. Le Faucheur, Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences; M. Mortimer, Bren School of Environmental Science and Management; S. Stoll, University of Geneva / Institute Forel Earth and Environmental Sciences; F.B. Aubry, ISMARCN; N. Bott, RMIT University / Biotechnology and Environmental Biology; R. Zonta, ISMARCN  
Understanding of the fate and effects of engineered nanomaterials in highly dynamic natural environment is a precondition for reliable assessment of their risks. However there is a paucity of studies exploring their behaviour and effects in natural transitional environment [1], which experience temporal and local changes in salinity and organic carbon concentrations (DOC), such as those encountered in a lagoon. The major goal of the present study is therefore to explore the fate and potential effects of nano TiO<sub>2</sub> in a dynamic transitional environment such as the Venetian Lagoon. More specifically the emphasis is on the influence of the salinity and DOC concentration gradients on the nano TiO<sub>2</sub> dispersion in terms of size and surface charge; and the influence on the membrane integrity of plankton *nauplii* sampled in different sampling locations. The salinity and DOC gradients changed from 0.41 to 32.4 g/L and 17.44 to 4.2 mg/L for freshwater site of River Dese to marine site near St. Maria del Mare [2]. The exposure concentrations of 10 and 100 mgL<sup>-1</sup> nano TiO<sub>2</sub> as well as exposure times of 2 and 24h were considered, simulating worst case exposure scenario. The results demonstrated that increase of the salinity and concomitant decrease of DOC concentrations induced the formation of larger agglomerates with less negative zeta - potential, with z-average hydrodynamic diameter increasing with nanoTiO<sub>2</sub> concentration and exposure duration. The effect of nano TiO<sub>2</sub> on the membrane integrity of *nauplii* isolated from different sampling locations of the Lagoon of Venice was more pronounced at

higher salinity and decreased with increasing DOC concentrations at 2h, while no trends were found at 24h exposure, as well as exposure to 100 mgL<sup>-1</sup> nanoTiO<sub>2</sub>. Taken together, the results showed that in addition to concentration and exposure duration both salinity and DOC gradients are essential for understanding of the stability and effects of nano TiO<sub>2</sub> in lagoon environment. [1] von Moos N, Bowen P and Slaveykova VI (2014) Environmental Science: Nano 1:214-232. [2] Pestrinaux et al. Aquatic Geochemistry 2014, doi 10.1007/s10498-014-9245-8.

#### MO296

##### **The Effect of Different Dispersion Methods on TiO<sub>2</sub> Nanoparticle Ecotoxicity**

A. Erdem, Akdeniz University / Department of Environmental Engineering; M. Ozkaleli, Akdeniz University / Dept. of environmental engineering  
In recent years, the rapid development of nanotechnological activities, nanoparticles (NPs) emerge in many commercial products, from paints to cosmetic creams and from textile products to children toys. The engineered NPs need to be evaluated in a broad biosafety assessment studies. NPs have unique physical and chemical properties, which would be an important factor in determining the possible effects on ecosystem health and the prevention of problems before they occur. However, there are limited scientific studies on the effects of NPs, and there is no environmental standard and implementations on the NPs, yet. The main mechanism of the inactivation of algae, the roles of TiO<sub>2</sub> NPs in the inactivation of those organisms, the properties of the NPs affecting the ecotoxicity still remain unknown. Moreover, there is a lack of standard methods on NP suspension preparation and NP characterization. Depend upon the different environmental conditions applied in the experimental systems, NP size and size distributions are highly affected by the applied conditions. Especially prior to the experiments, both particle size and agglomeration state of the suspension strongly depend on the dispersion regime. When current legislation on NPs were evaluated, no standard method on NP suspension preparation could be found. EU commissions recommend for further studies on standardization of those methods and conducting experiments to assess the behavior and fate of the NPs in real environmental conditions in technical reports. In this study, the effects of different concentrations (1, 10, 50, 100 mg/L) of TiO<sub>2</sub> NPs will be prepared with different dispersion methods (mixing, prob sonication and bath sonication) in synthetic surface water (SSWs) samples with different water quality parameters (very soft to very hard, low to high alkalinity, pH 6.5 – 7.5) on green- algae *P. subcapitata* were evaluated. Algal inhibition, membrane deformation and cellular respiration inhibition analyses were conducted. The results were expected to confirm the influence of the dispersion procedure on the NP properties and consequently on the toxicity of the NPs. The procedures differed in terms of dispersion method, time, and media. The results show that the resulting NP size in different SSWs showed a strong dependence on the dispersion and the dilution method. Authors would like to acknowledge the financial support from TUBITAK (114Y015), Turkey.

#### MO297

##### **In vivo exposure of marine clams to titanium dioxide nanoparticles: responses in haemolymph, gills and digestive gland**

i. marisa, Biology; V. Matozzo, University of Padova / Department of Biology; M.G. Marin, University of Padua / Department of Biology  
The rapidly growing use of nanotechnology products in a variety of applications is responsible for increased discharge of nanoparticles (NPs) into coastal marine environments. However, little is known about fate and potential toxicity of NPs in the aquatic biota. In this regard, efforts should be addressed to the evaluation of the biological impact of NPs in ecologically and economically relevant species. Titanium dioxide (nTiO<sub>2</sub>) is one of the most common nanoparticles and is part of many commercial products such as sunscreens, cosmetics, and paints. During recent years several studies have been performed demonstrating that this NP can affect biological responses at different levels of organization. In this study, *Ruditapes philippinarum* was selected to assess the potential adverse effects of nTiO<sub>2</sub> under *in vivo* exposure. Clams were exposed for 7 days to environmentally realistic concentrations of nTiO<sub>2</sub> (0, 1, 10 µg/L) and bulk TiO<sub>2</sub> (10 µg/L). Bulk TiO<sub>2</sub> was used to assess the potential differing action of metal oxide compared with the respective NP. At various time intervals during the exposure, several cellular and biochemical responses were evaluated in clam haemolymph, gills and digestive gland. TiO<sub>2</sub> NPs caused alterations in several parameters measured. Immunomarker results confirmed that haemocytes are a sensitive target of the NP action. In particular, significant increases were found in total haemocyte count, diameter and volume of haemocytes, and haemocyte proliferation. A modulation of both haemocyte Neutral Red uptake and lysozyme activity in cell-free haemolymph was also observed in NP exposed clams. TiO<sub>2</sub> NPs genotoxicity in haemocytes was revealed by SCGE and Micronucleus assay at both concentrations tested. DNA alterations may be due to ROS generation in cells, given that in gills and digestive gland an induction of antioxidant enzymes was found. Indeed, significant increases in catalase and superoxide dismutase activities, and changes in glutathione transferase activity, were showed. Only in digestive gland an increase in lipid peroxidation was revealed under nTiO<sub>2</sub> exposure. Different responses in nTiO<sub>2</sub>- and bulk TiO<sub>2</sub>-exposed clams, the latter showing overall lower detrimental effects, suggested different mechanism of action, toxicity of nTiO<sub>2</sub> depending not only on TiO<sub>2</sub> molecules, but also on NP specific features.

#### MO298

### Dispersion of the titanium dioxide nanoparticles in water

E.S. Costa, UFSCar / Departamento de Química; T. CARMO, Physiological Sciences Department; N.d. Souza, Federal University of Sao Carlos / Department of Physiological Sciences; J.B. Fernandes, Universidade Federal de São Carlos / Química; M.N. Fernandes, Universidade Federal de Sao Carlos / Ciencias Fisiologicas

Titanium dioxide nanoparticles are known to possess chemical stability and catalytic properties that generate industrial interest<sup>1</sup>. They are amorphous and crystalline materials, and their characterization and quantification in various matrices is an active research area due to concerns about the potential effects of exposure to humans and the biota. Tests were developed with 4 different concentrations, type and times of shaking in order to verify percentage of dispersion of nanoparticles of titanium dioxide (TiO<sub>2</sub>). The concentrations were 0.5, 1, 5, 10 and 50 g L<sup>-1</sup>. In the first experiment (control), the nanoparticle was dispersed in MILIQ® water and ultrasonically stirred for 30 minutes. In the second experiment, the dispersion was stirred for 30 minutes at ultrason and allowed to stand for 24 hours and again stirred. In the third experiment the dispersion was stirred for 30 minutes at each 24 hours during 14 days and the fourth experiment the dispersion was kept under gentle stirring for 48 hours. All samples were centrifuged at 5000 rpm for 20 min, the supernatant was removed and the residue dried in an oven to complete drying at 60 °C and the dried materials weighed. The percentage of nanoparticles dispersed in solution of the first experiment, the control, had an average percentage of 22.5%. Other experiments averaged 18.8, 29.9 and 28.3% for the second, third and fourth experiment, respectively. An increase in the percentage of TiO<sub>2</sub> in the third and fourth experiment was observed, probably because of long dispersion being stirred daily for 14 days and the fourth experiment the constant stirring maintained a higher percentage of TiO<sub>2</sub> dispersed in the solution. The recovery rate was 92.3, 93.3, 98.6 and 94.0% for the first to fourth experiment respectively. The nanoparticles in suspension after drying were analyzed by SEM and their images showed the same profile of nanoparticles that remained deposited. It was observed that the TiO<sub>2</sub> nanoparticles have a very similar profile of dispersion in water, regardless of the analyzed concentration and agitation of the solution cause a slight increase of TiO<sub>2</sub> dispersed in the solution. However, the morphological characteristics of both the dispersed and deposited nanoparticles have the same profile, without differentiating between them. Financial support: FAPESP Proc. 2014/05701-0, CNPq/INCT-TA.

### MO299

#### Effects of particle size-class and light intensity on the toxicity of ZnO nanoparticles to *Bufo arabicus* tadpoles: Laboratory and microcosm studies

M.J. Barry, F. Al Mamari, Sultan Qaboos University / Biology; J. Dutta, Sultan Qaboos University / Water Research Centre  
Manufactured zinc oxide nanoparticles (ZnO-NP) are used in many consumer products and may subsequently reach aquatic environments. It is important to assess the risk of these particles under a variety of environmental conditions. In this study, three experiments were performed: Exp. 1. Effects of three size classes of ZnO (10-30, 80-200 and bulk (>200 nm)) and two levels of light intensity on the survival and growth of Arabian toad tadpoles (*Bufo arabicus*) over eight days. Exp. 2. Effects of three size-classes of ZnO-NP on survival and growth of tadpoles over 21 days under natural light. Exp. 3. The effects of two size-classes of ZnO-NP on the growth and development of tadpoles over 7 weeks in semi-natural 10 L microcosms. Exp. 1. There was no mortality during the sub-chronic experiment. Growth was reduced only at the highest concentration of 50 mg/L, but there was no effect of NP size-class or light. Exp.2. There was 100% mortality at 100 mg/L Zn for all particle sizes, with first mortality recorded after 4 days, while no mortality was recorded in the control group. There was also 100% mortality at the end of the experiment at 50 mg/L Zn for large nanoparticles, but not for the bulk ZnO or small ZnO-NPs. In the microcosm experiment there was 100% mortality after 7 weeks at 50 and 100 mg/L zinc. Most of this mortality occurred in the final two weeks of the experiment. At 5 mg/L there was 16.7±8.2 % mortality in the NP treatment, but no deaths in the bulk ZnO. There was 26±9 % and 27±14% mortality in the 10 mg/L ZnO NPs and bulk ZnO treatments respectively. Mortality in the controls after 49 days was 3.3±3.3%. The LC50 for the ZnO-NPs was 10.8 (9.2-15.7) mg/L Zn compared with 13.9 (10.8-32.7) mg/L Zn for the bulk ZnO. The growth of the tadpoles was significantly affected by ZnO type and Zn concentration. The mass of the controls 142.9±24.4 mg was significantly greater than all other treatments (P< 0.001). Tadpoles exposed to the bulk ZnO were significantly heavier than tadpoles exposed to the NPs. The results of this study show that ZnO nanoparticles are not acutely toxic to *B. arabicus* tadpoles, but effects are highly dependent on the duration of exposure.

### MO300

#### The influence of zinc chloride and nanoparticles on air-time survival in freshwater mussels

F. Gagne, Emerging Methods, Environment Canada / Emerging Methods; J. Auclair, Environment Canada

The purpose of this study was to determine the cumulative effects of exposure to either dissolved zinc or nanozinc oxide and air-time survival in freshwater mussels. Mussels were exposed to each form of zinc for 96 hours, then placed in air to determine the air-time survival. A sub-group of mussels before and after 7 days of exposure to air were kept aside for the determination of the following biomarkers:

arachidonate-dependent cyclooxygenase (COX) and peroxidase (inflammation and oxidative stress), lipid metabolism (total lipids, esterases activity, HO-glycerol, acetyl CoA and phospholipase A2) and lipid damage (lipid peroxidation [LPO]). In mussels exposed to zinc only, the median lethal concentration was estimated at 16 mg/L for dissolved zinc and was > 50 mg/L for nanozinc oxide based on shell opening responses. However, the air-time survival dropped from 19 days in controls to 12 days in mussels exposed to 2.5 mg/L nanozinc oxide for 96 h. The air-time survival did not significantly change in mussels exposed to the same concentration of dissolved Zn. Significant weight losses were observed at 0.5 mg/L nanozinc oxide and at 2.5 mg/L for dissolved zinc chloride, and were also significantly correlated with air-time survival (r=0.53; p< 0.01). Air exposure significantly increased COX activity in control mussels and in mussels exposed to 0.5 mg/L nanozinc oxide and zinc chloride. LPO was significantly increased in mussels exposed to zinc chloride followed by exposure to air. Peroxidase activity was significantly decreased in mussels exposed to air only and to nanozinc oxide followed by air exposure. Exposure to air also increased phospholipase 2 (PLA2) activity and acetyl CoA levels, whereas pre-exposure to both forms of zinc mitigated this response. The levels of glycerol, an indicator of lipid catabolism, were also enhanced after air exposure where both forms of zinc increased this effect. The data suggest that air-time survival could be affected by exposure to chemicals such as dissolved and nanozinc oxide. Exposure to air produced an inflammation reaction (COX activity) and weight loss in mussels, which are also influenced by the presence of metals and nanoparticles, further suggesting that health impacts of prolonged exposure to air from low water levels could be increased in the presence of environmental contaminants.

### MO301

#### ZnO nanoparticles and bulk form and ionic Zn cause comparable toxicity in mussels, without evidence for Zn bioaccumulation

A.J. Romero, Zoology and Animal Cell Biology Research Centre for Experimental Marine Biology and Biotechnology PIEUPVEHU; U. Izagirre, University of the Basque Country (UPVEHU); M.P. Cajaraville, University of the Basque Country; I. Marigomez, Euskal Herriko Unibertsitatea / Zool Eta AnimZelulen DinamSaila; M. Soto, University of Basque Country / Zoology and Animal Cell Biology Research Centre for Experimental Marine Biology and Biotechnology PIEUPVEHU

The aim of the present investigation was to understand bioaccumulation, cell and tissue distribution, and biological effects of ZnO nanoparticles (NPs) of two different sizes and shapes in marine mussels, *Mytilus galloprovincialis*. With that purpose, mussels were exposed *in vivo* to 0.07, 0.7 and 7 mg Zn/L either as ZnO NPs stabilised with Ecodis P90 of 20-70 and 500x260x10-100 nm (Zn< 130-EcoP90 rods and Zn< 280-EcoP90 plates, respectively), bulk ZnO and ionic Zn for 3 days. A high mortality was recorded after exposure to all the Zn forms, except at 0.07 mg Zn/L. ZnO NPs exhibited a high solubility and agglomeration in seawater, but however Zn accumulation in mussel soft tissues was comparable to that found in control mussels, probably due to efficient mechanisms of metal handling developed by mussels. Nevertheless, severe histopathological alterations were observed in the digestive gland after exposure to all Zn forms, especially after ZnO NP exposure (i.e. epithelial thinning and vacuolisation of the digestive cells, apoptotic nuclei in epithelial cells, disorganisation of the interstitial connective tissue and haemocytic infiltration, necrosis of muscle tissue). Lysosomal membrane stability was reduced in mussels exposed to all forms of Zn even if intralysosomal metal accumulation could not be confirmed by autometallography and X-ray microanalysis. In conclusion, ZnO NPs behaved similarly to the bulk and ionic forms. Deleterious effects found at the cell and tissue levels may be caused indirectly by mechanisms put in place to regulate intracellular Zn concentrations. Acknowledgements: EU 7th FP (Project NanoReTox CP-FP 214478-2), Spanish Ministry (Project NanoCancer CTM2009-13477), Basque Government (Consolidated research groups (IT810-13) and the University of the Basque Country (UFI 11/37 and PhD fellowship to AJ-R).

### MO302

#### Exposure of nano zero valent iron (nZVI) results in transgenerational reproductive toxicities in *Caenorhabditis elegans*

Y. Yang, National Taiwan University; P. Chen, National Taiwan University / Agricultural Chemistry; V. Liao, National Taiwan University / Department of Bioenvironmental Systems Engineering  
Nanoscale zerovalent iron (nZVI) is widely used for environmental remediation, yet the toxicological effects to organisms are still mostly unknown. This study investigated the reproductive toxicities of carboxymethyl cellulose (CMC)-stabilized nZVI, nanoscale iron oxide (nFe<sub>3</sub>O<sub>4</sub>), and ferrous ion (Fe(II)<sub>aq</sub>) in *Caenorhabditis elegans*. The results showed that nZVI, nFe<sub>3</sub>O<sub>4</sub>, and Fe(II)<sub>aq</sub> did not significantly affect *C. elegans* survival in a 24-h lethality test. The offsprings of P0 generation were decreased in the order of CMC-nZVI > Fe(II)<sub>aq</sub> > nFe<sub>3</sub>O<sub>4</sub>. In addition, the reproductive toxicities of CMC-nZVI were transferrable to the F1 generation in *C. elegans*. Further evidence showed that the intracellular reactive oxygen species (ROS) were significantly increased when *C. elegans* was exposed to CMC-nZVI, nFe<sub>3</sub>O<sub>4</sub>, and Fe(II)<sub>aq</sub>. The results indicated that exposure of nZVI induces transgenerational reproductive toxicities in *C. elegans* and the toxicities of CMC-nZVI in *C. elegans* was ascribed to its high production of ROS and the toxicity of Fe(II)<sub>aq</sub>. This study implicates a potential ecotoxicological and health

### MO303

#### Effects of nFe<sup>0</sup> on growth of the alga *Pseudokirchneriella subcapitata*

G. Libralato, Veneto Nanotech SCpA / Department of Environmental Sciences Informatics and Statistics; P. Rousselle, LIEC CNRS Université de Lorraine; B. Yon, LIEC Université de Lorraine CNRS; L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIEC CNRS UMR; D.A. Vignati, CNRS / LIEC UMR

The high reactivity and catalytic properties of nano-zerovalent iron (nFe<sup>0</sup>) are finding several applications in environmental remediation. Field concentrations during typical application can reach between 5 and 50 g/L. Investigations were carried out to evaluate the effects of four types of commercial engineered nFe<sup>0</sup> along with bulk (FeCl<sub>3</sub>) and micro-sized Fe<sup>0</sup> and the citrate coating present in just one nFe<sup>0</sup> type. In this study, the short-term chronic toxicity (72 h) to *Pseudokirchneriella subcapitata* (Korshikov) was investigated in reconstructed freshwater according to ISO standard 8692 using a fluorimetric method. Iron nanoparticles ranged between 25 and 50 nm, whereas the batch of micro-sized ones was averagely of 60 µm (TEM). Suspensions of nanomaterials were prepared in ultra-pure water, sonicated, aged for at least 1 day, vortexed and transferred to the 96-well plates. Algae and growth medium were further added to reach the optimal initial exposure concentration according to the standard protocol. Experiments were iterated three times in at least three replicates per treatment. Results allowed to rank nFe<sup>0</sup> particles evidencing median inhibition concentration effects (IC50) of 18, 329, 512 and 967 mg/L. Bulk iron resulted more toxic, IC50=2 mg/L, than nano-sized particles, while micro-sized ones were not toxic within the tested range till 1600 mg/L.

### MO304

#### How nickel affect reproduction of the calanoid copepod *Acartia tonsa* (Dana): nanoparticles versus nickel chloride exposure

i. buttino, ISPRA / Ecotoxicology and plankton biology Lab; C. Zhou, CAISIAL - Università degli Studi di Napoli Federico II -Italy; V. Vitiello, ISPRA Italian Institute for Environmental Protection and Research; d. Pellegrini, ISPRA Institute for Environmental Protection and Research; F. Iamunno, G. Benvenuto, Zoological Station Anton Dohrn; V. Puentes, Institut Català de Nanociència i Nanotecnologia (ICN2)

With the increasing use of nanoparticles (NPs) in the fields of medicine, high technology, well-being industries NPs are inevitably released into the sea. Therefore, it becomes essential to evaluate the potential impacts of NPs on marine environment and organisms. One of the effective tools to assess toxicological risk of NPs in marine environment is the bioassay test, in which marine organisms are exposed to known NPs doses. Copepods are the most abundant organisms in the marine pelagic community, they are filter-feeding herbivores representing the link between primary producers to the carnivores. Therefore, copepods are considered model organisms to test the effect of pollutants on marine ecosystem. *Acartia tonsa* is one of the most common calanoid species proposed for ecotoxicology tests and in marine pollution assays protocols. This species is relatively easy to grow, compared to other calanoid copepods, has a short life cycle and has high fecundity rate. In the present study acute, semichronic and chronic exposure protocols with *A. tonsa* copepod, are proposed to test toxicity of nickel nanoparticles (NiNPs) in comparison with a more soluble NiCl<sub>2</sub> salt. Nickel element is naturally present in the water but have also been introduced by human activities at very high concentrations, under different chemical forms, such as dissolved NiCl<sub>2</sub>. NiNPs are widely used in industry as mining product, extraction and refining, and in food processing. The classical acute (48h) and semichronic (7-days) tests with *A. tonsa* were used to evaluate the effective concentration inducing larval mortality (EC50) in embryos exposed to NiNPs and NiCl<sub>2</sub>. Moreover, the chronic test involving the exposure of mature adult copepods for 4-days with toxicants, are proposed, as innovative test. The aim is to verify if toxicants act, through a maternal effects, reducing female fecundity and egg viability, with a future reduction of the population in the natural environment. In this last test daily egg production rate and egg hatching success were evaluated. Moreover, chemical characterization of NiNPs are reported and protocols and procedures are suggested to test, at the best, nanoparticle toxicity in pelagic marine copepods.

### MO305

#### Interactive effects of copper oxide nanoparticles and light to the green alga *Chlamydomonas reinhardtii*

G. Cheloni, Institute Forel Earth and Environmental Sciences; E. Marti, University of Geneva / Aquatic Biogeochemistry and Ecotoxicology, Institute F.-A. Forel, Earth and Environmental Sciences, Faculty of Sciences; V.I. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences

Light is one of the most important and most variable factor in natural environments and it might represent an environmental stressor for aquatic organisms. Standard toxicity tests are performed under constant and optimal light conditions and the influence that light might have on pollutant speciation, bioavailability and toxicity are never taken into account. Many nanomaterials are produced and applied thanks to their optical and photocatalytic properties, however, excepted for TiO<sub>2</sub> and ZnO nanoparticles (NPs), no or little information are available about their phototoxicity

to aquatic organisms once released into the natural environment. With this work we explored the effects of visible and UV light to the stability of CuO NP dispersion and its toxicity to the green alga *Chlamydomonas reinhardtii*. *C. reinhardtii* was exposed to 0.8 mgL<sup>-1</sup> CuO NPs under three different light conditions: 1) a low PAR laboratory condition, 2) a solar-simulated light (PAR+UV) and 3) a solar-simulated light (PAR+UVB\*) with increased UVB radiation. Rates of growth inhibition and changes in chlorophyll fluorescence, membrane integrity and intracellular ROS were monitored via flow cytometry after 2, 4, 8 and 24 hours exposure. The evolution of nano CuO hydrodynamic size, zeta potential and dissolution through time was studied under the chosen light conditions. The chosen UVB light condition in the treatment PAR+UVB\* resulted to be highly toxic for *C. reinhardtii* and in presence of CuO NPs the toxic effect was further increased. Synergistic effects were observed after 2 and 4 hours incubation for chlorophyll fluorescence, membrane permeability and intracellular ROS. The combined exposure of CuO NPs and solar simulated light (PAR+UV) had a synergistic effect on the induced oxidative stress. This finding contrast with our previous results obtained for combined exposure to light and ionic Cu(II), in that study antagonistic interactions were observed. The increase of intracellular ROS caused by CuO NPs in presence of visible light suggests that photocatalytic production of ROS might occur. The results of the present study imply that nanomaterial with specific optical properties might have increased toxicity to aquatic microorganisms under environmentally relevant light conditions. The introduction of light as variable factor in toxicity tests is highly sought to better estimate the potential risk correlated to the release of oxide nanoparticles into the aquatic environment.

### MO306

#### Testing the effect of a MWCNT on the reproduction of *D. magna*

M. Winther-Nielsen, DHI / Environment and Toxicology; M.V. Iversen, University of Copenhagen / Environmental Chemistry and Physics

Various methodologies of dispersing and dosing nanoparticles for testing in aquatic test systems have been applied, however, there is still no consensus on a standardised procedure for making stock suspensions of NPs for aquatic testing. We investigated how the application of a dispersant (fetal bovine serum (FBS)) in a *Daphnia magna* reproduction study with a well characterised MWCNT (27-30 nm with TEM) affected the test results compared to a parallel study without dispersant. The amount of dispersant needed for stabilising the MWCNT in the test media was examined initially and a concentration of 0.6 mg/L FBS was selected. The reproduction studies with *D. magna* were carried out in accordance with the principles of the OECD 211. Young *D. magna* females were exposed to 1, 5, 10, 25 and 50 mg/L of MWCNT in Elendt M7 media for 21 days and with renewal of test media three times a week. The particles agglomerated or aggregated immediately when transferring aliquots of a stock suspension of MWCNT to test beakers with Elendt M7 media without dispersant. Aggregation was also seen in test beakers with dispersant but it was less pronounced. The average particle diameter was 962 ± 908 nm and 2,918 ± 1,291 nm in test suspensions of 1 mg/L MWCNT with and without dispersant, respectively. Although DLS measurements are not recommended for particles exceeding 500 nm the results indicate the increase in particles size of the MWCNT when introduced in the daphnia media. The exposure of *D. magna* to MWCNT induced immobilisation of all daphnies after three days for concentrations of 5 mg/L MWCNT and above when no dispersant was added. In test suspensions with dispersant all daphnies were immobilised after eight days of exposure at the highest test concentrations of 25 mg/L and 50 mg/L MWCNT. The reproduction of *D. magna* exposed to 5 and 10 mg/L MWCNT with dispersant was significantly less than the control, and the EC10 and EC50 were 1.5 and 7.6 mg/L, respectively. There was no statistical significance between the reproduction in the control and the treatment group with 1 mg/L MWCNT without dispersant. The results show that application of dispersant in the reproduction study with *D. magna* reduced the number of dead parental animals compared to a study without dispersant and that it was possible to carry out a 21-days reproduction test according to the overall principles of the OECD 211 with estimation of EC10, EC50 and NOEC/LOEC.

### MO307

#### Effects of fullerenes (nC<sub>60</sub>) in lifetime-exposure on *Daphnia magna* through three generations

K. Pakarinen, University of Eastern Finland / Department of Biology; G.C. Waissi-Leinonen, University of Eastern Finland; I. Nybom, Department of Biology; J. Akkanen, University of Eastern Finland / Department of Biology Fullerenes (nC<sub>60</sub>) are used in commercial products in increasing volumes, which enhances their risk to be released into the environment. Some applications provide a direct route to aquatic environments, and water treatment systems do not fully remove nanoparticles. Thus, aquatic species can be exposed to fullerenes. Despite that C<sub>60</sub> are stable molecules and can remain in water for months or years, only very few studies have focused on their long term effects, and even less on effects through course of generations. This study presents effects of nC<sub>60</sub> in lifetime-exposure on crustacean *Daphnia magna* through three generations. Each generation were exposed to equal nC<sub>60</sub> concentration and their offspring were examined for fullerene accumulation, and changes in survival, growth, offspring production, and histology. Exposure conditions were pre-tested in artificial freshwater and then experiment executed in natural freshwater, which offers environmentally more realistic test medium. Results indicated that body burdens of nC<sub>60</sub> increased from

generation to generation which could lead more effective transportation in the food web over the time. There was no effect on survival of individuals, but possible changes in growth and the offspring production in nC<sub>60</sub> exposure compared to clean water controls were observed. Reduced offspring production may weaken populations and thus reflect to upper levels of the foodweb.

### MO308

#### **Investigations on the effect of wastewater borne contaminants on *Hyalella azteca* using two coupled test systems: a case study with nanomaterials**

C. Schlechtriem, Fraunhofer IME / Oekotoxikologie; K. Schlich, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; K. Hund-Rinke, Fraunhofer IME

Today we have a large variety of contaminants, which enter sewage treatment plants (STP) through the sewer system. For some of these substances, such as antibiotics it was shown that they leave the STP to a large extent within the effluent. For other substances, such as nanomaterials (NM) it was shown that they are efficiently adsorbed to sewage sludge and only a smaller part passes the STP. The fate and effect of NM in different matrices and on various organisms was already investigated under standardized laboratory conditions. Aquatic organisms are quite sensitive, if they are exposed to NMs. However, by passing STPs, NM are transformed to various degrees and their effect on aquatic organisms may differ from those obtained with standardized test systems. Therefore, there is a need to gather detailed information about the fate and behavior of NM under environmentally relevant conditions and their effect on aquatic organisms. Unfortunately, most test organisms commonly used for aquatic ecotoxicity testing are not suitable to be used in studies investigating STP effluent. The main goal of this study was to implement a test system to investigate the implications of environmentally relevant conditions on (I) the fate of NM in a STP and (II) the resulting effects on aquatic organisms. To achieve our goal we used a combination of two test systems. A STP was simulated in accordance to OECD TG 303A with a continuous influent of various NM concentrations over 10 days. During the exposure period the fate of NM in the STP was assessed by chemical analysis. In the following the effect of NM in STP effluent on the amphipod *Hyalella azteca* was investigated in a prolonged toxicity test. We found that *H. azteca* is quite robust against the exposure to STP effluent. Due to this they present a suitable test organism for the purpose of our study. Testing NM under environmentally relevant conditions is an important point regarding the risk assessment of NM. In addition, with the suggested test system, the influence of various substances, which reach the STP and leave it via the effluent such as antibiotics or other drugs and their metabolites, on aquatic organisms can be examined.

### MO309

#### **The role of feeding behaviour in the uptake of microplastics in two aquatic crustaceans: *Gammarus locusta* (Amphipoda) and *Daphnia magna* (Cladocera).**

R. Aljaibachi, University of Reading / Biological Science; A. Callaghan, K. Chappell, University of Reading

Microplastic particles in the environment continue to be a growing area of concern in terms of acute and chronic impacts to aquatic life and yet remain relatively poorly understood. Whilst increasing numbers of studies are providing important insights into microparticle behaviour and impacts in the marine environment a paucity of information exists regarding the freshwater environment. The potential for direct toxic effects of plastics in the environment are well documented and the level of ingestion can be considered to be an important factor in exposure to plastics and other toxins adhering to microplastic particles. This study focusses on uptake and toxicity of microplastics in two aquatic invertebrates, the marine amphipod *Gammarus locusta* and the freshwater cladoceran *Daphnia magna*. Uptake rates and the destination of microplastics within the organisms are investigated in both species which have differing feeding strategies: shredding (*G. locusta*) and filter feeding (*D. magna*). In both cases the impact of food availability on ingestion, toxic effects and passage of plastic particles is investigated. Whether particle ingestion is passive or active is investigated through differential exposure routes. *Daphnia* and *Gammarus* were fed fluorescently labelled particles with and without food. Uptake and fate was examined through the use of epifluorescent microscopy combined with spectrofluorimetry. We recorded a significant uptake of particles ranging from 30nm to 15µm. The presence of natural food was also found to be significant in the degree of ingestion. Scanning confocal laser microscopy was used to examine the destination of plastic particles within the animals, both within the gut and associated with other organs. These data will form the basis of further studies to look at the impact of microplastics on macroinvertebrates and freshwater communities

### MO310

#### **Combined effects of gold nanoparticles, microplastics and temperature increase on the common goby (*Pomatoschistus microps*): predatory performance, biomarkers and gold body burden**

P. Ferreira, ECT Oekotoxikologie GmbH; E. Fonte, ICBAS CIIMAR University of Porto; M. Soares, F. Carvalho, UCBIO-REQUIMTE University of Porto / Laboratory of Toxicology Department of Biological Sciences Faculty of Pharmacy; L. Guilhermino, CIIMAR University of Porto

The contamination of estuaries and other marine ecosystems by nanoparticles and

microplastics (MP), and the effects of temperature variation on the toxicity of these substances raise a high concern in relation to their potential adverse effects on environmental and human health. Despite the research that has been done in the last years, considerable gaps of knowledge still exist, particularly on the combined effects induced by multi-stressors exposure. Thus, the effects of gold nanoparticles (AuNP) and MP on the common goby (*Pomatoschistus microps*), a key-stone species in several European ecosystems, were investigated at 20°C and 25°C. Short-term (96h) laboratory bioassays with early *P. microps* juveniles exposed to AuNP and MP alone and in combination (ppb range) were carried out at both temperatures. Post-exposure predatory performance (PP), the activity of the enzymes acetylcholinesterase (AChE) and glutathione S-transferases (GST), and lipid peroxidation levels (LPO) as effect criteria. The post-exposure gold content of fish was also determined. At 20°C, AuNP alone caused a significant reduction of the fish predatory performance; MP alone caused no significant effects; and the AuNP/MP mixture caused a decrease of the predatory performance and increased LPO levels. The 5°C increase of temperature modified the effects induced by AuNP, MP and the mixture in some of the analysed parameters, and increased the concentration of gold in the body of fish exposed to AuNP alone and in combination with MP. Overall, the results indicate that AuNP (ppb range) are able to induce toxic effects on *P. microps* juveniles, and that both MP and temperature influence the toxicity of these nanoparticles to the tested species. These findings highlight the need of more research on the combined effects of multi-stressors.

### MO311

#### **Examination of nanoparticle uptake in *Euglena gracilis***

X. Li, Environmental Toxicology; K. Schirmer, L. Sigg, Eawag / Environmental Toxicology; R. Behra, Eawag / Department of Environmental Toxicology Worldwide, the use of engineered nanoparticles incorporated in consumer products has started to grow significantly. The entry of nanoparticles into aquatic environment is likely, with potential impacts on freshwater ecosystems. Among the few studies concerning interactions of nanoparticles with algae, toxic effects were documented and the effective concentrations were reported. While it has become clear that nanoparticles can be internalized into mammalian cells through plasma membrane, most likely via endocytic mechanisms, little is known on the uptake of nanoparticles in algae. The presence of a cell wall in addition to the plasma membrane has been considered as an barrier against nanoparticle entry. In the present study, we examined the uptake of fluorescent polystyrene nanoparticles (PSNP), 50 and 500 nm, in the alga *Euglena gracilis*. Instead of a typical cell wall, this alga species has a pellicle in surrounding the plasma membrane, and the pellicle stripes are arranged diagonally on the surface with alternating pattern of ridges and grooves. For the experiment, algae were cultured phototrophically and heterotrophically and were exposed to 0.25 mg/mL PSNP in both culture medium under light at 20 °C in a shaker. After 2, 24 and 72 hours, the cells and PSNP were imaged with confocal laser scanning microscopy. The confocal microscopy images did not evidence any uptake of PSNP in *E. gracilis* cells after 2 h exposure. The 50 nm PSNP were found mostly aligned with the pellicle stripes while in case of 500 nm PSNP, no nanoparticles were found associated with the cells. Long-term exposures for 1-3 days lead to cell death. These results suggest that nanoparticle internalization in *E. gracilis* cells is unlikely, even though cells are cultured in heterotrophic medium. The size preference for PSNP adsorption onto pellicle indicate that the adsorption is most likely driven by physical entrapment within the pellicle strips. Key words: nanoparticle, algae, uptake, adsorption

## **Biophysical Interactions at the Bio-nano Interface: Relevance for Aquatic Nanotoxicology (P)**

### MO312

#### **Toxicity of CuO nanoparticles to freshwater algae**

J. Zhao; Z. Wang, Ocean University of China; B. XING, Department of Plant, Soil and Insect Sciences / University of Massachusetts

CuO NPs exhibited toxicity to the eukaryotic alga *Chlorella pyrenoidosa*. This alga had a higher tolerance for CuO NPs than the prokaryote alga, with a 72 h EC<sub>50</sub> at 45.7 mg/L. Scanning electron microscopy (SEM) images showed that CuO NPs were attached on algal cells and interacted with extracellular polymeric substances (EPS) excreted by algae. Further transmission electron microscopy (TEM) observation on the un-sectioned algal cell showed that EPS layer of algae was thickened after CuO NPs exposure, indicating a possible protective mechanism. Even though the presence of EPS layer, CuO NPs could still be internalized through endocytosis and disposed in algal vacuoles. During interacting with algal cells, transformation of CuO NPs was observed via TEM analysis. The toxicity investigation revealed that the CuO-algae attachment did not induce any shading effect but severe membrane damage was observed. Also, ROS generation and mitochondrial depolarization could be another two reasons for the CuO NPs toxicity. This is the first comprehensive study looking at the role of CuO attachment and uptake in the toxicity to algal cells. This work will provide essential information on understanding the role of NPs-algae physical interaction rather than ion solubility in the nanotoxicity.

### MO313

#### **A certain shade of green: new insights into shading effects of nanoparticles on**

## algal growth

R. Hjorth, Department of Environmental Engineering; S.N. Sørensen, DTU Environment / Department of Environmental Engineering; M.E. Olsson, Technical University of Denmark / Dept of Environmental Engineering; N.B. Hartmann, Technical University of Denmark (DTU) / DTU Environment

Inhibitory effects of nanoparticles on algal growth have been the subject of many scientific studies, of which some were designed also to elucidate the role of shading as a potential cause of effects. Most of these studies have applied a physical separation of algal cells and nanoparticle suspensions (e.g. Hartmann et al., 2010). By using such methods, shading has generally been rejected as a cause of effects. For very dark suspensions of platinum nanoparticles tested in a double-vial setup, however, shading was found to contribute to the observed effects (Soerensen et al., 2014). Nonetheless, such a test designs cannot detect effects caused by shading on a cellular level caused by the encapsulation of the cells by particles. Encapsulation of the algal cell may lead to a change in the physical growth conditions (light intensity). A change in chlorophyll/carotenoid pigment ratio upon nanoparticle exposure has been hypothesized to indicate shading on a cellular level (Wei et al., 2010). Pigment composition is known to be affected by changes in light conditions as a result of photoacclimation. Here we investigate the pigment composition of green algae, *Pseudokirchneriella subcapitata* and how the composition change as a result of nanoparticle exposure. Test glass vials with 4 mL algae and test solutions were incubated on a shaker (300 rpm) at  $20 \pm 2$  degrees C and continuously illuminated using a cold light fluorescent tube emitting light in the visible spectrum. We made a light intensity 'calibration curve' using natural density filters that allow for 71, 50, 25, 13 and 6 % light transmission respectively and analysed the pigment composition and content in the incubated algae by HPLC. Based on this calibration curve, comparisons were made to the pigment composition in algae exposed to nanomaterials. These investigations will assist to elucidate the effect mechanisms of nanoparticles towards algae. Hartmann NB, et al 2010, Toxicology 269(2-3):190–197. Soerensen SN, et al 2014, in *Science Across Bridges, Borders and Boundaries: Programme Book*. SETAC-Europe, Basel, Switzerland. Wei, C. et al 2010, Journal of Environmental Sciences 22(1): 155-160.

## MO314

### Comparative performance of three photosynthetic species exposed to an engineered nanomaterial with anti-corrosion properties

R. Martins, Department of Biology, University of Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; M. Avelas, Smallmatek Small Materials and Technologies Lda; D. Tedim, Universidade de Aveiro / Department of Materials and Ceramic Engineering CICECO; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; S. Loureiro, Universidade de Aveiro / Biology

Corrosion of metallic structures is a serious worldwide problem, which has been minimized with environmentally harmful corrosion inhibitors that are added to protective coatings. Recently, some of those active compounds were successfully encapsulated in novel "smart" engineered nanomaterials, namely layered double hydroxides (LDHs). LDHs can be loaded with corrosion inhibitors such as 2-mercaptobenzothiazole (MBT), storing and releasing MBT only in specific conditions coinciding with degradation phenomena. A potential advantage of this approach is the limitation of spontaneous leaching of the loaded active ingredients into the environment. In spite of LDHs being considered as prospective additives for protective coating systems, both active compounds and nanocontainers may also be bioavailable to organisms when released from the coating. Considering their potential presence and fate in the environment, in the present study, two microalgae species (chlorophyte *Tetraselmis chuii* and diatom *Phaeodactylum tricornutum*) and one bacteria species (filamentous cyanobacteria *Arthrospira maxima*) were exposed during 96h to MBT, unloaded LDH and LDH loaded with MBT (exposure concentrations ranged from  $10 \mu\text{g.L}^{-1}$  to  $100 \text{mg.L}^{-1}$ ), following the OECD guideline 201. Growth inhibition, pigments production, lipid peroxidation, antioxidant responses (activity of catalase, glutathione reductase, glutathione peroxidase), and detoxification mechanisms (glutathione-S-transferases activity) were evaluated. Toxicity patterns were related to the behavior and fate of the three compounds during the 96h of exposure. Comparing the toxicity of the three compounds, higher concentrations of the free MBT were responsible by inducing significant changes ( $p < 0.05$ ) in the majority of the endpoints evaluated for all species, particularly growth inhibition in most concentrations, along the exposure period. Therefore, encapsulating anticorrosion compounds in smart nanocontainers can be a promising and "green" approach for a sustainable environment.

## MO315

### Toxicity of novel anti-fouling engineered nanomaterials in two marine photosynthetic species

M. Avelas, Smallmatek Small Materials and Technologies Lda; R. Martins, Department of Biology, University of Aveiro / Department of Biology and CESAM Centre for Environmental and Marine Studies; M. Malheiro, M.J. Ferreira, Smallmatek; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; R. Freitas, Biology; J. Tedim, Universidade de Aveiro Smallmatek Small Materials and Technologies Lda / Department of Materials and Ceramic Engineering; S. Loureiro, Universidade de Aveiro / Biology

Marine fouling affects immersed structures (e.g. bridges; buoys) in seawater causing damages in their stability and security, loss of vessel's speed with increase

of CO<sub>2</sub> emissions and an overall increase of costs on their maintenance. The FP7 project BYEFOULING combines diverse types of antifouling strategies and targets specific fouling stages, where the Portuguese company Smallmatek is involved in the development of novel engineered nanomaterials (ENMs) with antifouling properties, and their toxicity assessment. Some of those ENMs were loaded with commercially available biocides to achieve control over the leaching rate. These biocides are specific for target species, but their toxicity to non-target species is still sparse and additionally, no knowledge exists in terms of toxicity of those encapsulated biocides. Therefore, before their industrial application in coatings, an integrative ecotoxicity assessment is required, since in a real scenario these compounds and their coating may be available to biota. In the present study two marine species, the green microalgae *Tetraselmis chuii* and the diatom *Phaeodactylum tricornutum*, were exposed during 96 h to free biocides, unloaded ENMs and ENMs loaded with the biocides, following the OECD guideline 201. Test concentrations ranged between  $10 \mu\text{g.L}^{-1}$  and  $100 \text{mg.L}^{-1}$ . Growth inhibition of both species was evaluated daily. Results showed that *P. tricornutum* was more sensitive than *T. chuii* to the selected free biocides and their encapsulated forms. Both biocides decreased significantly *T. chuii* growth above  $100 \mu\text{g.L}^{-1}$ , while growth inhibition was observed in all exposure concentrations using *P. tricornutum*. Unloaded ENMs did not induce toxicity in both species, apart from  $100 \text{mg SiN.L}^{-1}$  that showed a significant growth inhibition. The encapsulated biocides were less toxic for both species than the free ingredients. Further studies should be carried out to assess potential biochemical and physiological changes on non-target species, in order to have a holistic overview of their toxicity and to promote a safe design of those ENMs.

## MO316

### The role of free metal ions in the interaction of zinc oxide and silver nanoparticles with *Chlamydomonas reinhardtii*

A. Tierbach, Eawag; S. Pillai, Eawag Swiss Federal Institute of Aquatics; M. Suter, Eawag; K. Schirmer, Eawag / Environmental Toxicology

Metal nanoparticles, such as zinc oxide and silver nanoparticles, are a source of free metal ions and therefore of high concern. Bioaccumulation of metal ions dissolved from nanoparticles can induce adverse effects by inhibiting biochemical processes within the cell and perturbing metal homeostasis. In the present study the behavior and toxicity of zinc oxide and silver nanoparticles towards the green freshwater algae *Chlamydomonas reinhardtii* was investigated as part of the EU project NanoMILE. In a first step, the nanoparticles were characterized in an exposure medium with an ion composition similar to the surface waters of Switzerland. The changes in the mean particle size, poly dispersity index, zeta potential and the amount of released metal ions were measured over time. To investigate, in the second step, the interaction of nanoparticles with the algae, different physiological endpoints, including cell growth, photosynthetic yield and ATP content were chosen. Our results demonstrate that a considerable amount (>50%) of zinc oxide nanoparticles dissolved quickly in the exposure medium, independent of the coating, making it difficult to address the effect of nano zinc. In contrast, not more than 2% of silver nanoparticles were present as free silver ions. Silver nanoparticles induced a 20 times lower toxicity (in terms of EC<sub>50</sub>) on the growth rate, photosynthetic yield and the energetic state of the cell than silver nitrate, based on the total added silver. However, as a function of the free silver ion concentration, silver nanoparticles were more toxic. Nevertheless, in the presence of cysteine, a strong ligand for silver ions, the adverse effects of silver nanoparticles were neutralized, indicating that silver nanoparticle toxicity is solely mediated by free silver ions. The interaction of algae cells with nanoparticles is of high concern as it influences the particle dissolution and bioaccumulation of silver ions. However, upon exposure to silver, algae cells incite a defense mechanism which enables them to mitigate the silver toxicity and to recover over time.

## MO317

### Influences of the coating on silver nanoparticle toxicity in a chronic test with *Daphnia magna*

Y. Sakka, University of Bremen / General and Theoretical Ecology; A. Mackevica, Technical University of Denmark / Environmental Engineering; L.M. Skjolding, DTU / DTU Environment; A. Baun, DTU Environment / Department of Environmental Engineering; J. Filser, University of Bremen

Sources for differences in silver nanoparticle toxicity at standardized conditions can be numerous. They range from particle properties and their actual concentrations to differences in uptake or depuration by the test organisms. In the present study we compared the toxicity of two differently coated AgNP in a chronic *Daphnia* test. One type of AgNP was coated with citrate (cAgNP), the other AgNP were generally uncoated (pAgNP; p= pure), but sterically stabilized by an organic dispersant. Particles with a similar shape and diameter were chosen. The focus of the study was to relate observed differences in toxicity to characteristics of the AgNP, like size or surface potential, or to their corresponding behaviour during the test, like dissolution or uptake. The characteristics and the behaviour of the AgNP were investigated for changes in stability and especially the release of silver ions. In addition, uptake and depuration by the daphnids were compared. A chronic test was run with both AgNP at the same time. The results of the study are currently being analysed. The overall pattern of toxicity appears similar for both AgNP types, however, the less stable citrate AgNP (cAgNP) are more toxic than the more stable sterically stabilized AgNP (pAgNP). Whether this can be related to the

concentrations in the test media, to the release of silver ions or to differences in uptake or depuration by the daphnids will be presented on the poster.

### MO318

#### **Toxicity of Ag decorated ZnO nanocrystals to *Daphnia magna***

C.S. Azevedo, Biology; J. Rodrigues, T. Monteiro, F.M. Costa, Universidade de Aveiro / Physics; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; S. Loureiro, Universidade de Aveiro / Biology  
Nanoparticles (NP) are widely used in a variety of applications such as personal care products, pigments, plastics, photovoltaic cells, biosensors, etc. With the increase of their usage, research is being developed to increase or improve their applicability. An example is the combination of more than one type of NP in the same matrix in order to enhance/modify their properties and capabilities. The addition of noble metals, such as silver, to the surface of zinc oxide nanoparticles can enhance ZnO photocatalytic efficiency in a numerous applications such as in photocatalysis, antibacterial effects and gas sensors. Since the toxicity of ZnO and Ag nanoparticles has been already widely investigated, it is important to understand if as combined they will have the same effects on organisms as expected, regarding their individual toxicity. So, the aims of this work were: 1) to understand if the toxicity of Ag decorated ZnO nanocrystals was similar to the toxicity of a separated mixture of ZnO-NP and Ag-NP and 2) if their toxicity prediction can be based on the toxicity of the mixture, and consequently on the individual toxicity. To achieve that, immobilization (OECD 202), reproduction (OECD 211) and feeding inhibition tests were carried out with *Daphnia magna*. First, single exposures were done with ZnO-NP, Ag-NP and Ag decorated ZnO nanocrystals and then combined exposures with a mixture of ZnO-NP and Ag-NP were performed. The results of the toxicity of the Ag decorated ZnO nanocrystals were then compared with the toxicity of the mixture, and it was observed that there were some deviations from the expected, when predicting mixture and Ag decorated ZnO nanocrystals toxicity from individual nanoparticle toxicity.

### MO319

#### **Immunotoxicity and genotoxicity of pristine and purified SWCNT to the freshwater mussel *Elliptio complanata***

M. Revel, INRS-Institut Armand-Frappier; M. Fournier, Institut Armand Frappier-INRS / Immunotoxicology Laboratory; P. Robidoux, Université de Sherbrooke / Aquatic and Crop Resource Development Portfolio  
Production and development of carbon nanomaterials has increased for the past few years. In Canada, the forestry industry experienced an economic crisis which has led to the elaboration of new forestry products: nanomaterials, including single-walled carbon nanotubes (SWCNT). Because carbon nanomaterials have a large specific surface area giving them high adsorption capacity, they are closely studied for drug targeting and water treatment. Indeed, this property is very interesting for the removal of contaminants like metals in wastewater. Adsorption of metals is greater for purified or functionalized carbon nanotubes. Production increase of nanomaterials and applications for water treatment raises the question of their direct but also indirect toxic effects on benthic organisms which may be exposed. The adsorption properties of SWCNT may alter the bioavailability of contaminants present in the medium and change the global toxicity of the mixture. It is crucial to study the potential interactions between carbon nanomaterials and environmental contaminants. Immunotoxicity and genotoxicity are frequently investigated to study the effects of contaminants in aquatic environments. The immunotoxic and genotoxic measurement parameters were highly developed with bivalves because these organisms are present in a large distribution area and are in contact with various contaminants. These parameters are relevant for assessing the health of organisms and the quality of genetic information. The aim of our study is to measure the direct and indirect immunotoxic and genotoxic effect of pristine and purified SWCNT to the freshwater mussel *Elliptio complanata*. Our first goal is to investigate the effects of SWCNT on viability, phagocytosis and DNA strand break alone. Our second aim is to measure the same parameters in the presence of Cadmium. Results of Immunotoxicity and genotoxicity testing will be presented.

### MO320

#### **Uptake and localization of fluorescent labelled gold nanoparticles in living zebrafish (*Danio rerio*) using Light Sheet Microscopy.**

L.M. Skjolding, DTU / DTU Environment; G. Asmonaite, University of Gothenburg / Department of Biological and Environmental Sciences; R. Jolk, DTU Technical University of Denmark / Department of Micro and Nanotechnology; A. Baun, DTU Environment / Department of Environmental Engineering; J. Sturve, Göteborg University / Zoophysiology Dept  
Despite nanoparticles being used in many different products and applications, the effects and fate in the environment are still not well understood. Uptake of nanoparticles into cells has been shown in vitro and in vivo. However, it is challenging to find suitable methods to identify uptake and determine localization on a whole organism level. Furthermore, methods used to identify nanoparticle uptake have been associated with artefacts induced by sample preparation including staining methods for electron microscopy. This study used Fluorescent Light Sheet Microscopy (FLSM) to determine uptake and localization of fluorescent labelled nanoparticles in living whole organisms with minimal sample preparation. Two strains of *D. rerio* (wildtype AB and transparent Casper) were exposed to 50 nm PEG coated gold nanoparticles (Au NP) synthesized with 1% of a fluorescent probe

(FITC). The fish were exposed to the particles through the diet or the water phase in a series of separate experiments. In the dietary exposure experiments *Artemia salina* were exposed to 1 mg Au/L for 24h before being fed to *D. rerio*. For exposure through the water phase 1 mg Au/L was added directly to aquaria holding the fish and non-exposed *A. salina* was used for feeding. Imaging of *D. rerio* was done after 1, 3 and 7d of uptake and again after 1 and 3d of depuration with FLSM for both dietary and aqueous exposures. Though the FLSM proved to be excellent for in vivo detection of NP, it was found that the opaqueness of wildtype AB zebrafish hindered deep penetration of the light thus yielding less clear images compared to the Casper strain. A time dependent increase in fluorescence was observed in the gut region of the fish after dietary exposure. No fluorescence was observed outside the gut channel indicating no or limited transfer of AuNP outside the gut region. Fish exposed through the water phase showed adherence of AuNP to fins and especially gills. Strong fluorescence signal was also observed in guts of fish due to passive intake or drinking of exposed water. Fluorescence was also detectable in parts of the head which could indicate uptake to the brain through the olfactory tract. During the depuration phase the fluorescent signal decreased with time for both exposure scenarios. These results suggest that the route of uptake is pivotal for localization and transport of nanoparticles in zebrafish. Furthermore, the study shows the suitability for whole imaging of living organisms using FLSM.

### MO321

#### **Development of an in vitro tool based on the use of fish cell lines to assess the cytotoxicity of engineered nanomaterials**

L. GALBIS, INIA - National Institute for Agricultural and Food Research and Technology / Department of Environment; M. Fernandez-Cruz, INIA - National Institute for Agricultural and Food Research and Technology / Environment; J. Navas, INIA - Madrid

The production and application of engineered nanomaterials (ENMs) is rapidly increasing. Development of suitable models for screening possible toxic effects of ENMs is essential to protect aquatic organisms and support the sustainable development of the nanotechnology industry. Studying the toxicity of ENMs with *in vitro* systems will provide valuable information for risk assessment, and help to determine their interactions with cellular biomolecules. We have studied the effects of several ENMs in two fish cell lines (macrophages and hepatocytes), to elucidate their involvement in cellular viability and immunity mechanisms. The ENMs tested were the pristine forms of CuO (used as antimicrobial wood coating), WCCo (a ceramic material that improves the hardness of the products), Multi-Walled-Carbon-Nanotubes (MWCNTs; used as antifouling bio-adhesion and coating lightweight, conductive plastics), Organic Pigment Red 254 and Fe<sub>2</sub>O<sub>3</sub> (coloured plastic composites). Cells exposed to CuSO<sub>4</sub>, CoCl<sub>2</sub> and Na<sub>2</sub>WO<sub>4</sub> salts were used as controls. Before exposing the cells, a suitable method for dispersion of ENMs in cell culture media was established. The effectiveness of this method was evaluated by measuring the stability and hydrodynamic size of particles by Dynamic Light Scattering, at 0h and after 24h of incubation under culture conditions. Stable dispersions were obtained, except for CuO, where some aggregation is detected. MWCNTs yield a polydisperse pattern that is maintained along 24h. Cytotoxicity assays were performed after 24h of ENMs exposure, evaluating simultaneously three different endpoints that cover three mechanisms of cytotoxicity: metabolic activity (using the Alamar Blue assay), plasma membrane integrity (CFDA-AM assay) and lysosomal functionality (NR assay). The involvement of ENMs in cell viability was also studied at subcellular level by electron microscopy. Cytotoxic effects (cell viability below 80% of control levels) are mainly produced by CuO (25 µg/ml) and MWCNTs (12.5 µg/ml), at metabolism and membrane levels, respectively. The rest of ENMs show negligible effects on cell viability. The implementation of these *in vitro*, short-term cytotoxicity assays for testing different nanomaterials is the first step for the development of predictive tools that allow estimating the possible toxicity of ENMs in more complex (*in vivo*) systems. Acknowledgements - This research was supported by FP7-SUN project (Grant Agreement No. 604305).

### MO322

#### **Association between aqueous phase nanoparticles (TiO<sub>2</sub> and SiO<sub>2</sub>) and dissolved Cu<sup>2+</sup> assessed by evaluation of Cu<sup>2+</sup> bioavailability in zebrafish.**

D. Patsiou, Heriot Watt University / School of Life Sciences; J. Kalman, School of Life Sciences; T.F. Fernandes, T.B. Henry, Heriot-Watt University / School of Life Sciences

Environmental concerns over engineered nanoparticles (NPs) include the potential that NPs can associate with other substances (e.g., toxicants) and these associations lead to changes in NP physicochemistry, environmental fate, and toxicity of the NP and the associated substances. Some NPs present a negative surface charge in the aqueous phase and dissolved cations (e.g., toxic metal ions) may become associated; however, there is little information on the changes in NP physicochemistry or cation bioavailability after these associations occur. The objective of this study was to investigate whether copper ions (Cu<sup>2+</sup>) associate with negatively charged NPs in the aqueous phase, impact NP physicochemistry, and lead to changes in Cu<sup>2+</sup> bioavailability in larval zebrafish, *Danio rerio*. Initial work focused on TiO<sub>2</sub> NPs, P25, and a 1 g/L stock of TiO<sub>2</sub> NPs was prepared in deionized water and sonicated twice for 8 min at room temperature before dilution to 1-10 mg/L and evaluation of NP physicochemistry by dynamic light scattering and nanoparticle tracking analysis. The potential for Cu<sup>2+</sup> to associate with TiO<sub>2</sub> NPs

was determined by evaluating changes in the concentration-response (mortality) curve for larval zebrafish exposed to Cu<sup>2+</sup>. Parallel Cu<sup>2+</sup> dilutions (0-410 µg/L) were prepared, 1 mg/L of TiO<sub>2</sub> NPs (non-toxic based on previous experiments) was added to one dilution series, and mortality of zebrafish was assessed from age 96-168 h post fertilization. Larvae exposed to sub-lethal Cu<sup>2+</sup> concentrations were collected for assessment of metallothionein (*MT2*) gene expression. For 5 mg/L TiO<sub>2</sub> NP, the z-potential was -6.45 mV and the hydrodynamic diameter was 522 ± 160 nm (PDI>0.5) (mean ± SD). When larvae were exposed to Cu<sup>2+</sup>, the 48-h lethal concentration (LC50) was 185 µg/L, and when 1 mg/L of TiO<sub>2</sub> NPs were present the acute toxicity of Cu<sup>2+</sup> was reduced (LC50 was 138 µg/L). Results support the hypothesis that TiO<sub>2</sub> NPs have a negative surface charge in the aqueous phase, and that Cu<sup>2+</sup> ions associate with TiO<sub>2</sub> NPs and become less bioavailable. Ongoing research will investigate changes in TiO<sub>2</sub> and SiO<sub>2</sub> NP physicochemistry upon association with other substances and how these associations influence substance bioavailability. This research is supported by EU FP7 Future Nano Needs, “Framework to respond to regulatory needs of future nanomaterials and markets”.

### MO323

#### **Ecotoxicology of Gold Nanomaterials: Effects on periphyton, *L. Stagnalis*, and *H. Azteca* in an aquatic food chain study**

M. Hudson, University of Michigan / School of Natural Resources and Environment; A. Burton, University of Michigan / School of Natural Resources Environment; D. Costello, Kent State University / Biological Sciences  
The field of nanomaterials has been rapidly expanding and, in particular, gold nanomaterials (AuNM) are of special interest because of their growing number of applications in medicine, therapeutics, cosmetics, sensing, catalysis and the electronic industries. This expanding use of nanomaterials could pose a serious concern to aquatic environments and research into the toxicity and potential trophic transfer of nanomaterials at environmentally relevant exposure concentrations is needed. This study investigated the uptake and movement of AuNMs through an aquatic food web. Field-collected (Huron River, Ann Arbor, Michigan, USA) and lab cultured (*Oscillatoria*) periphyton were exposed to AuNM in a closed recirculating flume system with three treatments: control (0 µg/L), low (100 µg/L), and high (500 µg/L), respectively. AuNM quickly aggregated and precipitated from the water column and gold was measured in periphyton. *Hyalella azteca* and *Lymnaea stagnalis* were then exposed to periphyton from the flumes for 24 h before being transferred to clean systems for a 24 h depuration period. Gold was detected in *L. stagnalis* (high average 2.3 µg/L and low average 1.8 µg/L dry weight) but not in *H. azteca*, which may have been attributed to their unique feeding mechanisms. No significant mortality or biomagnification in either *L. stagnalis* or *H. azteca* was observed. The results suggest that the trophic transfer of AuNM is organism specific and that selective feeding by macroinvertebrates, and the settling and aggregation properties of AuNM are important when considering its fate in the environment and movement through aquatic food webs.

### MO324

#### **The cytotoxic effects in human prostate carcinoma cell line (22Rv1) exposed to different sized silver nanoparticles**

J. Kang; N. Hong, Chonbuk National University; Y. Jung, R. Kim, Korea Institute of Toxicology; J. Park, Korea Institute of Toxicology / Center for Environmental Biotechnology

Silver nanoparticles (AgNPs) are widely used in a various industrial and commercial fields because of their strong antibacterial activity. In many previous studies, however, the cytotoxicity of AgNPs in several human cells were suggested. Additionally, the accumulation around brain, ovary and testis of rat was recently reported. In this study, we exposed three different sized AgNPs (10, 20 and 50 nm) to the human prostate carcinoma cell line (22Rv1) and measured the cytotoxic effects such as cell viability, reactive oxygen species (ROS) generation and change of calcium ion concentration. The cell viability and ROS generation on 22Rv1 exposed to AgNPs were size- and dose-dependent. The cell viability was the lowest at 10 nm AgNP (AgNP-10) whereas the highest at AgNP-50. Also, the highest level of ROS was observed at AgNP-10 whereas the lowest was did at AgNP-50. Besides, we investigated the potency of endocrine disruption of AgNPs by measuring the luciferase activity induced by binding between androgen and androgen receptor, from which the reduced luciferase activity. These results suggests that a long-time exposure of AgNPs in human can cause the toxicological effects in the reproductive or endocrine systems.

### MO325

#### **The non-invasive continuous monitoring of sub-toxic oxidative stress triggered by nano-TiO<sub>2</sub> in *Chlamydomonas reinhardtii* using a new biosensor**

N. von Moos, University of Geneva, Institut F.A. Forel / Institut FA Forel; V. Koman, C. Santschi, EPFL Swiss Federal Institute of Technology in Lausanne; V.I. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences  
Thanks to its photoactivity and opacity, nano-TiO<sub>2</sub> is one of the most common engineered nanomaterial found both in industrial applications as well as in numerous consumer products. Its release into natural aquatic systems is inevitable. Its ecotoxicological hazard mainly lies in its photocatalytic activation by UV, the generation of reactive oxygen species (ROS) and subsequent oxidative stress. Though the current knowledge base suggests moderate overall toxicity of

nano-TiO<sub>2</sub> towards aquatic microorganisms, further monitoring and investigation is nonetheless required to elucidate its sub-toxic and especially chronic effects. The aim of this study is to follow the dynamics of extracellular and intracellular ROS generation within 1 h, elucidate the modifying effects of exposure conditions (exposure concentration, medium, UV) on the sub-toxic effects of nano-TiO<sub>2</sub> as well as to compare the results obtained by two different, ROS detecting techniques viz. flow cytometry (intracellular ROS) and a newly developed, highly sensitive biosensor (extracellular H<sub>2</sub>O<sub>2</sub>) based on the absorbance spectrum of cytochrome c. By integrating the data obtained this way, we aim to both contribute to a better understanding of the underlying toxicity mechanisms of NPs towards aquatic microorganisms as well as to show the applicability of a promising new method for the non-invasive, real-time and continuous investigation of sub-toxic oxidative stress in AMOs. Results suggest that environmental matrices may mitigate ROS inducing effects at the tested exposure concentrations. Furthermore, we found that nano-TiO<sub>2</sub> exert sub-toxic effects to *C. reinhardtii* despite the heavy agglomeration observed in the exposure media at physiological pH. What is more, the biosensor seems to provide a higher sensitivity towards ROS levels than the fluorescent probes used for flow cytometry and as such may lend itself well to the mechanistic investigation of sub-toxic, cellular effects by a new approach.

### MO326

#### **The marriage of biological systems with carbon nanomaterials: Systematic investigations of interactions and induced mechanisms**

C. Dinu, R. Eldawud, West Virginia University / Chemical Engineering; Y. Rojanasakul, West Virginia University / Basic Pharmaceutical Sciences  
Carbon nanomaterials have been explored for a wide variety of applications from fiber optics, to conductive plastics, and from composites to molecular electronics. More recently, their “bottom-up” functionalization with proteins, carbohydrates, or nucleic acids opened up exciting research directions in biolabeling, biodetection, biomolecule delivery, bioseparation or regenerative medicine and tissue engineering. This research presentation will provide an overview of the research directions in Dinu’s Lab at West Virginia University; aspects related to the nanomaterial-biological molecule nanointerface reactions, nanomaterial-induced toxicity and cellular biophysical changes, as well as nanomaterial-induced effects on the cell-cell interactions and nanomaterials-induced toxicity will be discussed. The goal is to provide a systematic analysis of the “good, the bad and the ugly” sights of carbon nanomaterials and means to understand and control their interface with biomolecules and cellular systems for applications ranging from molecular diagnostics to environmental protection.

### MO327

#### **Influence of copper oxide nanoparticle shape on bioaccumulation, cellular uptake and effects in the estuarine sediment-dwelling polychaete, *Nereis diversicolor***

A. Thit Jensen, Roskilde University / ENSPAC; A. Dybowska, Natural History Museum London / Mineralogy; C. Købler, Technical University of Denmark; G. Kennaway, Natural History Museum / Imaging and Analysis Centre; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change  
CuO nanoparticles (NPs) released into the aquatic environment will likely accumulate in the sediment, where sediment-dwelling organisms may be exposed. Here we synthesized, characterized and studied bioaccumulation, internalization and effects of CuO NPs with different shapes: Spheres (CuO-S), Rods (CuO-R) and Spindles (CuO-Spi) in the benthic ragworm *Nereis diversicolor*. Worms were exposed for 10 days to uncontaminated sediment (control) or Cu-spiked sediment with CuO NPs or aqueous Cu (Cu-Aq, CuCl<sub>2</sub>) at 7, 70 and 140 µg Cu g<sup>-1</sup> dw sediment. All Cu forms were accumulated in worms in a concentration dependent manner. Only Cu-Aq resulted in avoidance behavior, suggesting that worms can detect and avoid aqueous Cu in sediment, but not CuO NPs. Transmission electron microscopy of gut sections indicated limited presence of CuO NP-like objects in the gut. Whether accumulated Cu from CuO NP exposure was internalized as particles is still unclear. Overall, Cu form (Cu-Aq vs CuO NP) and exposure concentration may be more important for bioaccumulation and adverse effects than CuO NP shape.

### MO328

#### **Enhanced toxicity in human and fish cell lines after co-exposure to Cu nanoparticles and non-toxic concentrations of ZnO nanoparticles.**

D. Hernandez-Moreno, INIA / Environment; L. Li, Research Center for Eco-Environmental Sciences; M. Connolly, INIA National Institute for Agricultural and Food Research and Technology / Environment; E. Conde, M. Fernandez, CIEMAT; M. Schuster, Technische Universität München / Chemistry; J.M. Navas, M. Fernandez-Cruz, INIA - National Institute for Agricultural and Food Research and Technology / Environment  
The main goal of this study was to evaluate the response of a human and a fish hepatoma cell lines (HepG2 and PLHC-1, respectively) to the coexposure of increasing concentrations of a copper nanoparticle (CuNP) and a non-toxic concentration of zinc oxide nanoparticles (ZnONPs) after a 48 h exposure. Cell lines were exposed to a 50 nm CuNP at a range of concentrations (0.39-25.0 µg/mL) alone or together with a non-toxic concentration (6.25 µg/mL) of two different ZnONPs (25 and 100 nm). To establish the contribution of Zn ions to the toxicity caused by ZnONPs, cells were also co-exposed to CuNPs and to supernatants

obtained after centrifugation (5500 rpm for 2 h at 4 °C) of ZnONPs suspensions. Viability of cells was evaluated by three different cytotoxicity assays, the tetrazolium salt reduction (MTT) assay, the CFDA-AM assay and the neutral red uptake (NRU) assay. In order to obtain additional data, to clarify the mechanisms of toxicity, the total intracellular copper and zinc content in both cell lines after 48 h of exposure was determined by means of inductively coupled plasma-mass spectrometry (ICP-MS) after acid digestion. Metal content was evaluated using a non-toxic and the highest concentration of CuNP (6.25 and 25 µg/mL), alone or in co-incubation with ZnONP suspensions. The co-incubation of both cell lines with CuNPs and ZnONPs increased the toxic effect observed for the CuNP alone with a more pronounced effect in the human cell line. The highest toxicity was reached with the largest NP of ZnO. There was no cytotoxic effect when co-incubation with Zn ions was performed, indeed Zn ions seems to modulate the cytotoxic effect of copper, showing an enhancement of viability at all the concentrations of Cu in PLHC-1 cells and at 25 µg/mL in HepG2 cells. This result indicate that the ZnONP is the responsible of the toxic effect and not the Zn ion. In both cell lines, the intracellular zinc content increased with the increasing CuNPs concentrations although it was not statistically significant in the fish cell line. Additionally, a concomitant decrease in the intracellular copper concentration was only observed in the human cell line. The obtained results suggest that the presence of increasing concentrations of CuNPs enhanced the internalization of ZnONPs, which could be the responsible of the increased toxicity in the co-exposure experiments.

## Modelling of pesticides and biocides fate and exposure in a regulatory context (P)

### MO329

#### Evaluation of a new test design for the determination of a substance specific plant uptake factor (PUF) for use in regulatory fate modeling

**M. Lamshoeft**, Bayer CropScience AG / RD; H. Ressler, Syngenta Agro GmbH; G. Reinken, Bayer CropScience AG; C. Schriever, BASF; S. Schubert, Dow Agro Sciences LLC; J. Webb; S. Webb, The Institute of environmental and human health; B. Zillgens, DuPont de Nemours Deutschland GmbH; D. Keenan, Ricerca Biosciences; W.J. Doucette, Utah State University / Utah Water Research Laboratory; G. Fent, RLP Agrosience; V. Gourlay, Rheinland-Pfalz AgroScience GmbH; K. Malekani, Smithers Viscient / Environmental Fate and Metabolism; S.P. McLaughlin, Smithers Viscient / Department of Environmental Fate; P. Rooney, W. vanBeinum, FERA; B. Rieder, Eurofins Agrosience; M. Traub; S. Swales, Smithers Viscient ESG; K. Weinfurter, K. Derz, IME Fraunhofer; K. Kemmerling, VCI; M. Letourneau, J. Martin, N. Marchessault, Smithers Viscient In recent years the estimation/quantification of uptake into plants of plant protection products (PPP) has received increasing attention as the process reduces the quantity of PPP and their metabolites available for leaching. The plant uptake factor (PUF) accounts for this process in the commonly used fate models for leaching i.e. FOCUS PEARL, FOCUS PELMO and FOCUS MACRO. However, an approved protocol for a standardized test design is not yet available from official bodies such as the OECD and consequently the level of acceptance of experimentally derived PUF values differs across various authorities. The German Crop Protection Pest Control and Fertilizer Association (IVA) as well as the European Crop Protection Association (ECPA) have made proposals in the past of how to derive the PUF from simple laboratory studies. These proposals have been discussed with stakeholders and a new study design has been developed for deriving plant uptake values for plant protection products to be used in regulatory leaching models. The IVA/ECPA working group "PUF" has therefore coordinated a ring test to evaluate the new protocol which has taken into account improvements that were suggested by academia and regulatory authorities during a workshop held in York (UK) in September 2013. The workshop was conducted to establish a common understanding of plant uptake science and its implementation in the leaching models. Ten participating organizations conducted a ring test based on the new protocol to derive plant uptake factors for [<sup>14</sup>C]-1,2,4-Triazole (conc. 100µg/L) in wheat by means of a hydroponic system. During eight days of incubation data on pH, oxygen level, biomass, and evaporation loss were generated. The stability of test substance and the translocation into roots and shoots was determined by separate quantification of both plant parts and the resulting plant uptake factors were calculated. The ring test experiments within the ten participating laboratories were completed late 2014. The IVA/ECPA working group "PUF" performed the overall statistical analyses including reliability, reproducibility within and across laboratories and evaluated reports on the practicability of the test design. Here we are presenting the results of the ring test and proposed further actions in order to generate future guidance and a standardized protocol for the determination of plant uptake factors of plant protection products for use in regulatory fate modeling.

#### Statistical analysis of MARS weather data to derive a "Realistic worst case rainfall" for a simple wash-off estimation

**G. Reinken**, Bayer CropScience AG; T. Schad, EnSA; S. Bub, BCS A recent draft EFSA guidance published on the 10 July 2014 introduces a proposal of crop canopy processes to be employed for the soil exposure assessment. This

proposal to consider effects of wash-off introduces a significant change to the status quo which needs to be discussed and adequately aligned to other exposure areas. Alternative approaches may be equally valid but may offer particular advantages. An alternative approach to consider effect of wash-off on the fraction reaching soil is to estimate a simple soil loading by assuming a realistic worst case rainfall event. Suitable rainfall amounts and return frequencies of rainfall can be derived from publicly available data, such as weather data of the FOCUS scenarios or MARS weather data. A detailed statistical analysis of MARS weather data is presented and discussed. The analysis is based on daily MARS weather data (25 km x 25 km grid, JRC 2014) focusing on grids of agricultural use (CORINE CLC 2006, EEA 2013). Simple and appropriate statistical endpoints were derived for the temporal and the spatial dimension and were discussed against potential protection goals. The outcome is compared to an evaluation of FOCUS weather data. [1] JRC (2014): AGRI4CAST Interpolated gridded meteorological data of Europe. <http://agri4cast.jrc.ec.europa.eu/DataPortal/Default.aspx> [2] EEA (2013): CORINE Land Cover 2006 – European Environment Agency, Denmark. ### MO331

#### Understanding foliar wash-off: Elucidating structure-function relationships from nanoscale simulations of plant protection products on leaf surfaces

**M.N. Jochum**, L. Garcia, Crop Protection; B. Gottesbueren, BASF SE / Crop Protection Wash-off of foliar applied plant protection products can result in different temporal exposure patterns of pesticides on soil (i.e. determined by the rain distribution pattern). Current environmental fate regulatory assessments may use worst case assumptions, but higher tier refinements are not yet available due to a lack of understanding of the key factors involved. Using molecular modeling, we aim to gain a better understanding of the relevant contributions from the formulation components at the nano/micro-scale. To do this, we have developed a software tool which builds a coarse-grained model based on a fragment-based representation of the underlying chemical structure and the octanol-water partitioning for (i) the active ingredient(s), (ii) the dispersing agent(s), and (iii) the solvent composition for a given formulation. The leaf surface is represented by a generic wax layer with tunable roughness (from a plain surface to a nano-pillar coverage of variable density) to take into account a wide range of surface morphologies representative for crops of different type/age. By determining how individual components of a given formulation are distributed on the leaf surface with respect to the aqueous phase of the applied product, we can then estimate its wash-off potential.

### MO332

#### Experimental determination of foliar wash-off factors for modelling purposes

**E. Hein**; G. Reinken, Bayer CropScience AG The foliar wash-off factor is a compound and product (formulation) specific modelling input parameter relevant for the aquatic exposure assessment after foliar application [1]. To ensure a realistic worst case for soil residues, the foliar wash-off factor was originally set to a default value of 0.5 cm<sup>-1</sup> for FOCUSsw calculations. EFSA proposed later a more conservative default value of 1 cm<sup>-1</sup> [2], if no experimental data are available. The use of measured refinement values for the wash-off fraction reflects specific compound behaviour and is part of FOCUS guidance [1] and accepted by EFSA [2]. Recently EFSA published a draft guidance document in which the foliar wash-off factor also needs to be considered for the soil exposure assessment [3]. Thus, the foliar wash-off factor may be experimentally determined if a refinement is needed for the aquatic or soil exposure assessment of a specific compound. A generic frame work of an experimental study design has been derived in a workshop organised by the European Crop Protection Association (ECPA). This frame work was used for the experimental determination of wash-off factors for modelling purposes. Measured wash-off factors are presented and discussed for different compounds of foliar applied products. **References** [1] FOCUS (2001) "FOCUS Surface Water Scenarios in the EU Evaluation Process under 91/414/EEC". ### MO333

#### Analysis of wash-off impact on soil loading of agrochemicals at European level

**J. van de Veen**, Tier3 Solutions GmbH; G. Reinken, Bayer CropScience AG Jan Renger van de Veen<sup>1</sup>, Gerald Reinken<sup>2</sup> <sup>1</sup>tier3 solutions GmbH, <sup>2</sup>Bayer CropScience AG E-mail contact: janrenger.vandeveen@tier3.de, jrvandeveen@hotmail.com **Keywords:** soil risk assessment, plant protection products, fraction reaching soil, wash-off A recent draft EFSA guidance published on the 10 July 2014 introduces a proposal of crop canopy processes to be employed for the soil exposure assessment of agrochemicals. This proposal to consider effects of wash-off introduces a significant change to the status quo which needs to be

adequately aligned to other exposure areas. The described EFSA approach is limited to PECsoil, covers only a limited number of crops and allows no use of measured wash-off refinement values. An alternative approach may be to consider effects of wash-off not by the means of insufficient harmonized FOCUS models, wrt canopy processes, but based on a model independent calculation assuming a single realistic worst case rainfall event. In this way the additional soil loading due to wash-off could be manually added to the amount reaching the soil at day of application. Within this study detailed analyses were investigated to evaluate the additional soil loading caused by wash-off of agrochemicals at European level. The spatial computation assumes standard FOCUS weather data and a simplified crop canopy model as proposed in the draft EFSA soil guidance. Effects of the weather data of different agro-climatic regions within EU on the wash-off soil loading are presented and discussed. Outcome is compared to a wash-off loading based on a single realistic worst case rainfall event. The impact of additional parameters, resulting from application timing or product label, is addressed.

### MO334

#### **A simple Approach for the Estimation of Crop Interception Values for Leaf Development Stages**

D. Nickisch, Environmental Fate Modeling; U. Böttcher, Christian-Albrechts-Universität zu Kiel / Institute of Crop Science and Plant Breeding; E. Ditter, Environmental Fate Modeling  
Crop interception values established by the FOCUS Groundwater Scenarios Workgroup in 2000 and used for the estimation of predicted environmental concentrations in soil and groundwater are remarkably based on a limited experimental dataset. Thus, a literature review was carried out in 2010 on behalf of EFSA to collect data for spray plant interceptions. Out of a total of 55 relevant references, not more than 20 were available for a few arable crops, and data for leaf developmental stages (BBCH 10 - 19) was even more limited. Surprisingly, there were even negative interception values in a few cases. The EFSA literature review showed that reliable data is not publicly available in an appropriate amount. Thus, we tested a simple approach that allows an estimation of the interception values for early crop development stages. The leaf area index (LAI) or soil cover determines to a great extent the potential fraction of the substance that is intercepted by the crop. Therefore, we determined the soil cover by taking digital photographs for several crops (wheat, maize and oilseed rape) at early growth stages. Photographs were taken directly above the crop. Afterwards, the proportion of the green parts of the photograph was determined with an algorithm to estimate the ground cover of the crops. Since a digital photograph represents a two dimensional area, we assume that the ground cover represents a conservative estimation for the interception values. In addition, the LAI values were occasionally measured by a destructive method, representing the three dimensional area, which represents the maximum interception potential of a crop. First results confirmed that the interception values estimated by a photograph are conservative in comparison to the LAI values. The interception values varied considerably within the range given by the FOCUS guideline for BBCH 10 – 19. In general, a considerable soil cover could be estimated at early crop growth stages. The magnitude of soil cover at emergence depends to a great extent on the row spacing and sowing distances of the crop. Our simple approach represents a cost effective method for a conservative estimation of interception values for leaf development stages of all FOCUS crops.

### MO335

#### **A Pesticide Application Timer (PAT) for the FOCUS groundwater models**

M. Wang, WSC Scientific GmbH / Dept Efate Modelling; B. Kind, A. Guckland, WSC Scientific GmbH

For the registration of plant protection products in the EU a groundwater risk assessment must be performed to demonstrate the safe use. The FOCUS groundwater models (e.g. FOCUS-PEARL 4.4.4, FOCUS-PELMO 5.5.3) used in the risk assessment, require the input of application dates, which will then be used for each year of the simulations. Consequently, some applications might co-occur with bad weather conditions, i.e. heavy rainfall on day of application or on the following days. The modelling contradicts with good agricultural practice, as farmers would choose more appropriate dates. As the timing of rainfall on the days following application influences the amount of the pesticides washed off from plant surfaces and leaching into soil, the current procedure can result in unrealistic groundwater contamination. In the surface water assessment, this problem was solved by inventing the "Pesticide Application Timer" (PAT) in FOCUS-SWASH, which selects the application dates on the basis of certain rules. The user provides a time window in which the application(s) should occur. For groundwater modelling, however, no such tool is available up to date. Therefore we developed such a tool, which is capable to identify realistic application dates for groundwater modelling. This tool is based on the same rules and suitable application dates are identified for each year. These dates can be entered in the groundwater models ensuring that this procedure corresponds well with the good agricultural practice of farmers. We show that groundwater concentrations can be considerably different when using realistic vs. unrealistic application dates. The magnitude of these differences depends on substance properties, scenario and climate.

### MO336

#### **Evaluation of software packages for degradation kinetics**

J. Ranke, Johannes Ranke, wissenschaftlicher Berater; M. Winkler, Federal

Environment Agency (UBA); S. Meinecke, Umweltbundesamt

Data from degradation experiments in various environmental media are routinely evaluated using different software packages to derive parameters that can be used for the purpose of fate modelling or for comparison with regulatory trigger values in the environmental risk assessment. Especially parameter estimation for degradation models including formation and decline of transformation products or phase transfer processes, while possible in almost any programming language or mathematical software toolkit, is greatly simplified by software tools that have been tailored to this task. The software packages ModelMaker and KinGUI v.1 that were frequently used for this purpose have not received any updates since many years. Meanwhile, some new, actively maintained tools have been published that specialise in fitting solutions of systems of differential equations to experimental data. This poster reports the results of a multicriteria evaluation of these software tools on behalf of the German Federal Environment Agency (UBA), including a validity check using a number of example datasets. The system of evaluation criteria established for this purpose includes the areas of functionality, performance, user interface and user friendliness, extensibility and documentation. The weighting of the criteria, which was agreed with UBA, is different for two user groups A and B. For user group A, which should represent 80% of the use cases, the focus is on usability. For user group B, the flexibility in the model definition is most important. After the screening of at first 15 candidate tools the software tools KinGUI, gmkIn, CAKE and OpenModel were selected for the further check of validity and final rating. A validity check was performed by comparing the results for a suite of partly newly generated test datasets. Generally, good agreement between the tools was observed for datasets with up to three metabolites. For the different tools, user options were identified that should be taken care of in order to obtain results that are as reliable as possible. KinGUI and gmkIn obtained the highest scores in the final evaluation for user groups A and B. CAKE was found to be a valid alternative for user group A, provided the degradation scheme is sufficient for the dataset at hand. Subject to some caveats, the flexible OpenModel software package that is built using a different technical basis was found to be a possible independent alternative for user group B.

### MO337

#### **Long-Term Freundlich Sorption Coefficients Derived from Terrestrial Field Accumulation Studies**

R. Sur, Bayer CropScience LP / Environmental Safety

Time-dependent sorption (TDS) is a common compound property that allows for a realistic description of the mobility of agrochemicals in the vadose zone of the soil and can eventually improve the predictions of leaching to groundwater. In the present study two terrestrial field accumulation studies, that had been run between six and eight years to reach plateau levels in soil, were used to derive Freundlich sorption coefficients representative of the long-term transport characteristics of an active ingredient in the field. Depending on the trial site Freundlich sorption coefficients were found to be 1.5- to 2.5-fold greater in the field than the equilibrium Freundlich sorption coefficients derived from standard laboratory adsorption/desorption studies according to OECD guideline #106. It was shown that using these increased sorption coefficients is equivalent to using the two-site TDS model as implemented in the European FOCUS numerical leaching models to describe downward movements of compounds in the soil column more realistically than using equilibrium sorption only. The findings were further backed by results of a laboratory TDS study suggesting that the TDS effects observed in the field were at least as pronounced as found in the laboratory.

### MO338

#### **Modelling and experimental evidence of low pesticide persistence in the context of PBT assessment**

B. Jene, BASF SE / Environmental Fate

Substance persistence needs to be evaluated for PBT assessment which is required under different regulations for chemicals, biocides and pesticides. For pesticides the REGULATION (EC) No 1107/2009 does not permit EU registration of substances that meet all three PBT criteria. If two out of three criteria are met the substance will become candidate for substitution (Cfs) with limited registration time (only seven years) and comparative assessment on product level in the member states. A crucial aspect is the reference temperature of the half-lives that are used as criteria to characterize a substance as persistent in soil and sediment (DT50 > 120 days) or fresh water (DT50 > 40 days). Whereas for pesticides the DG SANCO working document on POP, PBT and vPvB requires a reference temperature of 20 °C for industrial chemicals and biocides the DT50 values are usually normalized to a reference temperature of 12 °C. Using a Q10 value of 2.58 (EFSA, 2007) extrapolation from 20 °C to 12 °C results in a 2.1-fold greater half live and substances that are considered not persistent at 20 °C could be labelled as persistent at a reference temperature of 12 °C. In the context of harmonization of the PBT criteria amongst different legislations it should be evaluated which reference temperature is appropriate to characterize substance persistence. Regarding the history of the criteria setting it can be assumed with certainty that a reference temperature of 20 °C (room temperature) is consistent with the original studies with which those substances against the threshold values were benchmarked. In a modelling exposure assessment in soil it can further be shown that for substances with soil half-lives between 56 and 120 days (not P with T<sub>ref</sub> of 20 °C but P with T<sub>ref</sub> of 12 °C) extrapolation to relevant outdoor temperatures does not result in any

accumulation of the substances even after regular multi-year application. After terminating pesticide application these substances will be completely degraded after a few years. By analyzing multi-year experimental accumulation studies under real agricultural use conditions of concerned pesticides (DT50<sub>soil</sub>: 56 – 120 days) it was found that the maximum soil concentration did not further increase after a few years of application (2-5 years). The maximum concentration found after multiple-year application was not greater than twice the initial concentration after the first application and a pronounced decrease of the concentrations between the applications was measured in all cases. It can therefore be concluded that a reference temperature of 20 °C linked with the trigger half-lives of the PBT P-assessment would not only be consistent with the history of the criteria setting but also sufficiently discriminating to identify substances of concern. Setting the reference temperature to 12 °C would result in P-labelling of many substances that do not show any concerns regarding accumulation in the environment (false positives).

### MO339

#### **Slower degradation of fungicides in soils from cold temperate climate as compared to warm temperate climate**

M. Almvik, Norwegian Institute for Agricultural & Environmental Research / Plant Health and Plant Protection; R.I. Bolli, A.L. Christiansen, Norwegian Institute for Agricultural and Environmental Research / Plant Health and Plant Protection; O.M. Eklo, Norwegian Crop Research Institute; R. Holten, Norwegian Food Safety Authority; P. Mulder, The Norwegian Food Safety Authority

The degradation half-life (DT50) of a pesticide in soil is an important input parameter in pesticide fate models. However, as DT50 data on fungicides is very scarce for soils in cold temperate climates, DT50 values derived in soils from warmer temperate zones in Europe are used instead. But will this give a relevant risk assessment of fungicide fate in the Nordic climate? We present here the degradation rates of four fungicides (propiconazole, boscalid, fenpropimorph and pyraclostrobin, Koc > 400) in four Norwegian soils from three climatic zones (latitudes 58-69°). In the laboratory, the degradation of the fungicides was studied at two temperatures (10°C and 20°C) in topsoils (0-20 cm) in accordance with OECD 307 Guideline (2002). In the field, the dissipation of the fungicides in the 0-50 cm zone was studied during one year, in accordance with the FOCUS guideline (2006). In the laboratory studies, the soils with the highest content of organic carbon displayed the slowest degradation rates of the fungicides. Propiconazole showed half-lives from 119 - >500 days in the Norwegian soils at 20 °C, whereas the EU agreed endpoints are 29-70 days. In two of the Norwegian soils, boscalid and fenpropimorph degraded more slowly than indicated by the EU endpoints. Pyraclostrobin had half-lives from 22-79 days, which were within the EU agreed range (12-101 days). At lower soil temperatures (10°C), the average DT50<sub>Lab</sub> values of propiconazole, boscalid and fenpropimorph ranged from 2 to 4 years in the Norwegian soils, and were predominantly longer than the EU agreed endpoints. In the field studies, the DT50 values of the fungicides were seen to increase with increasing latitude; i.e. the degradation slowed as the soil temperatures decreased and the winter period duration increased. Propiconazole had a DT50 of 241 days at the southernmost site and a DT50 of >3000 days at the northernmost site (EU endpoints: 17-411 days). Boscalid DT50 values were between 113 - >1000 days (EU endpoints: 28-208 days), fenpropimorph showed DT50 values between 54-218 days (EU endpoints: 9-51 days) whereas pyraclostrobin had DT50 values from 55-329 days (EU endpoints: 8-55 days). Conclusion: A proper risk assessment of fungicide fate in Nordic climate should be based on degradation data derived from studies performed with Nordic soils and climate, and/or the models should be adjusted for a slower degradation rate in the Nordic climate.

### MO340

#### **Regulatory risk assessment of Copper in Austrian vineyard soils - how to consider copper background concentrations and ageing?**

A. Dellantonio, AGES; M. Stemmer, Austrian Agency for Health and Food Safety / Institute for Plant Protection Products; E. Berger, Department Aquatic Ecotoxicology; B. Moebes-Hansen, Austrian Agency for Health and Food Security / Institute for Plant Protection Products; M. Schwarz, Austrian Agency for Health and Food Security / Department for Data management; G. Dersch, Austrian Agency for Health and Food Safety

In the context of the EU approval of copper (Cu) under Regulation (EC) 1107/2009, safe use conditions of Cu containing plant protection products could be demonstrated only for greenhouse applications. Toxicity of Cu fungicides towards soil organisms is strongly dependent on physico-chemical properties, Cu background concentrations and ageing processes in soil - all of which were not sufficiently addressed at EU approval in order to support outdoor applications. In contrast, the method applied in the context of the voluntary risk assessment procedures of Council Regulation (EEC) No 793/93 and 1488/94 takes into account these factors and was therefore deemed appropriate for calculating regional and local predicted no effect concentrations (PNEC) of Cu in soil. The method is based on an extensive set of ecotoxicological endpoints, which are normalised against soil properties such as soil organic matter, cation exchange capacity, pH and texture. Based on these normalised endpoints, site-specific PNEC values were calculated for the relevant viticulture areas of Austria taking into account the digital Austrian soil map eBod. In this presentation, results of soil Cu monitoring programmes and

calculated site-specific PNEC values will be presented and the implications discussed.

### MO341

#### **Mixture-toxicity exposure assessment in FOCUS surface water scenarios - Development of a software tool and implementation of a promising risk assessment approach into a user-friendly interface**

D. Weber, Eurofins Regulatory AG / Bio V; G. Eck, Eurofins Regulatory AG  
The registration of plant protection products in the EU requires a standard risk assessment for aquatic organisms, where toxicity endpoints are compared to PEC<sub>sw</sub> (Predicted Environmental Concentrations in surface waters). The FOCUS model calculations use realistic worst-case scenarios, where pesticides can enter surface waters via spray drift, runoff or drain flow. Simulations result in complex exposure patterns with multiple peaks over long periods. An aquatic risk assessment for mixture toxicity is required for formulations that contain two or more active substances. A common known approach is to evaluate combined effects based on Toxicity/Exposure Ratios for all actives. This approach evaluates the cumulative risk and conservatively assumes a simultaneous occurrence of exposure peaks. However, the FOCUS surface water scenarios often show exposure patterns where occurring maximum concentrations differ in time for active substances, when applied with identical crop/scenario/application timings. A detailed analysis of the 'realistic worst-case' exposure profiles for each of the actives is a promising refinement option for critical scenarios. A software tool was developed that allows the user to perform a step-wise evaluation of mixture toxicity in FOCUS surface waters scenarios for formulations containing up to three active substances. The scenarios can be evaluated individually or simultaneously in a first step, resulting in detailed results and visualizations. If scenarios fail the first evaluation step, an in-depth scenario analysis can be performed in a second step, resulting in the identification of relevant key characteristics (e.g. maximum peak duration) for the scenario-compound combinations. Detailed results and professional visualizations provide a profound basis for decision-making in higher-tier risk assessment. An example for a time-dependent additive mixture toxicity assessment is presented introducing the step-wise approach and explaining the results.

### MO342

#### **PRIMET\_Registration\_Ethiopia\_1.1 for assessment of risks in the environment and for human health in Ethiopia**

M. ter Horst, Alterra, WUR; P.I. Adrianse, Alterra Wageningen University and Research Centre / ERA team; L. Wipfler, Alterra Wageningen UR; J.W. Deneer, Alterra Wageningen University and Research Centre / ERA team; J. Vlaming, Envista Consultancy; A. Woldeamanuel, PHRD Ministry of Agriculture Ethiopia; B. Teklu, Wageningen University / Environmental Sciences Aquatic Ecology and Water Quality Management Group  
PRIMET\_Registration\_Ethiopia has been developed within the Pesticide Risk Reduction Programme ([www.PRRP-Ethiopia.org](http://www.PRRP-Ethiopia.org)) to support the Plant Health Regulatory Department (PHRD) of the Ministry of Agriculture to assess risks prior to introduction on the Ethiopian market. The tool integrates a risk assessment for the environment and for humans. The software is freely available at [www.pesticidemodels.eu](http://www.pesticidemodels.eu). Protection goals have been selected and prioritised together with Ethiopian stakeholders. Risk assessment procedures were developed for these protection goals, focussing on cropping systems in which pesticides with a high toxicity are used or in a high volume, or both. Eleven risk assessment procedures were developed for the environment, three for drinking water and five for human health. The risk assessments were either based on procedures in the European Union or elsewhere in the world or Ethiopia-specific exposure assessments were developed to account for typical Ethiopian crops and (agricultural) practices, pathways and hydrological conditions. Furthermore, the risk assessments were based on the ETR, Exposure Toxicity Ratio. The ETR values were classified by expert judgement into three classes: low risk, possible risk and high risk. The developed risk assessment procedures were implemented into PRIMET\_Registration\_Ethiopia. PRIMET\_Registration\_Ethiopia is a user-friendly software tool. The tool fits within registration practices as risks are assessed according to compound-crop-application scheme combinations, in the tool referred to as projects. Properties of active ingredients and data on pesticide application are to be provided by the user. For each project possible risks can be identified at a glance, as the risks are indicated by traffic light colours. Results can be reproduced easily by rerunning the saved project and input and output of the calculations can be exported into Microsoft Excel sheets and stored following a project-based directory structure, thus fulfilling the requirements of reproducibility, transparency and archiving that are essential for use in a registration procedure. The tool can relatively easily be adapted for use in other countries. Calculations can be tailored to specific countries without changing major parts of the software. As in many countries in the world a proper pesticide registration system is missing, this tool has a high potential to support the protection of human health and the environment all over the world.

### MO343

#### **Sources and outcome of pesticides in an estuarine ecosystem: application to the case of Gironde estuary**

H. Budzinski, University of Bordeaux / UMR EPOC Equipe LPTC; J. Cruz; K. LE MENACH, LPTC; P. Pardon, University of Bordeaux / UMR CNRS 5805

EPOC-LPTC; M. Dévier, LPTC-EPOC, University of Bordeaux / Oceanic and Continental Environments and Paleoenvironments; D. Granger, M. Chambole, X. Litricot, LyRE

Climate change and urbanization can be key factors affecting water quality. In this context of long-term environmental changes it is important to improve knowledge about ecosystem functioning and to characterize urbanization impacts, like wastewater treatment plant (WWTPs) effluent discharge. The aim of this study was then to characterize Bordeaux's WWTP contamination and to evaluate its input on Garonne River contamination by pesticides. This study covered the two main Bordeaux urban agglomeration (CUB) WWTPs, Louis Fargue (LF) and Clos de Hilde (CdH) between May 2012 and March 2013. Two sites of the fluvial estuary (Bordeaux and La Réole) and one site on a small river which flows in the Gironde Estuary, characterized by a lower flow but impacted by a large WWTP (Cantinolle one), the Blanquefort River (Blanquefort) were studied between March and September 2013. A wide range of 58 pesticides including herbicides, insecticides, fungicides and metabolites was studied. 55 molecules were extracted and analyzed by a multi-residues protocol using solid-phase extraction and liquid phase chromatography. Fipronil and its metabolites (fipronil sulfide and fipronil sulfone) were extracted and analyzed by a specific protocol using solid-phase microextraction or stir-bar sorptive extraction and gas chromatography. Pesticides were detected in influents and effluents of the two main Bordeaux WWTPs. Pesticides quantified at higher concentrations were diuron, imidacloprid, terbutryn, fipronil, fipronil sulfone and carbendazim. Removals were globally very low (under 50 %) and variable in both WWTPs. Pesticides appeared to be very stable compounds not eliminated by secondary treatments of Bordeaux WWTPs and they are discharged into the Garonne River. Median inputs range approximately from 500 mg.d<sup>-1</sup> (fipronil) to 5000 mg.d<sup>-1</sup> (diuron) and WWTPs can have a significant contribution to Garonne River contamination by pesticides. Main pesticides in river and estuarine samples were metolachlor and its metabolites with concentrations comprised between 10 and 250 ng.L<sup>-1</sup>. Typical WWTP pesticides were also quantified but at lower levels. Nevertheless some concentrations (even low) could raise environmental concern. Fipronil for instance was detected in Blanquefort site at concentrations exceeding its predicted no effect concentration (PNEC, 0.77 ng.L<sup>-1</sup>). Further investigations are then needed to document its presence in the Gironde estuary but also to understand its sources in WWTPs.

#### MO344

##### **Measurement and model estimates for an insecticide in closed cropping system in Turkey**

M. Yalçın, Adnan Menderes University / Faculty of Agriculture; C. AHAT, Adnan Menderes University / Faculty of Agriculture Lab Environmental Toxicology; A. Rein, TU Munich; A. Gavcar, E. CAMCI, Adnan Menderes University / Faculty of Agriculture Lab Environmental Toxicology; C. Turgut, ADU  
Acetamiprid is a neonicotinoid insecticide used to control sucking insects on many crops including tomatoes. Farmers prefer to use it because of the short pre harvest interval to ensure pesticide residue level under MRL values. The aim of the study to use the cascade model to predict the measured increase and decrease of residues following two foliar application to tomatoes. Tomato plants were cultivated in a autumn winter cycle. The treatment was carried out using a portable sprayer. Fruits were sampled before and after application with different days. The analysis of acetamiprid residues was carried out by LC/MS/MS. Total acetamiprid residues were between 0.016 and 0.115 ppm in fruits. The highest concentration in tomato was measured 0.115 ppm in tomato fruits. Model calculations showed that foliar repeated application of acetamiprid in greenhouse extend the PHI after second treatment, therefore the model should improve for pesticide legislation in Turkey.

#### MO345

##### **European-wide ecological scenarios for the exposure assessment of chemicals in aquatic systems**

A. Di Guardo, M. Morselli, University of Insubria / Department of Science and High Technology; G. Morabito, Institute for Ecosystem Study Italian National Research Council; P.J. van den Brink, Alterra and Wageningen University; F. De Laender, Université de Namur ASBL / Laboratory of Environmental Ecosystem Ecology

The growing need of enhancing ecological risk assessment (ERA) recently led to a number of attempts to introduce more ecological relevance and realism in both exposure and effect assessment. For example, on the exposure side, this was pursued by incorporating compartments and subcompartments describing primary producers and particulate/dissolved organic carbon (POC/DOC) into fate models for aquatic systems. However, the lack of coherent measured data to parameterize the most comprehensive modelling approaches often limits their applicability and suggests the need for environmental and ecological scenarios to be adopted for ERA purposes. In this work, 5 scenarios representative of European lentic shallow water bodies were developed, including information on water temperature and fluxes, phytoplankton biomass and POC/DOC concentrations. Such scenarios were developed using a two-step approach. First, we considered the case of Lake Candia, a small shallow lake for which monthly limnological observations were available for 25 years, as a typical scenario for Northern-Italy. Next, we adapted the parameters characterizing this reference scenario according to a climatic gradient to produce datasets for 4 other scenarios. We then compared these 4 scenarios, reconstructed from the reference scenario, to data found in the literature on water

bodies located in the considered range of climatic conditions. The 5 scenarios were used to run the spatially-resolved dynamic model "ChimERA fate", in order to assess the influence of environmental and ecological conditions on chemical fate and exposure. One-year simulations of emissions to a phytoplankton-dominated pond were performed for two chemicals differing in hydrophobicity and persistence. Two sets of simulations were performed: (1) considering the same emission and water regime for all scenarios and investigating the differences in bioavailable concentrations among scenarios as a consequence of temperature and ecological conditions and (2) adopting scenario-specific emissions and water regimes and comparing bioavailable concentrations among scenarios in an absolute fashion. Results allowed making considerations on the influence of specific environmental and ecological characteristics on exposure levels and identifying the highest-risk conditions for aquatic ecosystems. *Acknowledgement* - The Chimera project is financed by the Long Range Initiative of CEFIC ([www.cefic-lri.org](http://www.cefic-lri.org)) (project code: LRI-ECO19).

#### MO346

##### **Predictive Performance of Coastal Fate Model for Multimedia Environment (CFM-ME)**

S. Kim, Department of Marine Science, College of Natural Sciences, Incheon National University / Department of Marine Science; Y. Kim, Greencos Inc.; D. Chae, Department of Marine Science College of Natural Sciences Incheon National University; I. Kim, Incheon National University / Department of Biology  
Coastal wetland is one of the most sensitive regions to the global climate-change. We developed a Coastal Fate Model for Multimedia Environment (CFM-ME), which is a multi-box dynamic multi-compartmental model to simulate the fate of hydrophobic organic chemicals (HOCs) in coastal region including intertidal wetland. Incheon coastal region, the western mid-part of Korean peninsula, was chosen as a case study region for modeling and field measurement. The CFM-ME model covers sub-tidal zone, inter-tidal zone, and inland watershed zone in space, and simulates the semidiurnal tidal change (i.e., ebb- and flood-tidal flow) by which the exposed area of tidal flat changes. To evaluate the predictive performance of CFM-ME model, the concentrations of PAHs were determined for air (gaseous-phase), seawater (dissolved and particulate phases), sub-tidal sediment, inter-tidal sediment, and soil every season during one year. Thereafter, the relative concentrations (Pred\_C/C<sub>j</sub> versus Mea\_C/C<sub>j</sub>), which was proposed to use to avoid the problems of uncertainties or lack of emission estimates, were compared between predicted and measured ratios for model evaluation. In this study, we present (1) the differences of PAHs fate in sub-tidal v.s. inter-tidal zones, and (2) the results of sensitivity analysis and uncertainty analysis for main processes and/or parameters to influence chemical fate and transport in each zone. As a next step, this model will predict and assess the effect of climate-change on environmental pollutant fate in the coastal wetland.

#### MO347

##### **Which surface water pH is relevant for Risk Assessment of pesticides in Europe?**

A. Weyers, Bayer CropScience / Environmental Safety Ecotoxicology; M. Ebeling, Bayer CropScience AG EnSa-ETX-TV / Environmental Safety Ecotoxicology; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

The behaviour of the active ingredients (AI's) of plant protection products in surface waters is often influenced by the pH of the surrounding media. However, comprehensive European-wide information about relevant pH-levels of aquatic ecosystems potentially receiving AI inputs is lacking. Given this lack of data, a realistic worst-case for regulatory approaches can currently not be established without considering an uncorroborated, rather wide range of pH values as potentially relevant. The aim of the present study was therefore to determine, which ranges of pH-values are realistic and relevant for surface waters actually receiving AI input. For our study we have searched for pH-values from surface waters all over Europe (both standing and flowing) where at least one AI has been detected at least once during either an official surface water monitoring campaign (governmental data) or as part of a study published in the peer reviewed literature. The search resulted in a large set of relevant data (n = 3075 cases), and the evaluation showed that 95% of the European surface waters with a documented history of AI exposure actually fall within a rather narrow pH-range from neutral (pH=7.0) to slightly alkaline (pH=8.5), which therefore could qualify as 95<sup>th</sup> percentile realistic worst case range. The spatial and temporal variability in the data is presented and discussed with regard to e.g. the calcareous characteristics of parental rock material, the affiliation of the sampling site to a freshwater ecoregion, or the photosynthetic activity of macrophytes. The range of field relevant pH-values compiled by the present study provides a reliable basis for an adequate consideration of this parameter in modelling, or fate and effect assessment experiments in the context of the regulatory risk assessment, but also academic research, for plant protection products in Europe.

#### MO348

##### **Exploring the influence of environmental and ecological dynamics on exposure predictions: a modelling approach**

M. Morselli, University of Insubria / Department of Science and High Technology; M. Scacchi, University of Insubria Como / Department of Science and High Technology; M. Semplice, University of Turin / Department of Mathematics; F. De Laender, Université de Namur ASBL / Laboratory of Environmental Ecosystem Ecology; P.J. van den Brink, Alterra and Wageningen University; A. Di Guardo, University of Insubria / Department of Science and High Technology

In currently used approaches for ecological risk assessment (ERA), exposure is generally modelled assuming steady-state in emissions and environmental properties and neglecting the potential role of ecological dynamics in affecting bioavailable concentrations. This variability may create a spatio-temporal mosaic of exposures, which should not be ignored when performing ERA. In this context, a spatially-resolved dynamic fate model ("ChimERA fate") was developed, incorporating spatial and temporal dynamics of emissions, environmental parameters (e.g., water temperature, sediment properties), primary producers biomass and particulate/dissolved organic carbon (POC/DOC) concentrations. In this work, model output verification and corroboration against field data for macrophyte-dominated and phytoplankton-dominated systems were performed, in order to verify the correctness of the implementation of macrophyte and phytoplankton compartments and to assess model performance in a number of environmental situations. A local sensitivity analysis identified the most influential parameters (among physical-chemical properties, environmental and ecological parameters and mass-transfer coefficients) on bioavailable concentrations. Following this, illustrative model runs were performed for two chemicals characterized by different hydrophobicity and persistence emitted to a stream-pond-stream system in order to illustrate the potential spatio-temporal variability of exposure deriving from changes in environmental and ecological parameters (e.g., temperature and water fluxes, macrophyte/phytoplankton biomass, POC and DOC concentrations). Results showed, for example, that for the most hydrophobic chemical, bioavailable concentrations varied up to a factor of 3 during a simulation year in response to dynamics in primary producers biomass, and by orders of magnitude along the water flow direction when sufficient biomass was present to significantly sequester chemical from water. The results presented here revealed that the ChimERA fate model could be a vital tool for the identification of those combinations of emission, environmental and ecological conditions potentially causing the highest risk for aquatic ecosystems.

### MO349

#### Quick Estimation of Italian Mitigation Measures for Step 4 Surface Water Modelling

D. Nickisch, Environmental Fate Modeling; N. Boisselle, Rifcon GmbH / Environmental Fate Modeling; G. Wiedemann, Rifcon GmbH; E. Ditter, Environmental Fate Modeling

Currently, the FOCUS PEC<sub>SW</sub> approach to estimate the risk of plant protection products to enter surface waters via drift, runoff and drainage is widely used in the European registration process. The final step of the FOCUS approach is Step 4. In principle, Step 4 can be regarded as a higher tier exposure assessment step. This usually includes a variety of mitigation measures like runoff buffer zones or drift reduction by nozzles, as suggested by FOCUS in the Landscape and Mitigation report. Not all are accepted in the single member states. However, Italy is the only country which provides a variety of additional mitigation options next to the FOCUS ones. The most appropriate but time consuming way to include the mitigation measures would be to rerun Step 4 with e.g. SWAN. We prepared a tool for the quick implementation of the Italian mitigation measures based on the FOCUS calculations. Statistical fits to the commonly used Rautman drift reduction values, which are used in the FOCUS tools, were performed in R. The best fit for all crops collectively was a hyperbolic function. We used this fit to estimate the overall reduction difference between the FOCUS runs and the Italian ones. The difference was then converted in buffer distances which were subtracted from the FOCUS drift buffer. It is possible that the main entry path can change from drift to runoff or drainage considering additional drift mitigation measures. Thus, a FOCUS run considering 100% drift reduction was conducted to estimate the maximum reduction potential. For the validation of the approach, we tested Step 4 calculations for several substances considering the new Italian mitigation measures. Afterwards we compared the maximum predicted concentrations with ecotoxicological endpoints of the substance. Results showed that our simple time-saving approach can be used to estimate Italian mitigation measures at Step 4. However, for Italian runoff mitigation measures with an overall reduction < 60% it is still necessary to re-run Step 4 calculations.

### MO350

#### Development of representative groundwater leaching scenarios for greenhouse crops

p. Sharma, Crop Protection; R. Juraske, DR. KNOELL CONSULT GmbH

The recently published EFSA guidance document on emissions of plant protection products emitted from greenhouses provides information on how to perform risk assessment according to EU regulation. Although an example scenario for leaching to groundwater is given, it is stated that the representativeness of the scenario on national and European level has not been established. As described by EFSA, a greenhouse scenario requires specification of crop and soil parameters as well as

soil management information and (in-system) climatic conditions. Crop-specific information should include crop stage as a function of time, information on emergence and harvest dates, leaf area index, rooting depth, and crop water requirements. The standard FOCUS scenarios usually used for open-field assessments do not contain climate files that reflect conditions in greenhouses. For that reason the pertinent weather files were modified to reflect typical irrigation volumes in greenhouses at different times of the year and were subsequently parameterized with worst case application parameters. Typical water requirements for greenhouse crops were collected from experimental stations. Temperatures are typically higher in greenhouses compared to outdoor conditions. However, also indoor temperatures follow natural amplitudes (in greenhouses where temperature is non controlled). As a result it seems acceptable to use standard FOCUS temperature scenarios to mimic greenhouse conditions. Regarding the information on soil properties, as a first approach, generalized soil profiles defined by the FOCUS groundwater group were used. The leaching behavior of active substances and their soil metabolites was assessed by means of simulation runs with the leaching model FOCUS PEARL 4.4.4 for applications in greenhouse crops using the modified scenarios. Results were compared with simulations conducted using the FOCUS standard scenarios and the example scenario provided in the latest EFSA guidance document. In conclusion, model simulations indicate that predicted environmental concentrations in groundwater can vary by up to two orders of magnitude depending on the scenario used in the calculations.

### MO351

#### Spatial distribution of percolate pesticide concentrations in Germany calculated with PELMO

M. Klein, Fraunhofer IME; M. Trapp, RLP AgroScience, IfA / Institute for Agroecology; K. Thomas, Institute for Agroecology; D. Guerniche, RLP AgroScience GmbH; W. König, Federal Environment Agency; P. Klaas, G. Holdt, Federal Environment Agency (UBA); A. Osterwald,

In the registration procedure of plant protection products in Germany the groundwater risk assessment for active substances and their metabolites at tier 1 and 2 since 2012 is based on the 80th percentile of predicted groundwater concentrations from the FOCUS Hamburg scenario and in some cases the FOCUS Kremsmünster scenario simulated over 20 years with the FOCUS PELMO model. Results from the Europe-wide FOCUS analysis indicate, that primarily the Hamburg scenario represents 'realistic worst case' soil and climate conditions from arable lands in terms of chromatographic flow in soil. A new GIS based analysis was conducted with PELMO using national geo-datasets with high spatial and temporal resolution to assess the representativeness of those FOCUS groundwater scenarios with respect to German climate and soil properties. The spatial distribution of percolate concentrations in Germany was finally calculated with the new GISPELMO over 20 years for 3348 different soil weather combinations, for different substance properties referring to sorption and degradation in soil and for different crops and application times. Based on preliminary results it can be concluded that the FOCUS Hamburg scenario is not representing the 80th spatial percentile of pesticide percolate concentrations in 1 m soil depth for German soil and weather conditions. This might be essentially affected by less organic carbon contents in widely spread soil profiles in German arable land. Vulnerable locations identified with GISPELMO, which appeared to be nearly independent on pesticide or crop properties, could be the base for selection of alternative scenarios which may better describe the percolate concentrations for the German groundwater risk assessment than the FOCUS Hamburg scenario. Such recommendations will be discussed against the background of the FOCUS approach for spatial and temporal percentile selection. And finally, simulations with a tool like GISPELMO could more precisely guarantee to always select the same targeted spatial and temporal percentile of percolate concentrations in the groundwater risk assessment for different plant protection products, crops and application patterns.

### MO352

#### Consideration and parametrisation of photodegradates in PEC<sub>gw</sub> simulations with FOCUS-PELMO 5.5.3 in the risk assessment within the authorisation of plant protection products

J. Priegnitz, Umweltbundesamt / FG IV Pflanzenschutzmittel; R. Herr, Federal Environment Agency Germany / Section IV Pesticides Fate and Behaviour Groundwater Risk Assessment; M. Winkler, Federal Environment Agency (UBA); C. Pickl, Federal Environment Agency Germany / Section IV Pesticides Fate and Behaviour Groundwater Risk Assessment

The groundwater risk assessment of an active substance includes all transformation products formed in relevant amounts according to SANCO/221/2000 rev.10-final. If photodegradates were formed in a soil photolysis study or in field studies in relevant amounts, there is a need to assess their leaching potential to groundwater. Until now there is no EU-agreed approach how to deal with data from those studies. Therefore the applicants offer individual approaches in their dossiers that can lead to time-consuming expert discussions, to subjective case-by-case views and, in the consequence, to potentially unequal authorisation decisions. First recommendations how to parameterise the soil photolysis pathway in the groundwater risk assessment especially regarding photodegradates in a tiered approach were provided by Federal Environment Agency Germany (UBA) to other authorities in EU member states and applicants, involved in the process of authorisation of plant protection products, with a call for annotation. These

recommendations have the intention to support the EU harmonization process in the risk assessment of plant protection products to ensure an agreed approach in future. With FOCUS-PELMO 5.5.3 it is possible to model both the photodegradation of an active substance and the biodegradation of the active substance and its photodegradates/ metabolites in one run. There is no need to simulate a fixed apportionment of the total application rate within two virtual pathways. The model keeps track of the increasing depth of the modelled molecules and considers the photolysis only in the upper 1 mm of soil. Soil photolysis is driven by its own parameters like photolytic rate constant and the corresponding reference irradiance. EFSA guidance (2014) describes how to derive separate rate constants for surface processes and biodegradation in the soil matrix from field studies. From field dissipation studies evaluated with biphasic kinetics, the degradation rate constant of the fast phase can be assumed as representative for the soil photolysis of non-volatile substances. The reference irradiance at the application time and location of the field trial can be retrieved online from NASA. NASA provides extensive, global satellite data, daily averaged from July 1983 up to recent time. Prospective field studies should provide trial specific measured irradiance data.

### MO353

#### **An updated landuse dataset for use in European regulatory environmental risk assessments**

G. Hughes, H. Lyons, Cambridge Environmental Assessments

Spatial analyses as well as spatially distributed environmental fate simulation modelling are increasingly used to refine estimates of pesticide exposure within environmental risk assessments. A key dataset underpinning these analyses is the distribution of crops within the European Union. The CAPRI2000 landuse/landcover dataset is frequently used for this purpose and is currently distributed as part of an EFSA data package available from the JRCs European Soil Portal. However, this dataset is ~15 years old for most crop types and as such does not account for changes in crop areas and distributions in the intervening period and does not necessarily compare well with the agricultural areas reported in recent agricultural census datasets. In order to update this dataset with more recent agricultural census statistics but not recreate the dataset given its regulatory acceptance by EFSA, a dasymetric approach was used to scale the CAPRI2000 data using current agricultural statistics and alter it only where this was necessary, e.g. where more crop area is now present. During this process additional landuses were also defined by unbundling groups of crops/landcovers. This poster describes this updating process in more detail and outlines the strengths and utility of the final product(s).

### MO354

#### **Development of a UK higher tier groundwater environmental risk assessment for pesticides**

G. Hughes, Cambridge Environmental Assessments

At present there are limited options for higher tier refinement of exposure estimates of pesticides leaching to groundwater outlined within the UK regulatory process. This poster describes the development of a new spatially distributed higher tier modelling approach drawing on the example of the UK Higher Tier Drainflow approach as well as the NL GeoPEARL approach. The framework encompasses 15 soil classes and 4 climate zones. The soils classes reflect: 7 soils classes that are free draining and would contribute to groundwater; 4 soils classes that contribute to groundwater at 1m depth, but would ordinarily have agricultural drains; 2 soils classes that are peaty and the leaching of PPPs to groundwater would not be expected owing to their high organic carbon contents; 2 soils classes overlying substrates that are largely impermeable and the leaching of PPPs to groundwater would not be expected; Four weather stations were selected to represent the climate zones of < 600 mm, 600 mm-750 mm, 750 mm-1000 mm and >1000 mm rainfall. The seven free draining soils classes were modelled using PEARL while the four drained soils were modelled using MACRO. Peaty soils were assumed not to contribute to groundwater contamination along with soils overlying an impermeable substrate. These climate/soil scenario concentrations, when combined with the area that they represent were used to define a cumulative frequency distribution akin to that produced by GeoPEARL. Example outputs from FOCUS compounds applied to typical crops are used to illustrate the utility of this new HT GW ERA approach. The impact of using the 1m depth protection goal versus the base of the soil horizon is also discussed.

### MO355

#### **French Regulatory Feedback on new EFSA guidance for predicting environmental concentration of active substances of plant protection products in soil: Impact on the risk assessment of active substances**

a. conrad, E. FARAMA, A. Boivin, ANSES; V. Poulsen, ANSES / French Agency for Food Environmental and Occupational Health Safety

The draft Guidance Document <sup>1</sup> on "Predicting environmental concentrations of active substances of plant protection products and their transformation products in soil" was released by EFSA in July 2014 for public consultation. This document provides procedures for calculating concentrations that are potentially needed for terrestrial risk assessment. The current draft guidance is devoted to the spray applications on annual crops under conventional and reduced tillage (excluding tillage systems with ridges and furrow). The guidance document proposes a tiered approach (from Tier 1 to Tier 5) including both analytical and

numerical models. To achieve PECsoil calculations the PERSAM tool was also made available in addition to the FOCUS tools already available at the European level. This new guidance on PECsoil calculations aims at producing a more robust risk assessment for soil organisms consistent with the assessment performed for groundwater and surface water compartments. During the commenting period, issues regarding the results from the PERSAM tool as proposed with the draft guidance and the impact of the tiered approach as proposed in this guidance document on the risk assessment were raised. ANSES proposes some feedbacks on the use of this draft guidance on the foreseen consequences on terrestrial risk assessment at zonal level. It includes worked examples to allow discussion on the foreseen impact when using this new guidance. <sup>1</sup>European Food Safety Authority, Draft EFSA Guidance Document for predicting environmental concentrations of active substances of plant protection products and transformation products of these active substances in soil. 20YY. EFSA Journal 2014; Draft document

### MO356

#### **Assessing co-formulants used in Plant Protection Products under REACH - A case study of when a chemical use doesn't fit the standard assessment framework**

C. McMillan, A. Terry, Cambridge Environmental Assessments; C. Dobe, Syngenta

Environmental exposure assessments for chemicals assessed under the European REACH Regulation generally follow the ECHA R.16 Environmental exposure estimation guidance (ECHA, 2012) which is based on the EU-TGD Part II (EC, 2003). This approach of estimating environmental exposure assumes a local scale and a regional scale. For wide dispersive uses the local scale focusses on the municipal STP of a standard town containing 10,000 inhabitants with releases to water assumed to go via the municipal STP and subsequent release into an adjacent river. Direct release to air and soil from wide dispersive uses is not assessed at the local scale, but at the regional scale. The regional scale is assumed to be a densely populated area of 20 million inhabitants and releases (both point and wide dispersive) are assumed to be constant and continuous. While this framework may represent the environmental exposure route of many wide dispersive uses, it assumes initial release of the substance will be directly to a municipal STP, and at the local scale releases to soil or air are not relevant. For some wide dispersive uses, such as co-formulants used in plant protection products, this is not representative. Instead, exposure of co-formulants is likely to be edge of field, with potentially direct release to an edge of field water body via spray drift, drainage and runoff and, depending on vapour pressure or formulation type, direct release to soil. To address this, ECHA have developed the Local Environment Tool (LET). This tool allows an edge of field assessment to be conducted, using the FOCUS Step 2 approach (FOCUS, 2003) for surface water and R.16 approach (ECHA, 2012) for soil and secondary poisoning. The LET also combines local concentrations with regional PECs (steady state concentrations) estimated from all uses of the substance including co-formulant use, where regional release of co-formulants is estimated according to ECHA SpERCs, to determine a safe application rate. An overview of the approach will be presented alongside some preliminary investigations into the appropriateness of assuming a regional release to water where 80% connectivity to an STP is the default. This is a case study on assessing environmental exposure of a use that sits outside the standard chemical assessment framework applied in the EU.

### MO357

#### **Demonstration of the new modelling tool "MERLIN-Expo": a case-study on environmental and human exposure to POPs in Venice lagoon.**

A. Radomyski, University of Venice / Department of Environmental Sciences Informatics and Statistics; E. Giubilato, Department of Environmental Sciences Informatics and Statistics; A. Critto, University Ca Foscari of Venice; P. Cifroy, EDF / LNHE Department I; C. Brochot, T. Tanaka, INERIS; A. Marcomini, University of Venice / Department of Environmental Sciences Informatics and Statistics

Risk managers and decision makers are in need of tools that inform environmental and human exposures in different spatial and temporal dimensions. We demonstrate a new modelling tool for the integrated assessment of exposure to chemicals, called MERLIN-Expo, which is currently being refined and validated within the FP7 project "4FUN". This tool provides a library of exposure models which can be flexibly combined to explore complex scenarios, coupling on the same platform multimedia and physiologically-based pharmacokinetic (PBPK) models for estimating human intake and internal exposure. The models can be used to dynamically simulate fate and exposure for all organic (e.g., PAHs, PCBs, pesticides) and inorganic contaminants. There is no limitation for temporal scale, and the combination of different model boxes allow to cover different spatial scales. Moreover, MERLIN-Expo incorporates advanced functionalities for uncertainty and sensitivity analysis. MERLIN-Expo is demonstrated on a case study in the Lagoon of Venice, aimed at estimating environmental and human exposure to different congeners of PCBs. Specifically, the modelling framework combines bioaccumulation modelling in aquatic species, human intake modelling through the diet, together with PBPK modelling of internal exposure. Past PCB concentration trends reconstructed from dated sediment cores are used as inputs to model the time-dependent bioaccumulation in selected aquatic organisms. Then lifetime dietary intakes from contaminated fish and seafood, as well as other food items collected from literature data, are used to estimate PCB internal exposure for local

population. Modelling results are compared to available monitoring data on chemical concentrations in edible aquatic species and concentrations in serum of adult men in Venice area to assess the reliability and applicability of the proposed tool to real complex scenarios. Different outcomes of MERLIN-Expo can be used for regulatory purposes. For example, chemical concentrations in environmental media and biota can be compared with Environmental Quality Standards, human daily intake can be compared with given regulatory threshold for human health (e.g. Reference Dose) and internal exposure estimates can be evaluated against Biomonitoring Equivalents or other thresholds defined by risk assessors. This makes the tool interesting and promising for potential applications in different regulatory domains.

### MO358

#### **Differential effects of high fat diet and DDE treatment alone or in combination on metallothionein gene expression in rat tissues**

R. Scudiero, Department of Biology; V. Migliaccio, R. Sica, R. Putti, L. Lionetti, University Federico II of Naples

In recent years the obesity, the result of increased calorie intake and decreased energy expenditure, has tripled in Europe. Inflammation is the major obesity-related metabolic disease, associated to the generation of superoxide and endoplasmic reticulum stress. Environmental factors play a role in the onset of obesity. Persistent organic pollutants (POPs) are a wide group of pollutants that accumulate in the adipose tissue. POPs include the p,p'-dichlorodiphenyldichloroethylene (DDE), DDT major metabolite with the highest persistence. Metallothionein (MT) is a cysteine-rich protein, induced by various physiological mediators. MT modulates the binding of essential or toxic heavy metals and the removal of hydroxyl radicals. MT expression is enhanced by inflammatory stimuli and is induced in adipose tissue during the development of obesity. In this study the effect of DDE exposure associated with high fat diet and subsequent caloric restriction on the MT expression was evaluated. Four groups of adult male Wistar rats were so treated: 1) standard diet (10% fat J/J) (N rats); 2) standard diet plus DDE (10 mg/kg b.w. by gavage) (N+DDE rats); 3) high fat diet (45% fat J/J) (D rats); high fat diet plus DDE (D+DDE rats). After 4 weeks, 8 rats for each group were restricted for daily energy intake for 2 weeks. qPCR analyses demonstrated a tissue-specific modulation of MT expression: the changes in MT expression following high fat diet and DDE treatment depended on tissues, as well as the response to the caloric restriction. In testis no significant differences were observed between the 2 diets; DDE treatment led to a decrease in MT transcripts in N rats, but a strong inactivation of MT expression was only observed following the caloric restriction, in all groups of rats. In liver the major amount of MT transcripts was found in N rats: both high fat diet and DDE treatment led to a decrease in MT expression. A significant increase in MT transcripts occurred in DDE-untreated rats following the caloric restriction. In DDE-treated rats the caloric restriction had no effect on MT expression. In kidney high fat diet was not able to change MT expression, while the DDE treatment greatly enhanced MT gene expression, in both N and D rats. Interestingly, the caloric restriction had opposite effects on the 2 experimental groups: in N rats induced MT expression, whereas in rats fed high fat diet inhibited MT expression, both in the presence/absence of DDE.

### MO359

#### **Method to assess human health risks from dermal exposure to pesticides**

K. Bányiová; A. Nečasová, Research Centre for Toxic Compounds in the Environment Faculty of Science Masaryk University; J. Kohoutek, Masaryk University / Research centre for toxic compounds in the environment RECETOX; P. Cupr, Masaryk University, Faculty of Science, RECETOX / RECETOX Research centre for toxic compounds in the environment

Plant protection products (PPPs) containing a wide spectrum of active substances are used to protect crops against noxious organisms. As a result, these compounds are released to the environment and they are being detected also beyond the area of application. They not only have adverse effects on target organisms, which is desirable, but also on non-target organisms, including humans. A complex process of assessing the properties and effects of active substances and PPPs precedes their releasing. However, not all the assays are strictly demanded. Further, even if the assays are carried out, their results and the methodology behind them are considered to be a property of their performer. Thus, when assessing the exposure to these pesticides (including the dermal exposure) and human health risks resulting from such exposure, the risk assessors do not have relevant data at disposal. In this study, the dermal absorption of chlorpyrifos, as a model compound we have chosen based on the large prioritization process, was studied. An automatic system of Franz diffusion cells and the human skin *ex vivo* were used. The experimental design was set to obtain the information on the absorption kinetics of this compound. The absorption kinetics were used to calculate the risks resulting from the human exposure to fresh water contaminated by chlorpyrifos. Equations by US EPA for calculating the dermally absorbed dose were used. By this, a simple tool to calculate the hazard quotient to quantify the risks resulting from dermal exposure to chlorpyrifos in fresh waters, is going to be presented. The available experimental data on dermal absorption of active substances are crucial for the human risk assessment of pesticides found in fresh waters all over the world, and this will be shown on an example of our data from dermal exposure experiments. The obtained data will be discussed in broader context of current issues regarding the PPPs dermal exposure assessment and regulatory context.

### MO360

#### **Introduction on the Agricultural Worker(Pesticide applicator) Risk**

##### **Assessment and Future Plans in Korea**

K. Park, NAAS, RDA / Chemical Safety Division; J. Oh, M. Paik, NAAS RDA; A. You, National Academy of Agricultural Science; N. Cho, NAAS RDA; M. Jeong, National Academy of Agricultural Science / department of crop life safety Internationally, OECD Working group on pesticide(OECD WGP), especially, Risk Reduction Steering Group(RRSG), efforts to reduce the risk of the agricultural worker from pesticide exposure. Korean farmer spray the pesticide during 19.3 days per year and 3.76 hours per day. For this reason, need special efforts to protect of pesticide-spraying-farmer's health. From 2009, Korean authority, division of Control of quality and safety of agro-materials/resources, start to assess the risk of Agricultural Worker(pesticide applicator) before registration, and announcement of the notice about establishment of Acceptable Operator Exposure Level(AOEL), Setting the pesticide exposure calculating method and risk assessment principle. From this notice, the TER(Toxicity Exposure Ratio) of some pesticides against the pesticides operator were calculated as devide AOEL by pesticide exposure dose. The AOEL which were established by authority get from the toxicity data, the AOEL from pesticide exposure model(Korean Predicted Operator Exposure Model, K-POEM). When the TER default over the 1, the risk is low. But below the 1, that pesticide have risk, eventually, can not registrate. At present, K-POEM was modified from UK-POEM, have many problem. Moreover, we assess the only pesticides operator's risk. We start study for pesticide operators health with college, CRO and government institute. In future, try to improve and revise pesticide exposure calculating model suitable to Korean farming style. Also add to assess the risk of various worker, such as re-entry worker, green house worker, bystander. etc.

#### **Advancements in life cycle impact assessment and footprint method development (P)**

### MO361

#### **Life Cycle Assessment of the photocatalytic degradation of contaminated water**

E. Zerazion, University fo Modena and Reggio Emilia; F. Bondioli, University of Parma / Department of Industrial Engineering; P. Neri, M. Pini, Università di Modena e Reggio Emilia / Dipartimento di Scienze e Metodi dell'Ingegneria; A. Ferrari, University of Modena and Reggio Emilia / Department of Sciences and Methods for Engineering

Waters are under increasing pressure from the continuous growth in demand for sufficient quantities of good quality water for all purposes. This highlights the need for a policy of preservation and restoration, aiming at both maintaining the existing good quality surface waters, preventing them from degradation on a long term, and improving the conditions of the whole aquatic environment by reducing industrial and urban discharges, emissions and losses of hazardous substances. In the last decades, several nanotechnology-based water treatment technologies have been developed and used to improve desalination, safe reuse of wastewater, disinfection and decontamination of water. Compared to traditional technologies, advanced oxidation processes (AOP), based on the presence of titanium dioxide (TiO<sub>2</sub>), provide an efficient alternative for water remediation. However, these processes are mainly exploited through photoreactors with floating catalyst that may release "free" nanomaterials in the environment posing a comparable or worse harm to the environment compared to that solved through the photodegradation process. The aim of this study was to assess the environmental and health effects of a novel developed photoreactor where the titanium dioxide catalyst is immobilized on suitable substrates and activated with proper irradiation. The Life Cycle Assessment (LCA) was applied in order to drive the research towards the best technology and contribute to the development of a new awareness and knowledge on using titania based nanoproducts and nanotechnologies in water purification. In this study a methodological framework developed in collaboration with Empa (Swiss Federal Laboratories for Materials Science and Technology) to identify human health characterization factors based on the USEtox model was applied.

### MO362

#### **Proposal of adaptation of the effect factor of the USEtox methodology for environmental labelling of rinse-off cosmetic products**

P. Martz, L'Oréal Research & Innovation / L'OREAL; J. Lharidon, L'OREAL / Life Sciences Direction; J. CHENEBLE, L'OREAL; j. campion, L'Oréal Research & Innovation

The USEtox model, developed for Life Cycle Assessment (LCA) within the framework of the joint project SETAC-UNEP LCA Initiative, is recommended (France) or is expected to be recommended (USA and EU) for calculating the environmental impact on aquatic ecosystems of certain consumer cosmetic products, especially shampoos and shower gels. In a previous work, presented at the SETAC Europe meeting in 2014, we showed that the USEtox model gives results on shampoo's ranking that are poorly correlated with the ones given by the CDV (Critical dilution volume) model, already applied for the awarding of the European Ecolabel to cosmetic products. This can be explained either by differences on the fate factor modelling and/or on the effect factor modelling. In this study, we have chosen to focus on the effect factor to better understand parameters driving these

differences in the ranking of shampoos between both models. There is indeed a conceptual difference between the two models: in USEtox, the effect factor is based on average toxicity for all species taken together and not on the toxicity observed in the most sensitive species, like in CDV. USEtox represents an average impact, while CDV estimates an impact on the most sensitive trophic level, thus aiming to protect aquatic food chains. The present study compares the results on cosmetic constituents and cosmetic formulae of the L'Oréal Group, obtained with three methodologies: USEtox, CDV and USETox with a recalculated effect factor, taking into account the most sensitive species.

### MO363

#### **Robust decision making on ecotoxicity of products: is USEtox ready for use or not?**

G. Van Hoof, Procter & Gamble Services / Environmental Stewardship Organizational; D. Schowanek, Procter & Gamble Services Company NV; J. Dewaele, Procter & Gamble / Brussels Innovation Center; M. Stalmans, Procter & Gamble Services

Nowadays it is widely accepted that decision making in sustainable product design should be based on a combination of economic, environmental and social indicators. Methods and databases underlying indicator results are still rapidly evolving. It is nevertheless paramount that decisions are based on robust information that is sufficiently stable over time. Decisions should be based on the latest science and data, as much as possible avoiding subjective decisions, taking uncertainty in the calculated scores into account. At the same time, the methods and data should be easy to apply and to communicate to decision makers. When evaluating the environmental footprint of products, normalization of indicators is a useful approach to benchmark vs. a reference situation. While normalization is not free of data gaps and uncertainty, a multi-indicator approach (vs. a single score) is maintained, which helps decision-makers set priorities. This poster illustrates these challenges on the freshwater toxicity indicator (USEtox) applied on a hand dishwashing product. While USEtox is a consensus method and offers a practical tool for calculation of characterization factors (CFs) for new chemicals, the method remains highly sensitive to input data interpretation and selection. Data sensitivity is demonstrated with effect data, in line with observations by Henderson et al (2011). The lack of uncertainty information on calculated USEtox CFs appears critical when formulations are compared which are composed of data rich and data poor ingredients. Results show that depending on data selected for the calculation of CFs, the product score ranges over 2 orders of magnitude. These constraints currently affect the application of USEtox for in market use, particularly when the most important decision (purchase intent) is based on such information.

### MO364

#### **Applicability of USEtox model for assessing ecotoxicity impact of copper as part of the product environmental footprint**

F. Verdonck, T. De Wilde, ARCHE; L. Perez Simbor, K. Delbeke, European Copper Institute; P. Van Sprang, ARCHE

To overcome the fragmentation of the internal market as regards different available methods for measuring environmental performance, the European Commission recommends Product Environmental Footprint (PEF) methods based on existing, widely recognised methods. The USEtox model (Rosenbaum et al., 2008) is proposed to assess the ecotoxicity for aquatic fresh water. Ecotoxicity addresses the toxic impacts on an ecosystem, which damage individual species and change the structure and function of the ecosystem. In this poster, it is assessed whether USEtox is applicable to assess ecotoxicity impact of copper. Copper plays a crucial role in "closing" the loop and enabling Europe to move towards a circular economy. USEtox has several similarities with ecotoxicity and exposure assessment principles from risk assessment. However, despite metal specific LCA development published in literature and high quality data sets generated under the REACH Regulation umbrella, the ecotoxicity data set underlying the effect factor, essentiality, natural background and bio-availability were found to be insufficiently covered in the current available USEtox version 1.01. As a consequence, environmental impact of copper is therefore insufficiently reliable for a comparative assessment of products.

### MO365

#### **Managing the integrated direct and indirect life-cycle impacts of sewers and WWTPs in Mediterranean and Atlantic cities**

A. Petit-Boix, Institut de Environmental Science and Technology; E. Eijo, Universitat Autònoma de Barcelona / Institute of Environmental Science and Technology Department of Chemical Engineering; Y. Lorenzo, University of Santiago de Compostela / Chemical Engineering; M. Amores, S. McEnnis, CETaqua, Water Technology Centre; G. Villalba, Universitat Autònoma de Barcelona / Chemical Engineering Department Institut de Ciència i Tecnologia Ambientals; e. sevigne, Department of Chemical Engineering; X. Gabarrell Durany, Universitat Autònoma de Barcelona / Institute of Environmental Science and Technology Department of Chemical Engineering; M. Moreira, G. Feijoo, University of Santiago de Compostela / Chemical Engineering; J. Rieradevall, Institute of Environmental Science and Technology ICTA Universitat Autònoma de Barcelona / sostenipra

Managing sanitation infrastructures is of paramount importance in order to meet the demand of an increasing urban population. From a life-cycle perspective, the

operation stage of the wastewater collection and treatment results in 2 different types of contributions to the Global Warming Potential (GWP). On the one hand, the indirect impacts consist of the energy, chemicals and materials required to pump and treat wastewater in sewers and Wastewater Treatment Plants (WWTP), respectively. On the other hand, the direct impacts of the system result from the gas emissions deriving from the wastewater degradation and sludge treatment. Among these gases, methane (CH<sub>4</sub>) and nitrous oxide (N<sub>2</sub>O) are crucial because their GWP is 25 and 298 times greater than that of CO<sub>2</sub>, respectively. So far, GHG emissions have been primarily assessed in WWTPs, but biological processes leading to wastewater degradation in sewers and, thus, emissions can potentially occur under certain conditions (e.g., aerobic/anaerobic/anoxic). The aim of this study is to quantify and compare the emissions that take place in WWTPs and sewers during different times of the year and in different climatic regions. To do so, 2 Spanish case study cities were analysed in the framework of the LIFE Aquaenvec project (LIFE10/ENV/ES/520): Calafell (Catalonia, Mediterranean climate) and Betanzos (Galicia, Atlantic climate). Sampling campaigns were conducted during summer and winter in all treatment stages of the WWTPs and 4 representative sites of the sewers. This analysis will help to determine and compare the relative contribution of the GHG emissions produced in sewers with respect to those produced in WWTPs. From a life-cycle perspective, these direct emissions will be integrated to the operation phase of both systems and compared with the energetic requirements of sewers and WWTPs. Hence, these results can assist urban planners in the design of future sanitation systems and reduce the carbon footprint of the system.

### MO366

#### **Integrated assessment of wastewater treatment technologies including their water consumption impacts at the endpoint level. Application of the water stress indicator at 3 contrasted locations**

E. Risch, IRSTEA Montpellier / UMR ITAP; P. Loubet, Veolia Eau d'Île-de-France / UMR ITAP ELSA; M. Nunez, IRTA; P.C. Roux, Irstea / UMR ITAP ELSA

Environmental impact assessment models are readily available for the assessment of pollution-related impacts in life cycle assessment (LCA). These models have led to an increased focus on water pollution issues resulting in numerous LCA studies to date. Recently, there have been significant developments in methods assessing freshwater use. These improvements widen the scope for the assessment of wastewater treatment (WWT) technologies, now allowing the first ever combination of operation (energy and chemicals use), qualitative (environmental pollution) and quantitative (water deprivation) issues in wastewater treatment. This enables us to address the following question: Is water consumption during wastewater treatment environmentally significant compared to other impacts? To answer this question, a classical life cycle inventory (LCI) was performed with a focus on consumptive water uses at plant level for several WWT technologies operating under different climatic conditions. The impacts of water consumption were assessed by integrating regionalized characterization factors for water deprivation within an existing life cycle impact assessment (LCIA) method. Results at the midpoint level, show that water deprivation impacts are highly variable depending of WWT technology (water volume used) and of WWTP location (local water scarcity). At the endpoint level, water deprivation impacts on ecosystem quality and on the resources damage categories are significant for WWT technologies with great water uses in water-scarce areas. Therefore the consideration of water consumption-related impacts is important and motivates a greater understanding of the water consumption impacts from WWT systems. This knowledge will help water managers better mitigate local water deprivation impacts, especially in selecting WWT technologies suitable for arid and semi-arid areas.

### MO367

#### **Gas emissions in municipal sewer networks in two climatic regions**

E. Eijo, Universitat Autònoma de Barcelona / Institute of Environmental Science and Technology Department of Chemical Engineering; A. Petit-Boix, Institute of Environmental Science and Technology; M. Amores, S. McEnnis, CETaqua, Water Technology Centre; G. Villalba, Universitat Autònoma de Barcelona / Chemical Engineering Department Institut de Ciència i Tecnologia Ambientals; e. sevigne, Department of Chemical Engineering; J. Rieradevall, Institute of Environmental Science and Technology ICTA Universitat Autònoma de Barcelona / sostenipra; X. Gabarrell Durany, Universitat Autònoma de Barcelona / Institute of Environmental Science and Technology Department of Chemical Engineering

A sewer network can be considered as a biological reactor where each constructive element can lead to different environmental conditions. Depending on these conditions, several biological reactions could take place resulting in gas formation, such as nitrous oxide (N<sub>2</sub>O), methane (CH<sub>4</sub>) and hydrogen sulphide (H<sub>2</sub>S). Problems like corrosion and odour are related to the presence of H<sub>2</sub>S in sewers. While, N<sub>2</sub>O and CH<sub>4</sub> contribute to greenhouse effect, as their Global Warming Potential (GWP) is 298 and 25 times greater than that of CO<sub>2</sub>. Despite the importance of N<sub>2</sub>O in terms of GWP, very few studies have paid attention to its formation in sewers and none of them has assessed the three gases simultaneously. In addition, of the entire urban water cycle, most attention has been placed on gaseous emissions from wastewater treatment plants (WWTPs). In the framework of the LIFE Aquaenvec project (LIFE10/ENV/ES/520), Calafell (Catalonia, Mediterranean climate) and Betanzos (Galicia, Atlantic climate) were the cities selected for the assessing of these gases production. Sampling campaigns were

accomplished during summer and winter in four selected points along the sewer network of each city. The purpose of this investigation was to study N<sub>2</sub>O, CH<sub>4</sub> and H<sub>2</sub>S formation, to identify the possible hot-spots of the network quantifying the concentrations and to establish measurement methodologies. The results show that high temperature favours gas production, as the highest concentrations were measured during summer and in Calafell: 316.7 µg L<sup>-1</sup> of methane, 18.3 µg L<sup>-1</sup> of nitrous oxide and 3.4 µg L<sup>-1</sup> of H<sub>2</sub>S. In addition, wet wells were found to have the highest concentrations of methane, as they have more turbulence than other sampling points, and can become anaerobic environments between breathing cycles. This research will highlight the contribution of these gases to the entire water cycle and it will help to apply Life Cycle Assessment for environmental analysis of the wastewater networks in order to improve the wastewater management and contribute to more sustainable cities.

### MO368

**SewageLCI 1.0 - A first generation inventory model for quantification of chemical emissions via sewage systems. Application on chemicals of concern**  
A. Gallice, Research Innovation; M. Birkved, Technical University of Denmark; S. Kech, Veolia

Lack of inventory data on chemical emissions often forces life cycle assessors to rely on crude emissions estimates (e.g. 100 % of the applied chemical mass is assumed emitted) or in the worst case to omit chemical emissions due to lack of emission data. The inventory model SewageLCI 1.0, provides a mean for assessors to obtain fractions of chemicals emitted to the environment via waste water collection and treatment systems. SewageLCI 1.0 is based on existing models capable of estimating chemical degradation in waste water collection and treatment systems and also on national European statistics concerning waste water treatment systems. By combining readily available statistics and models stemming from environmental chemistry and waste water treatment science, the SewageLCI 1.0 model was built to simulate national specific average waste water collection and treatment systems and the model is hence capable of estimating the national specific average emissions fractions for organic chemicals. In order to illustrate the applicability, versatility and the general use of SewageLCI 1.0, a case study set of 6 organic chemicals was assessed in 15 national waste water different treatment grids. The results obtained applying SewageLCI 1.0 model reveal that it's possible to account for many of the variations in emission quantities of chemicals, caused by variations in the chemical fate properties and in the composition of national waste water treatment grids. The results indicate that the total emission fraction of a chemical may vary as much as up to one order of magnitude across the 15 countries included in the case study. Further, the case study reveals that for most of the chemicals considered, the dominant emission route after transport in waste water collection systems and potentially waste water treatment is emission to surface water recipients, other environmental compartments such as agricultural soil may receive considerable loads of chemicals emitted by the national specific waste water grids. The SewageLCI 1.0 presentation and case study reveal how broad inclusion of chemicals emitted to the environment via waste water treatment grids ideally should be captured by LCA. Despite SewageLCI 1.0 simulates national and hence theoretical average European waste water treatment grids and thus can't be validated, it is concluded that the model provides the best possible general mean for including emissions of chemicals with wide and dispersive use in LCAs.

### MO369

**Accounting for land use change emissions and their timing for purpose-grown biomass in the energy sector: Review of best practices and application to a generic case study**

A. Gallice, Research Innovation; A. Levasseur, CIRAIG - École Polytechnique de Montréal / Chemical Engineering

Life cycle assessment and carbon footprint studies traditionally do not account for biogenic carbon, because it is considered neutral for global warming in a long-term perspective. However, experts have recently shown that biogenic carbon neutrality may lead to accounting errors and biased conclusions, raising the need to develop accounting methodologies that consider biogenic carbon emissions. We have identified two issues related to the consideration of biogenic carbon for purposed-grown short-rotation biomass in the energy sector: (1) quantification of land use change (LUC) emissions, and (2) treatment of temporal aspects. Within this study, we have investigated and compared methodological recommendations for quantifying and considering the temporal aspects of LUC emissions from several international standards, guidelines, governmental policies, and research papers. From this critical review, we have identified best practices and applied them to a generic case study addressing very-short-rotation poplar and miscanthus crops grown in different European countries. The first step was to determine what types of land have been converted after the increase in biomass production to identify whether direct (dLUC) or indirect (iLUC) emissions must be considered. Different scenarios have been developed using local data and statistics. Then, the quantity of carbon emitted during land conversion for each of these scenarios has been estimated using IPCC guidelines for dLUC, and a study performed by the European Commission for iLUC. The second step was to account for the warming effect of LUC emissions during their payback time. Usually, biogenic carbon emissions are amortized uniformly over the average number of years of the rotation period or over a fixed time horizon. However, as shown by some researchers, this leads to an underestimation of the global warming impact of biogenic carbon emissions

associated with LUC. We have used a Time Correction Factor (TCF) to take into account the warming impact of LUC emissions over time. For very-short-rotation poplar and miscanthus, the most likely scenario (use of abandoned agricultural lands) does not lead to LUC emissions, while the less likely scenario (use of forested lands) leads to LUC emissions of 100 gCO<sub>2</sub>-eq/MJ for poplar, and 18 to 49 gCO<sub>2</sub>-eq/MJ for miscanthus if amortized according to IPCC guidelines. If a TCF is used, these emissions become 178 gCO<sub>2</sub>-eq/MJ for poplar, and 32 to 87 gCO<sub>2</sub>-eq/MJ for miscanthus.

### MO370

**Spatial analysis of fertilizers application on agricultural land: a case study for Luxembourg**

S. Bourrelly, Aix Marseille Université; A. Marvuglia, Luxembourg Institute of Science and Technology (LIST) / Resource Centre for Environmental Technologies CRTEResource Centre for Environmental Technologies CRTE; E. Benetto, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE

Agricultural soil is a major source of nitrous oxide (N<sub>2</sub>O), nitric oxide (NO) and ammonia (NH<sub>3</sub>). NO<sub>x</sub> and ammonia play a key role in atmospheric chemistry, but little information is available on emissions of these gases from soils amended with organic fertilizers at different soil water contents. In this study fertilizers emissions to soil, surface and groundwater and air have been calculated for the country of Luxembourg based on data collected from national statistics and elaborated using the PestLCI 2.0 tool [1]. The spatial distribution of the crops is known for the entire country on a GIS support, therefore it was possible to spatialize also the related fertilizers emissions and characterize the territory of each commune from the point of view of environmental contamination. An Ascendant Hierarchical Clustering (HAC) algorithm has been used to classify the communes on the basis of their contamination level [2]. The determination of the centre of gravity of each cluster allowed the definition of 5 profiles of environmental contamination conditioned to the spatial distribution of the polluting substances, thus identifying spatial patterns of dishomogeneity. The most contaminated communes resulted to be Wincrange, Rambrouch and Junglinster. The KHI2 null hypothesis of independence between the spatial distribution of the contamination profiles and the spatial distribution of the profiles of human presence has been rejected with a p-value of 0.0084. This value has been confirmed by a p.value.mc=0.015 computed with the Monte-Carlo method with 2000 runs [3]. Therefore it is not possible to establish a correlation between fertilizers emissions and human presence. In future research, data on pesticides emissions will also be used to carry out a similar analysis, also exploring the correlation with other spatially distributed variables, such as access to healthcare facilities, economic conditions of the inhabitants, incidence of diseases, etc. *Acknowledgement*— The authors wish to thank Dr. Ian Vázquez Rowe (Pontificia Universidad Católica del Perú) for his contribution to data preparation. ### MO371

**Investigating the characterization and weighting schemes for footprinting**

K. Fang, Leiden University / Institute of Environmental Sciences CML; R. Heijungs, Leiden University / Faculty of Economics and Business Administration Department of Econometrics and Operations Research

This investigation is intended not only to show the hidden characterization and weighting elements in footprint analysis, but also to discuss the implications for classification and integration of multiple footprints. Our results demonstrate that each of the carbon, water, land and material footprints has two fundamentally different versions, addressing elementary flows on the impact assessment or inventory level. The impact-oriented footprints based on characterization models allow a variety of elementary flows to be characterized in a way that is scientifically robust and environmentally meaningful, while the pressure-oriented footprints based on subjective weighting factors contribute to inventory analysis with the aim of maintaining the physical meaning of elementary flows which in aggregate correspond to the pressure exerted by human activities. These two footprint categories have their own pros and cons, and thus are not substitutes but complements. The findings conclude that while value-based weighting is unavoidable when integrating a suite of footprints into a single composite metric, the impact-oriented footprints have the potential to prevent the integrated footprint family from double weighting through the use of characterization factors for each of the footprints prior to weighting them. Following the general weighting procedure for life cycle assessment (LCA), we formulate a calculation framework for integrating a footprint family consisting of a suite of the impact-oriented footprints into an aggregated footprint index. Not only would this footprint index assist decision makers in better understanding the life cycle environmental performance of a product, which is the central element of product LCA, it would also provide an overall picture of a citizen, a company, a city, a country or the whole economy with its reliance on the planet's environment. This paper in our view can serve as a starting point for clearing the footprint jungle and, more importantly, for further scientific discussions and development of the footprint family. **P.S. We would appreciate it if you could let us know your decision on our submission by 5 January 2015, as Leiden University Funds**

**(LUF) will be able to support Kai Fang for his conference visit provided that the proof of acceptance of his presentation is received no later than that date.**

### MO372

#### **Local emissions, local impacts: how LCA may evolve to include local detailed damage estimates**

M. Cervino, National Research Council of Italy (CNR) / Istituto di Scienze dell'Atmosfera e del Clima; A. Ferrari, University of Modena and Reggio Emilia / Department of Sciences and Methods for Engineering; P. Neri, M. Pini, Università di Modena e Reggio Emilia / Dipartimento di Scienze e Metodi dell'Ingegneria; C. Mangia, Consiglio Nazionale delle Ricerche / Istituto di Scienze dell'Atmosfera e del Clima

LCA studies have the strength to investigate the life cycle to detect any relevant process and related emission that may impact on ecosystems and human health; but, almost all LCA has taken the shortcut of first summing the emissions over all stages and then multiplying the result by site independent impact indices (reaching at best the national or continental resolution); spatial and temporal details at the local scale impacted by site specific emissions (e.g. stack emissions) are not accounted for. Some procedures have been proposed to couple the LCA approach with methods that could provide more spatially detailed damage estimations. One is the IPA (impact pathway analysis) developed under the Externe project and following works; it aimed to track the fate of a pollutant from where it is emitted to the affected receptors (population, crops, forests, buildings, etc.). This work involves a multidisciplinary system analysis, with inputs from engineers, dispersion modellers, epidemiologists, ecologists and economists. Whether an IPA of a single source or an LCA of an entire cycle is required, in general depends on the policy decision in question. One of the most relevant part of such a coupled IPA and LCA approach is the modeling of pollutant spatio-temporal fate in actual environment and human populated areas. In recent decades there was a huge development in modeling technical knowledge, that allows to reconsider the results achieved by the Externe project and that is promising in providing new ways to be coupled with the LCA approach. Some of these features will be shown in a specific study regarding a relevant local emitter activity, one of the biggest European coal power plant located in Apulia, Italy: the LCA approach can help in identifying relevant emitted species at the site, while a well assessed dispersion modeling system with adequate information input categories (orography, meteorology, land use and georeferenced population) provides a detailed space-time exposure fields to estimate actual damage response. How to integrate and make a robust new procedure with the "good" of both the approach is the perspective of this work.

### MO375

#### **Spatial differentiation? Yes, but, not only for impact characterization!**

S. Le Feon, Irstea Rennes; M. Pradel, Irstea Clermont Ferrand / Ecotechnologies; L. Aissani,

Life Cycle Assessment (LCA) faces with spatial differentiation issues that have been discussed for years in LCA community. A 77 papers review reveals that the most commonly studied one is the lack of spatial consideration in the environmental impact characterization step. This issue was the first to be identified by Potting and Hauschild (1997). More recently number of developments aim to include spatial and temporal information during the Life Cycle Inventory (LCI) carrying out. If theoretical methodologies are available for LCI and characterization steps, we only found practical ones for the two others LCA steps (Goal and scope definition and Results interpretation) despite identified issues (to overcome multifunctionality). This fact can be seen as a paradox as for the life cycle thinking and the iterative, holistic and global aspects of LCA. That is why we propose to develop a conceptual framework to consider the spatial differentiation all over the four steps of LCA in a continuous and heterogeneous way. This framework is called "the spatialization continuum". The first steps of the building of such a conceptual framework consist in the identification of the existing theoretical and practical considerations of spatial differentiation in LCA and the potentiality to combine them towards a continuous methodology. Two questions are explored: For each step of LCA, what is necessary to ensure the spatial differentiation consideration? What does a development on a precise step involve to the other ones? The conceptual framework also set the objective to examine different tools that appear to be indispensable when dealing with spatial information and their potential coupling with LCA methodology and practices. Among these tools, Geographic Information Systems (GIS) are the most commonly used. However GIS appear not sufficient to overcome all the spatial differentiation related issues. In fact the spatialization continuum should ask for multiple external tools, methodologies or concepts. Therefore, the spatialization continuum materializes as a "multi-plugin" that will call for different solutions depending on the concerned issue and the required level of robustness. In this context, it differs from the classification of strategies to overcome LCA limitations proposed by Udo de Haes (2004): LCA extension, Hybrid LCA and Toolbox. We decided to call this new strategy the multi-plugin LCA.

### MO376

#### **Prioritise the regionalisation effort in LCA**

L. Patouillard, CIRAIG - École Polytechnique de Montréal; C. Bulle, CIRAIG - ESG - UQAM / Strategy corporate social responsibility; M. Margni, École Polytechnique de Montréal / Mathematical and Industrial engineering; P. Collet, IDEEL; P. Jayet, INRA

Life Cycle Assessment (LCA) regionalisation refers to the integration of the spatial variability that really exists to improve the result representativeness and reduce spatial uncertainties. Life Cycle Inventory (LCI) regionalisation deals with increasing the geographic representativeness modeled in the inventory. Life Cycle Impact Assessment (LCIA) regionalisation consists in taking into account spatial variability of receiving environment sensitivity to characterise some environmental impacts. Using regionalised characterisation factors (CF) require the spatialisation of elementary flows. As regionalisation requires additional effort for LCA practitioners, it is necessary to ensure the interest of such an effort and to prioritise it. As LCA is a decision support tool, LCA practitioners should try to reduce the LCA uncertainty level to the acceptable uncertainty level required by the decision maker. This work proposes a new methodology to prioritise the regionalisation effort in LCA depending on the decision context and the type of study. This methodology is based on spatial uncertainty analysis and allows the selection of impacts, processes and regionalisation aspects that LCA practitioners need to focus on. Its relevance and applicability is illustrated by a LCA case study of biofuel pathways. The proposed methodology is stepwise. First most relevant impact categories and processes to be further investigated for regionalisation are selected according to their impact contribution and their uncertainty level by using Monte Carlo simulation and regression analysis. Next, CF uncertainty is compared to inventory one to determine which aspects between LCI regionalisation or spatialisation should be prioritise. Finally, the resulting uncertainty level is compared with the confident level required by the decision maker by applying statistical test. The regionalisation effort is estimated depending on the confident level required for the case study. Results underline the importance to take into account both the impact contribution and uncertainty to select process to be regionalised. The proposed methodology highlights the need to focus on the goal and scope at the early stages of a study to clearly identify the intended audience and their requirements regarding study quality. A dialogue with the decision maker during the study will be beneficial. This approach could be relevant for other types of uncertainty but should be adapted.

### MO377

#### **A spatio-temporal framework for life cycle analysis of bioenergy**

A. Ajayebi, University of Exeter; M. Maier, The University of Exeter; M.D. Mueller, Agroscope Changins-Wädenswil Research Station ACW; X. Yan, The University of Exeter

Evaluating the environmental repercussions of bioenergy is affected by many uncertainties including those related to spatial and temporal variables. In this study we investigate the application of a dynamic life cycle analysis (LCA) methodology which takes into account both temporal and spatial variables. While numerous studies have attempted to investigate the sustainability of bioenergy, the conclusions have remained different or even contradictory. The necessity of performing dynamic LCAs for bioenergy derives from the wide variety of options that are available for the production of biomass, processing, logistics and the end use. By incorporating both time and location into the holistic structure of LCA, we attempt to provide a methodology that is capable of rendering precise analytic results within designated temporal and spatial resolutions. This methodology involves calculating a dynamic life cycle inventory (LCI) that enables us to perform environmental impact assessment for site- and time-dependent impacts. This hybrid approach is considered a major step forward in increasing the accuracy of sustainability assessment of bioenergy and in the exposure of the uncertainties.

### MO378

#### **Constructive geometries: Transforming "Rest of the World" into an actual place**

C. Mutel, ETH Zurich / Laboratory for Energy Systems Analysis; K. Volkart, Paul Scherrer Institut / Laboratory for Energy Systems Analysis

Modern life cycle inventory databases usually have detailed process data for a few countries or regions, and then average data for the "Rest of the World". This lack of spatial poses challenges for regionalized LCA. The ideal solution would be a global set of consistent geometries for provinces, countries, and regions which could be combined using set operations. Unfortunately, the current geometries provided by theecoinvent centre were developed ad hoc, and cannot be combined or subtracted without floating-point errors. I constructed such a set by creating a topology of the world, including all country and sub-country borders. The input data and scripts are available as an open source package called "Constructive Geometries" [1]. These geometries will form the future spatial definitions for theecoinvent life cycle inventory database. One key idea in this procedure is to have geometrical definitions at a low level, so that any larger geometries can be defined by added together their constituents. For example, the UCTE is defined by a list of countries (Andorra, Austria, Belgium...) and a list of additional provinces in Denmark (Nordjylland, Midtjylland...), as Denmark was split between the UCTE and NORDEL. This recipe-driven approach is much more consistent, reproducible, and transparent than previous manual GIS editing. The "Rest of the World" geometry can now be easily defined, as the union of the set of countries and provinces which are not otherwise defined for a given market. "Rest of the World" market mixes could also be defined, if basic country-level production data was available from e.g. input-output tables. [1] <https://bitbucket.org/cmutel/constructive-geometries>

### MO379

### **A general framework for regionalized life cycle assessment calculations**

C. Mutel, ETH Zurich / Laboratory for Energy Systems Analysis; K. Volkart, Paul Scherrer Institut / Laboratory for Energy Systems Analysis; S. Hellweg, ETH Zurich / Institute of Environmental Engineering

Comprehensive and global regionalized impact assessment (IA) methods, such as LC IMPACT and Impact World+, are now widely available. At the same time, modern life cycle inventory databases include detailed geometrical definitions for the location of each process. The key remaining methodological challenge to performing regionalized life cycle assessment is matching the different spatial scales of the method and database. IA methods normally have a spatial scale derived from physical patterns in space, such as climate or topology. Inventory databases, on the other hand, are usually defined by political boundaries. We have developed matrix formulae for four different matching scenarios. We have implemented these approaches in the open-source software Brightway2-regional [1]. The first scenario is the simplest - no matching is needed if the regionalized IA method and inventory database share the same spatial scales. In this case, the modification to standard LCA matrix math is relatively minor, and no GIS calculations are needed. The second scenario is to allocate inventory spatial units to IA spatial units based on intersected areas. Area is a relatively poor predictor of spatial patterns of industrial activity, so this option should only be used if no additional information is available. In the third scenario, additional data provided by the IA method developers is used to estimate how much of the inventory activity occurs in each IA spatial unit. For example, an IA method with a spatial scale of watersheds probably has background data on withdrawals from each watershed, which can be used as spatial allocation weights. Finally, we develop the idea of spatial extension matrices, which allow new data sources on a third spatial scale to estimate the spatial pattern of inventory data. This approach requires additional data collection, but is quite powerful. Our matrix formulae have a number of advantages. First, they allow reprojection of regionalized LCA results to each spatial scale, making visualization and interpretation easier. Secondly, while GIS calculations are required for most scenarios, they only need to be done once for each method and inventory database, meaning that LCA software can use pre-calculated values instead of integrating GIS logic. [1]

### **MO380**

#### **Application of the LC-IMPACT impact assessment method to ecoinvent**

C. Mutel, ETH Zurich / Laboratory for Energy Systems Analysis; F. Veronesi, NTNU / Department of Energy and Process Engineering; K. Volkart, Paul Scherrer Institut / Laboratory for Energy Systems Analysis; S. Hellweg, ETH Zurich / Institute of Environmental Engineering

LC-IMPACT is a new, comprehensive and global impact assessment method that provides spatially differentiated characterization factors for water use, land use, terrestrial acidification, freshwater and marine eutrophication, toxicity, and particulate matter. Regionalized characterization factors are available in a standardized format. We describe how to systematically apply LC-IMPACT to the ecoinvent inventory database. The methodology for regionalized impact assessment is now well developed, and the key area of difficulty when combining inventory databases and impact assessment methods at appropriate spatial scales is the choice of spatial allocation weights [1]. A naive approach is to use the relative intersected areas of each inventory and impact assessment spatial unit. However, this approach produces incorrect results when inventory activities are not uniformly distributed in space. Additional data, which we call extension matrices, can be used to approximate the spatial pattern of inventory activity; these extension matrices would be industry-sector specific. We illustrate this concept with global maps of agricultural activity and GDP-weighted population density. The ecoinvent inventory database provides detailed spatial data for each inventory process [2]. However, the location "Rest of the World" is widespread – almost one quarter of all processes in ecoinvent 3.1 - but this location has no provided spatial definition, but rather is defined dynamically as whatever isn't covered by more specific datasets. We developed a new global topology of consistent and reproducible geometries for all countries, provinces, and ecoinvent-specific locations. We also developed a method, which we call constructive geometries, that can dynamically generate geospatial definitions for the "Rest of the World", making regionalized assessment of these processes possible. We compare regionalized impact assessment scores for a selection of processes from ecoinvent 3.1. The use of extension matrices produces more detailed and less uncertain scores, at the expense of complexity. More complete spatial disaggregation of the ecoinvent database is needed to realize the potential of regionalized LCA with consistent, global methods like LC-IMPACT. [1] Mutel, C. and Hellweg, S. Computational Methods for Regionalized Life Cycle Assessment. In Submission. [2] Geometry definitions in ecoinvent. Draft Report, available at <http://geography.ecoinvent.org/report/>

#### **Carrying capacity based normalization references at the endpoint level**

A. Bjorn, Technical University of Denmark / Department of Management Engineering; C. Bulle, CIRAIG - ESG - UQAM / Strategy corporate social responsibility; M. Margni, Ecole Polytechnique de Montreal / Mathematical and Industrial engineering; M. Hauschild, DTU Management Engineering

The popularity of the ecological footprint method and the planetary boundaries concept shows an increasing interest among decision makers in comparing

environmental impacts to carrying capacities of natural systems. Recently carrying capacity based normalisation references were developed for impact categories at the midpoint level in LCA. Building on this work we propose two sets of global average normalisation references compatible with the endpoint categories compiled in the Impact World+ methodology. The first set of references was based on a translation of the science-based thresholds for which the midpoint normalization references were based, combined with the use of additional thresholds for impact categories not covered by those references. The second set of references was based on defining carrying capacity as a consistent level of species protection at endpoint, here HC5(NOEC), the concentration at which maximum 5% of species are affected above their no observed effect level. The resulting endpoint normalisation factors were together with the existing references at midpoint applied to a life cycle inventory of food consumption in Denmark. The ranking of normalised impact scores for the different impact categories was compared for the three approaches to carrying capacity-based normalisation. The ranking was found to differ considerably between the approaches with the implication that the results only partly agreed on how to prioritise impact reduction efforts of Danish food consumption. Moreover large differences between the absolute values of normalised impacts were found between the three approaches for some impact categories, meaning that Danish food consumption may appear environmentally sustainable when using one set of normalisation references and unsustainable when using another set of references. This work expands the applicability of carrying capacity-based normalisation and furthermore shows the influence of value choices in the quantification of carrying capacity.

### **MO382**

#### **Recommended impact assessment methods for ILCD and Environmental Footprint: challenges, opportunities and updates**

S. Sala, European Commission DG Joint Research Centre / Institute for Environment and Sustainability Sustainability Assessment Unit; J. Dewulf, EC JRC - IES / Sustainability Assessment unit; L. Benini, JRC Institute for Environment and Sustainability - European Commission / Sustainability Assessment unit; S. Fazio, Institute for Environment and Sustainability; R. Pant, European Commission DG Joint Research Centre / Institute for Environment and Sustainability Sustainability Assessment Unit

Within the International Reference Life Cycle Data System (ILCD) Handbook, 14 methods were recommended for impact assessment in LCA. The Product Environmental Footprint (PEF) builds on these recommendations. The ILCD analysis, evaluation and selection of recommended methods refers to methods available by 2008. Several impact categories have experienced a significant development and should be subject to updates in ILCD. Thus, there is the clear need for an update of the recommendations both from a harmonisation perspectives as well as for scientific credibility. In the context of the PEF, the EC-JRC is in the process of updating ILCD recommendations, focusing mainly on 4 impact categories, namely: water depletion (WD), resource depletion (RD), land use (LU) and respiratory inorganics (RI). In order to support an update of the ILCD and PEF recommendations a three-step evaluation procedure has been put in place: i) qualitative screening for newly developed methods, ii) benchmark among the available methods; iii) applicability analysis with reference to life-cycle inventory data and elementary flows. This approach will ensure identifying not only the (theoretically/scientifically) best LCIA method but also whether there any significant gaps in LCI data availability to feed the LCIA models or issues regarding unexpected results and anomalies that need further attention. The limits of the LCIA methods related to day-to-day applicability will be carefully evaluated and some results of the screening are provided. As regards the LU, it seems reasonable to expand the LCIA method, at least at mid-point level, accounting more than one impact category, considering the multi-functionality of land. The selection of method(s) was also based on the availability of scientific literature and case-studies, and in order to facilitate the applicability with the currently available datasets containing inventory data on LU. Concerning WU, special attention is given to aspects such as consumptive use only vs. overall withdrawals, spatial differentiation, temporal scale environmental water requirements, as well as the applicability of the methods to currently available datasets. In case of RD, the three-step evaluation procedure is preceded by a careful consideration of what should be assessed in terms of impact on the Area of Protection Natural Resources (AoP), given the poor substantiation of this AoP in the LCA community so far.

### **MO383**

#### **Coupling nutritional and environmental aspects of food and beverage: how could it be tackled?**

F. Recanatì, Politecnico di Milano; G. Dotelli, Politecnico di Milano / Chemistry Materials and Chemical Engineering G Natta; P.A. Melia, Politecnico di Milano / Elettronica Informazione e Bioingegneria; P. Gallo Stampino, Politecnico di Milano / Chemistry Materials and Chemical Engineering G Natta; A. De Luca, Politecnico di Milano; A. Vesconi, Politecnico di Milano / Chemistry Materials and Chemical Engineering G Natta

Environmental sustainability of food is one of the most relevant issues within the sustainable development context. Since the primary scope of food is nutrition, environmental aspects should be assessed adopting an integrated approach with nutritional ones. In order to tackle this integration, in the present study a multi-criteria indicator coupling nutritional quality and environmental impacts

categories is developed. After a thorough survey of the scientific literature, a certain number of food and beverage products belonging to different food groups (i.e. proteins, vitamins, carbohydrates and beverage) were selected. Each one of the selected products was characterized in terms of both environmental and nutritional terms. At first instance, only two indicators are taken into account concerning environmental dimension: carbon footprint (adopting characterization factor estimated by IPCC, 2013) and water footprint, calculated following the recently published ISO 14046. The nutritional quality of food and beverage is addressed through the use of three indicators: the Fullness Factor indicator, the Nutrient Rich Food Index and the Calories for Nutrient. The Fullness Factor (developed basing on data provided by USDA's National Nutrient Database for Standard Reference) is a dimensionless index which tries to quantify the satiety of a food or recipe, consisting in a multivariate analysis involving a weighted sum of value of main nutrient content values (i.e. calories, proteins, fibres, lipids). The Nutrient Rich Food Index is a consumer-driven index recently developed by Drewnowski (2010) and based on 2005 Dietary Guidelines; the calories for nutrient is an elaboration of the energy content referred to nutrients (Drewnowski, 2005). Basing the present analysis on the above mentioned indicators, a global assessment tool which takes into accounts both nutritional and environmental aspects has been devised and tested against dietary approach. A. Drewnowski, *Am J Clin Nutr* 2005;82:721–32 A. Drewnowski, *Am J Clin Nutr* 2010;91(suppl):1095S–101S

### MO384

#### How environmentally significant are water consumption and water impact assessment approaches for microalgae cultivation systems?

m. cornelus; P. Collet, IDEEL; A. Helias, INRA

The first generation of biofuels has been largely criticized due to its rising effect on market prices, damages to biodiversity and land competition with food crops. Microalgae-based biofuels are looking promising with high production yields and no direct competition with arable lands. Nevertheless, its large-scale production gives rise to a serious concern about the impact on water usage. As a consequence, it is crucial to assess the water consumption on the entire life cycle to be aware of the intensity of its water withdrawal indicator. Several studies have focused on water in microalgae cultivation and tried to assess this issue. Nonetheless, for an appropriate assessment of water use, regionalization is crucial to capture hydrological conditions. Recent methodological developments on water resource analysis in Life Cycle Assessment (LCA) have been pursued. Those new approaches fulfil the same goal as the current models assessing water quality (ecotoxicity, acidification and eutrophication). Pfister et al. calculated a Water Stress Index (WSI) as a characterization factor for a midpoint category “water deprivation”. According to Pfister et al. the use of freshwater can affect the three areas of protection: Human Health, Resources and Ecosystem. Motoshita et al. developed an impact pathway of water scarcity on domestic users. Boulay et al. studied consequences of water scarcity and proposed an approach including compensations. The purpose of this paper is to undertake a life-cycle water footprint assessment of different cultivation systems related with specific location and temporal period. In the current study an LCA is conducted on two systems: open-raceways and photobioreactors cultivating *Chlorella vulgaris*. To our knowledge this is the first time that LCA is used to apply recent developments in LCA about water resource based on WSI to different microalgae cultivation systems. For both systems, the water withdrawal and returned water are mainly due to evaporation and cleaning process. The evaporation flows were calculated based on meteorological data, empirical formula and design hypothesis as the cleaning water output flows were. The results of LCA have been discussed at two stages: midpoint and endpoint levels. Yearly and monthly water stress indicators have been applied on the couples system/location. Conclusions about system water footprints were highly dependent on location and seasonal period.

### MO385

#### Environmental impact of freshwater consumption due to dietary patterns in Mediterranean countries

C. SINFORT, Montpellier SupAgro / ELSA Group UMR ITAP; E. Paolo da Silva, ESALQ; S. Drogue, INRA / UMR MOISA; G. FERRARI, INRA; N. DARMON, M. AMIOT-CARLIN, INRA / UMR NORT

The type of diet consumed in a given region (how foods are combined) influences environmental impacts considering how and where foods are produced. LCA offers a global methodology to evaluate such impacts. This study focusses on freshwater consumption and the objectives are to propose a method suitable for the evaluation of the impacts of a national diet taking into account the origin of the raw food materials and to apply it in the case of Mediterranean diets. A list of 254 food items commonly consumed in France and the corresponding quantities consumed each day on average by a representative sample of French adults were derived from two national surveys conducted in 2006–2007 by the ANSES (French agency for food, environmental and occupational health safety): the EAT2 and INCA2 surveys, respectively. Corresponding raw food product amounts were computed knowing the composition of each food product and losses between national supplies and food intake. Water consumption was then obtained per raw product and per country combining data on international trade and economic data (UNComtrade and FAOSTat databases) with blue water national data (Mekonnen and Hoekstra, 2011 and 2012). Finally, a freshwater ecosystem impact (FEI) was computed, as suggested by Mila I Canals (2008), taking Water Scarcity Index (WSI) data

computed by Pfister (2009) as characterisation factor. Freshwater ecosystem impacts of the French diet were computed and reported on global world maps. The same scenario (same diet) was also applied with Tunisian market data to evaluate the importance of the origin of the products: it appeared that the total FEI would be 7 times higher if the products were originated from Tunisian market. Applying the method, uncertainties in raw product origin and incompatibilities with databases appeared, inducing hypotheses that are explained and discussed. Computations were made with blue water values averaged per year and per country and the pertinence of such spatial and temporal scales is discussed as well.

### MO386

#### Fate factors for airborne contributions to acidification, eutrophication and photochemical ozone formation in Brazil

N.C. Mendes, DTU Management Engineering; A. Laurent, Technical University of Denmark / DTU Management Engineering; A. Ometto, Universidade de Sao Paulo / Departamento de Engenharia de Produção Escola de Engenharia de São Carlos; M. Hauschild, DTU Management Engineering

Brazil is the largest country in Latin America. Its extensive geographical area, with important variations in population density and environmental properties makes it difficult to properly assess environmental impacts using site-generic characterization factors. The application of spatially-differentiated Life Cycle Impact Assessment (LCIA) methods could better capture the differences of climate, topography, soil, fauna, flora and diverse activities of each region in Brazil. In this context this work aims to provide a first step towards spatially-resolved characterization factors for acidification, eutrophication and photochemical ozone formation in Brazil. Fate factors (FF) for airborne pollutants, i.e. nitrogen oxides, sulfur oxides, ammonia and non-methane volatile organic compounds (NMVOC), contributing to these impacts were thus determined from source-receptor matrices (SRMs) based on simulations at a 2° x 2.5° grid resolution. The simulations were performed by GEOS-Chem v9-02 model, which was assessed as the most comprehensive and robust model for the purpose of the study. The resulting fate factors were analyzed with respect to their variations across the country and were compared with the fate factors developed at global scale as used in the recently-released IMPACT World+ LCIA methodology. The observed large variations between grid scales within and across the states of Brazil demonstrate the relevance of spatial differentiation of the fate factors. To adapt to frequently unspecified emission data, possible alternatives to divide the country in regions, at which meaningful aggregated characterization factors could be derived, was investigated using criteria such as states division, biomes, climate or GDP distribution. These division approaches however need to be revised with additional consideration of exposure and effect factors. The developed fate factors can therefore support the development of more environmentally relevant characterization modelling of acidification, eutrophication and photochemical ozone formation impacts in Brazil.

### MO387

#### USEtox 2.0: Recommended characterization factors for human and freshwater ecotoxicity for new and updated substances, exposure pathways, and regions

P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment; O. Jolliet, University of Michigan / Environmental Health Sciences School of Public Health; M. Huijbregts, Department of Environmental Science; M. Margni, Ecole Polytechnique de Montreal / Mathematical and Industrial engineering; T.E. McKone, University of California / School of Public Health; R.K. Rosenbaum, National Research Institute of Science and Technology for Environment and Agriculture - Irstea / UMR ITAP; D. van de Meent, RIVM / DMG; M. Hauschild, DTU Management Engineering

USEtox is the UNEP/SETAC scientific consensus model for assessing human toxicological and ecotoxicological impacts of chemical emissions. The model is being widely used in comparative toxicity assessments and officially endorsed by the UNEP/SETAC Life Cycle Initiative since May 2013. We present the next official release version, USEtox 2.0. The new USEtox 2.0 provides midpoint and endpoint characterization factors for human toxicity and freshwater ecotoxicity for more than 4000 organic and inorganic chemicals. Major improvements and scientific consensus have been achieved for including into the new USEtox 2.0 the following updates: (a) ionizing organic chemicals, (b) residential and occupational indoor environments, (c) exposure to pesticide residues via food crop consumption, (d) generic freshwater ecotoxicity for metals, (e) 900+ new substances and updated substance data, (f) continent- and sub-continent-specific landscape parameters, and (g) a user-friendly and intuitive user interface. With these updates, USEtox contributes to addressing the high demand for improving the characterization of toxic chemical emissions and is readily operational for use in life cycle assessment, footprinting and other comparative assessments. The new USEtox 2.0 model and factors can be exclusively accessed free of charge at <http://usetox.org>.

### MO388

#### Integrating real metal runoff data to the life cycle assessment of alloys

S. Roos, Swerea IVF AB / Chemical Engineering; C.J. , Swerea IVF AB; J. Hedberg, I. Odnevall Wallinder, The Royal Institute of Technology (KTH); C. Kaplin, Outokumpu Stainless AB

One of the most commonly used qualities of stainless steel is the AISI grade 304,

typically consisting of 18 wt% chromium, 8 wt% nickel and 74 wt% iron. When the life cycle performance of alloy products and metals processing is described in life cycle assessment (LCA), several sources for errors exist. The research presented here aims to investigate whether the modelling of metal runoff from stainless steel surfaces is an important factor for its life cycle performance. A stainless steel roof is chosen as a case study in which two ways of modelling of metal runoff is exerted: (1) based on the individual alloy components, and (2) based on measured long-term runoff data (4 years) from the alloy at field conditions. A life cycle assessment of a stainless steel roof was performed for a base case and an alternative case. The use phase was in the base case modelled with metal runoff data based on experimental findings for the main individual alloy components (Fe, Cr, Ni), and in the alternative case with runoff data based on long-term metal runoff measurements at urban conditions for an AISI grade 304 steel. The modelling of the metal runoff data showed to have a great importance for the end result. The results from the case study also compared the order of magnitude of the modelling of metal runoff as an error source, and compared this with two other error sources: the LCIA and the data inventory of the metal production. All three error sources showed to have large influence on the end result, but that the metal runoff data was the error source of largest importance. We therefore suggest that real observed metal runoff data will be integrated in future LCA studies of metals and alloys.

### MO389

#### **Integration of the metal bioavailability in freshwater for the ecotoxicity footprinting with the USEtox™ model database**

J. Cettier, Cycleco; O. Hugonnot, ToolsEnv; J. Payet, Cycleco

**Keywords:** Bioavailability factor, metals, USEtox™ model Many pollutants are found in the environment with several physicochemical properties which provide different behaviours. Metals behaviour differs from organic compounds: they are infinitely persistent, octanol-water partition doesn't predict their tendency to bioaccumulate and only the truly dissolved fraction is considered to be bioavailable. For these reasons, physicochemical properties to take into account for metals in the USEtox™ model differs from organic compounds. The USEtox™ model was developed under the UNEP-SETAC Life Cycle Initiative, by a team of researchers, and provides the state-of-the-art for the ecotoxicological impact assessment of substances. Conscious of the specificity of metals and the need to take into account bioavailability to avoid overestimation, we wished to update the characterization factors (CF) available in the ecotoxicological footprinting database using the USEtox™ model. Dong et al. (2014) publication provided CF for 15 cationic metals. The  $K_{ps}$  and the  $K_{DOC}$  were calculated with the model WHAM 7.0 which takes into account the equilibrium-based metal speciation model, for a specific water chemistry. Physicochemical parameters and Effect factors (EF) from Dong et al. were implemented preferentially. If not available, the EF came from the AiIDA database and the physicochemical parameters came from the USEtox™ inorganic database, from Echachem database or finally estimated by calculation. The landscape was changed to approach a representative European freshwater river and physicochemical parameters of metals were selected for this same river. Updates relate to the 15 cations from the Dong et al. publication and the seven cations from the USEtox™ inorganic database. Changing  $K_{ps}$  and  $K_{DOC}$  found by Dong et al. in the ecotoxicological footprinting database allows to find the same bioavailability factor (BF). This shows that other physicochemical parameters implemented before this work don't have a significant impact on this factor. The new CF for the freshwater range from  $9.6E^0$  (Fe III) to  $1.1E^6$  (Cd II). From now on the ecotoxicological footprinting with the USEtox™ model database, the bioavailability of the metals are taken into account in the CF calculation. This is now available in the online database for 22 cations. Up to now, BF existed in recent publications but had not been yet implemented in models to calculate CF.

### MO390

#### **Including zinc speciation in LCA terrestrial ecotoxicity: does it make a difference for LCA results?**

G. Plouffe, CIRAI-École Polytechnique de Montréal / Chemical Engineering; C. Bulle, CIRAI-ESG - UQAM / Strategy corporate social responsibility; L. Deschenes, École Polytechnique de Montréal / Génie Chimique Metals are often the main contributors to ecotoxicological impacts in life cycle assessment (LCA), mainly because models were developed initially for organic compounds and are applied without distinction to metals even if their properties differ greatly. A framework has been developed for including metal speciation in freshwater ecotoxicity by integrating a bioavailability factor in the characterization factor definition and by using freshwater archetypes to consider the spatial variability of the physicochemical parameters influencing speciation. The goal of this project was to determine the importance of including zinc (Zn) speciation in terrestrial ecotoxicity in LCA. A case study on the ecoinvent *market for electricity, low voltage CA-QC* data was carried out using the IMPACT 2002+ methodology. Results obtained using present terrestrial ecotoxicity characterization factors (CFs) from IMPACT 2002 were compared to results obtained using new regionalized CFs that take Zn speciation into account. These CFs were obtained by using modified USEtox fate factors, WHAM 6.0 derived bioavailable factors and effect factors calculated using the AMI method with available terrestrial ecotoxicity data. Generic default CF values for the world based on either soluble or true solution (free ion and ion pairs) Zn as well as minimum and maximum regionalized CF values were tested in this study. Results indicate that for this specific case study, the contribution of Zn

emitted to soil to the terrestrial ecotoxicity impact score falls from 26% to a maximum of 1.27%, impact scores being reduced by 1.44 to 14.37 orders of magnitude, when Zn speciation is taken into account. Also, when including Zn speciation in terrestrial ecotoxicity, the total terrestrial ecotoxicity and ecosystem quality impact scores decrease by approximately 25% and 21%, respectively, and among the major contributors to terrestrial ecotoxicity, Zn falls from the 2nd to between the 9th and 255th position. Results show that integrating Zn speciation into the CF definition highlight the significance and feasibility of accounting for metal speciation in soil in an LCA context.

### MO391

#### **TOX-TRAIN: the user-friendly toolbox for human and ecotoxicity assessment in LCA**

X. Bengoa; M. Birkved, Technical University of Denmark; P. Fantke, Technical University of Denmark / Quantitative Sustainability Assessment; S. Humbert, Quantis; S. Sourisseau, VEOLIA Environnement Recherche et Innovation; R. Van Zelm, Radboud University

It is estimated that 10 to 20 thousand different chemicals are regularly used in the life cycle of products, many of which can potentially have harmful effects on humans or ecosystems. Industries are more and more interested in understanding the toxicity of their products constituents and are willing to act on their supply chain to reduce the amount of dangerous substances emitted through all stages, from manufacturing and processing to end-of-life. The four-year EU-funded TOX-TRAIN<sup>1</sup> project aims at creating a user-friendly toolbox based on the scientific consensus model USEtox<sup>®</sup> and promoting this model, in order to assess human toxicological and ecotoxicological impacts related to emissions over the life-cycle of technologies. Developed under the supervision of the Life Cycle Initiative lead by the UNEP-SETAC, USEtox<sup>®</sup> assesses such impacts for numerous chemical substances<sup>2</sup>. The main output of TOX-TRAIN will be a toolbox that combines the official USEtox<sup>®</sup> model with additional assessment tools in a user-friendly interface along with a full documentation TOX-TRAIN has already achieved several of its objectives. A thorough literature review of existing chemical inventory models was made, which led to the development of the sewage emission model SewageLCI<sup>3</sup>. This model is based on a set of chemical and national input parameters capable of quantifying the fraction of a chemical emitted to sewage systems ending up being subsequently released to the individual USEtox<sup>®</sup> emission compartments. Exposure models for household, workers, and direct exposure were developed and will constitute additional modules of the TOX-TRAIN toolbox. Characterization factors for persistent bioaccumulating chemicals, persistent active surface chemical compounds, pesticides and biocides have been developed and their uncertainty quantified<sup>4</sup>. All these developments will be tested and evaluated in case studies. Finally, several courses and workshops have been organized at different venues to inform and train on USEtox<sup>®</sup> and its application within the LCA framework. Outputs and development from TOX-TRAIN will all become publicly available and will be evaluated for future integration into USEtox<sup>®</sup>.

### **LCA of complex systems: delusion or reality? (P)**

### MO392

#### **Integration of simple LCA into complex systems: the CaSIE<sup>2</sup> project**

E. Lees-perasso, CODDE; J. Orgelet, Bureau Veritas CODDE / EcoDesign; P. Ravel, G. Sibiude, N. Couillaud, CSTB Recent scientific, technical and normative works insist on the relevance of life cycle assessment (LCA) as a methodology to evaluate the environmental performance of materials, systems and buildings. Though, those systems are complex by nature, evolving numerous subsystems, elements and materials and, particularly at building scale, a long service life. They interlock and overlap with one another, making any evaluation a long and fastidious task. In order to allow a better diffusion of the LCA practices, the building sector have to adapt and to acquire operational decision-making LCA tools that can be used by all actors while reducing the complexity and amount of work required. The CaSIE<sup>2</sup> project has been launched in order to answer this need. This study will be supported by the ELODIE and EIME software. It will be providing a simplified environmental impact calculator for equipment systems. This tool will be used by the building sector to facilitate conception, calculate, decide and communicate on the environmental aspects of their products, building-integrated equipment. Ultimately, it will lead to global optimization of building systems (energy and environment) and could provide a decision-aid to define coherent environmental policies towards the definition of energy-plus building French regulations. In order to achieve this goal, some issues need to be solved. One of the main aspects to deal with is related to the heating, ventilating and air conditioning (HVAC), and the electric and electronic equipment (EEE). The integration of their environmental evaluations within building systems is confronted to multiple issues: lack of reliable and compatible data on some equipment, characterisation methods and perimeter compatibility issues, and a reduced accessibility to information about system dimensioning (quantity and type of installed equipment within a complex system). This presentation focuses on the first step of the project and aims at identifying and describing the main issues faced when dealing with the integration of HVAC and EEE within building complex systems. This work will lead to the definition of the CaSIE<sup>2</sup> tool methodological and technical requirements.

### MO393

#### Life Cycle approaches for holistic assessment redevelopment urban projects (brownfields)

C. Hidalgo, LEITAT Technological Center / RD Safety Sustainability Division; M. Escamilla, LEITAT / Sustainability Unit; J. Boronat, L. Nadal, Medi terra; G. Louwagie, European Environment Agency

In many cities there are abandoned or under-used industrial areas, which were developed previously and can have residual in-situ contamination from earlier activities. These areas, also called brownfields, can be remodelled in order to satisfy the increasing demand for new urbanized areas with different purposes, including residential, infrastructure or green areas. Urban planning actions have associated environmental impacts over a long time period, as the result of planning conditions the behaviour of cities over several years. From a sustainability point of view considering all life cycle stages, including early stages, is desirable. Holistic approaches supported by comprehensive tools are needed to guarantee this view. Existing literature suggests that the environmental impacts of brownfields projects are not considered in a holistic manner. Usually only specific aspects such as selected impacts from remediation or construction activities are assessed. Therefore, applying the Life Cycle Assessment (LCA) approach to brownfield developments is seen as a good opportunity to assess their overall environmental profile and identify possible management improvements. Recently EEA has led a study to explore the feasibility of applying LCA approach to reusing brownfields as part of urban planning. Three case studies were analysed including two brownfields and a greenfield (non-urbanised area). The study includes all life cycle stages and the associated impacts: i) primary impacts, associated with the site status including soil and groundwater contamination; ii) secondary impacts, related to the development stage (soil investigation and remediation, demolition of existing buildings, levelling works, infrastructures construction and construction of new buildings); and iii) tertiary impacts, associated with the use of the site after development. Outcomes from the study show potential to successfully apply life cycle thinking approaches to brownfields and urban (re)development projects. The selection of a representative functional unit (depending on the planned use, the surface, the built surface, or the number of residents/users) proved to be a key parameter affecting the results. The findings show that, for the three cases, the most relevant life stages in terms of environmental impacts are the use stage (with a duration of 20 years), as well as the development stage with important contributions from the construction of new buildings and construction works.

### MO394

#### Where to look for the complexity of EcoInvent v3 process networks?

T. NAVARRETE GUTIERREZ, CRTE CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; A. Marvuglia, Luxembourg Institute of Science and Technology (LIST) / Resource Centre for Environmental Technologies CRTE; Resource Centre for Environmental Technologies CRTE; B. Rugani, Centre de Recherche Public Henri Tudor (CRP Henri Tudor) / Centre de Ressources des Technologies pour l'Environnement CRTE; E. Benetto, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE

The latest ecoinvent database (version 3.1) includes several new features like updated and new datasets, and more system models. As the database improves in quality and features, one could assume that its representation of the complex real world is also improved. One way to confirm or deny this assumption is by looking at the structure of the process network of the database and evaluate its degree of complexity, when compared to other networks known to be complex (that is, that they exhibit non-trivial characteristics absent in random networks). With this in mind, we shall present a comparison of the graph obtained from the ecoinvent version 2 database and the one of version 3. We are interested in measuring the graph following traditional network analysis methods to characterize each network. The measures include determining the importance of a node, in regard to the number of paths that go through it, or the number of neighbours, as well as the diameter of the network. Creating such graphs allows to compare both graphs (ecoinvent v2 and v3) against each other, but also against well equivalent complex networks of the small-world family, random networks, and scale free networks (of the Barabasi-Albert family). Different libraries for network analysis, including NetworX and igraph, scripted through the Python language. Also, we used implemented different algorithms present in the literature using R. Finally, gephi was used for creating the figures depicting the graph structure. Preliminary observations suggest that although the ecoinvent networks are definitely not random, they exhibit some characteristics also present in scale-free networks (power law distribution of the cumulative degree distribution), but not those of small-world networks (short average path length, high clustering coefficient).

### MO395

#### Agent-based modelling for consequential life cycle assessment of policies fostering multi-modal mobility in Luxembourg: the CONNECTING project.

F. Querini, Resource Centre for Environmental Technologies CRTE; T. NAVARRETE GUTIERREZ, CRTE CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; T. Ma, CEPSINSTEAD Social & Economic Research Centre; E. Benetto, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; P. Gerber, CEPSINSTEAD Social & Economic Research Centre

Passenger cars, which heavily rely on the internal combustion engine, are the source of several environmental burdens, from contribution to climate change to urban air pollution. To reduce its environmental impact, sustainable transport policy focuses on promoting the use of less pollutant alternative means of transport (e.g. bicycle, train, bus) and the development of "green" vehicles (e.g. hybrid or electric vehicles). Attributional life cycle assessment (LCA) usually aims at assessing either the environmental impact of one means of transport or comparing two, using simplifying generic hypotheses. In CONNECTING, we aim at assessing the impacts at the policy level, which could be for instance the installation of charging infrastructure at railway station public parking, decreasing train ticket prices. For this purpose, we develop an agent-based model (ABM), which simulates a population of commuters in the cross border area of Luxembourg taking various transportation means to go to work. These commuters, represented in the model by agents who have their own characteristics (purchase power, mobility needs, personal behaviour, etc.), can interact with each other and react to external stimuli. This ABM is fed by numerous data at both macro-level (e.g. national statistics) and micro-level (e.g. individual surveys). The ABM is then coupled with an LCA model, which calculates the environmental impacts of the agents. The model is first run without a specific policy and the sum of the environmental impacts corresponds to the reference situation. Then, the policies under study are applied to the model and their consequences are evaluated as the difference between the results obtained and the reference. The ABM-LCA coupling differs from traditional consequential LCA, where scenarios or economic macro-modelling are used to derive inventories. In this project, the impact of the policies is the result of the interactions of a large number of individual decisions, which is not known *a priori* (contrary to the more conventional scenario approach). Additionally, CONNECTING aims at fostering the dissemination of LCA to policy makers through a collaborative approach and by developing tools allowing policy makers to interact with the model, influencing the policies during the course of the simulation and visualizing the results.

### MO396

#### Life Cycle Assessment of Power-to-Gas for Integrated Energy System Analysis

X. Zhang, Laboratory for Energy Systems Analysis; C. Mutel, Paul Scherrer Institute / Laboratory for Energy Systems Analysis; C. Bauer, Group Environment, Health & Safety

The future Swiss electricity supply system is expected to rely strongly on stochastic renewable generation such as photovoltaic and wind power. As a consequence, more and more flexibility is required and storage technologies and conversion of different types of energy carriers will play a vital role in the integrated energy systems of the future. As part of the recently established "SCCER Storage<sup>[1]</sup>" research center, integrated assessment for various storage technologies will be performed to better understand the impacts of these technologies in terms of environment, economy and their technology performance, and how they could be integrated into the Swiss energy system in the future. Life Cycle Assessment (LCA), as a key component in the technology assessment framework, has been applied to investigate the environmental impact of these technologies. In this poster, an example of how LCA is performed for technology assessment within the complex overall energy system is going to be presented based on a case study on the power-to-gas system that is going to be built in Switzerland. The system is designed to convert electricity generated from renewable energy to hydrogen through electrolysis. The hydrogen generated is further reacted with carbon dioxide to produce methane, which will be dehydrated, compressed and eventually supplied to power cars. The work addresses LCA-implications of using methane from the power-to-gas system versus employing natural gas from conventional gas grid, and more importantly, it demonstrates an example of how LCA of storage technology is performed differently from the conventional LCA applications, and how the results fit into the broader analysis of an integrated energy system. <br clear="all" /> [1] Swiss Competence Center for Energy Research - Heat and Electricity Storage: <http://www.sccer-hae.ch/>

### MO397

#### Environmental impact assessment of rail freight intermodality

A.L. MERCHAN, University of Liege / Applied Chemistry

The European Commission's White Paper on transport [1] seeks to achieve an efficient and sustainable balance between the various transport modes. In this context, BRAIN-TRAINS is a project supported by Belgian Federal Government that deals with rail freight intermodality, approaching the problem from an interdisciplinary perspective. BRAIN-TRAINS will be able to answer the transition involved in transportation in Belgium. Environmental impact studies on intermodality transport show that rail freight transport is the land-based transport that has a higher environmental performance (more fuel-efficient shipping alternative) compared to intermodal road-rail and all-road transport [2]. This is especially the case when electrified railway is used. But there is not always a direct rail link, so the intermodal road-rail transport is generally shown as the best alternative. The increased demand for rail transportation raises the need for the expansion of the railroad system and the environmental effects that infrastructure construction entails should be taken into account. Life Cycle Assessment (LCA) methodology allows us to model as best as possible the environmental impacts of several pollutants in numerous categories: CO<sub>2</sub>, NO<sub>x</sub>, SO<sub>x</sub>, NMVOC, particles, and CO<sub>2</sub> emissions. For other categories such as accident damages, noise impact and

land use, new developments have to be performed. For the environmental impact assessment of the Belgium rail freight intermodality, all lifecycle phases of rail freight transport operation, rail infrastructure (construction, maintenance and disposal), and rail equipment (manufacturing, maintenance and disposal) are taken into account [3]. **References** [1] European Commission (2011) *White Paper on transport. #### **A Probabilistic Fuzzy Multiobjective Linear Programming Model to Design Reverse Logistics Networks Based on Life Cycle Assessment**

W. Ocampo-Duque, L.I. Duque, Pontificia Universidad Javeriana Cali / Industrial Engineering; O.O. Ortiz, Universidad de Pamplona / Industrial Engineering; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering  
Vehicles in cities generate thousand of tires as hazardous wastes. Such wastes produce serious environmental problems due to their inappropriate management and disposal in developing countries. Therefore, adequate final treatments with lower environmental impacts are required. The aim of this study was to develop a probabilistic fuzzy multiobjective linear programming model to design a reverse logistics networks to deal with management of used tires produced in a Colombian region. The model considered both environmental and economic objectives. The proposed network included diverse activities such as picking, selection, and primary uses of tires. Incineration in cement kilns, crushing and retreading were also considered. The network included secondary uses to produce floor coverings, modified asphalts, and wires. The CML-2001 method was used for Life Cycle Assessment to quantify environmental impacts of the logistics network. The multiobjective model was solved with a hybrid method combining fuzzy mathematical programming and  $\epsilon$ -constraints. The model solution involved linear programming with fuzzy numbers in objective functions and constraints. Acceptable feasibility degree vectors offering better alternatives to the decision makers were applied. Different configurations of the logistic network were assessed by varying percentages of product devoted to primary alternatives, and Pareto charts with optimal solutions were generated. Finally, the configurations with better economic and environmental benefits were selected. The better environmental alternatives were crushing, alternative fuel in cement plants, and floor coverings production. Model calculations showed that the proposed network is economically feasible and constitutes an efficient alternative to solve such complex environmental problem.

### MO400

#### **Life Cycle Assessment of territorial biogas production by anaerobic digestion of local wastes**

A. Bouter, IFPEN

Anaerobic digestion (AD) at local scale is an example of circular economy. It allows an efficient waste management on a territory and the production of both bioenergy (biogas) and fertilizers (digestates). Biogas can be converted into heat and electricity by cogeneration, or upgraded into biomethane and injected in the gas distribution network. The coproduction of digestates is also valuable as they can be substituted to the use of chemicals fertilizers. The use of local wastes to produce valuable resources is in line with objectives of being less dependent on non-renewable resources by diversifying the energy mix and of reducing the environmental impacts of a territory. Greenhouse gases emissions (GHG) of a local project in the Rhône-Alpes region (France) of biowastes valorisation have been assessed by Life Cycle Assessment. Several wastes are treated by the AD plant: manure (61%), industrial biowastes (24%), biowastes (9%). Dedicated crops (silage maize) are also part of the composition of the inputs (6%). The AD process supplies both waste treatment and energy production. Consequently two functional units have been chosen to evaluate this system. First the waste treatment service provided by the AD plant has been assessed, with a functional unit defined as the treatment of 1 kg of organic matter. Upgraded biogas and digestates produced by the AD plant are substituted to natural gas and chemical fertilizers. A reference scenario has been built, in which organic wastes are processed according to French statistics for bio wastes management. The second functional unit is the production of 1 MJ of energy. Biogas is purified into biomethane and then injected in the natural gas grid. Digestates are substituted to chemical fertilizers. A reference scenario has been defined as the production of 1 MJ from natural gas. Sensitivity analyses have been done on purification technologies and methane losses management. Waste treatment by anaerobic digestion reduces GHG emissions, mainly because of the substitution of biogas to natural gas. Similarly, GHG emission of energy production from biomethane are lower than the fossil reference, because of the substitution of the digestates to chemical fertilizers. The choice of the purification technology does not affect environmental results but has an effect on results. Both waste treatment and energy production are quite sensitive to methane losses management.

### MO401

#### **An approach for regional agricultural LCA**

A. Avadí, INRA-Agrocampus Ouest / UMR SAS; M. Corson, INRA Institut National de la Recherche Agronomique

Life cycle assessment (LCA) is rarely used to estimate environmental impacts of regions, given its product-level scope and costs of analysing all processes in a region. Nonetheless, one can analyse individual samples (e.g. farms) and extrapolate the analysis to describe a population (e.g. all regional agricultural activity). Linear aggregation is often used to extrapolate farm-level impacts, but modular approaches (e.g. a region as an aggregation of farm activities) are also used. These approaches infrequently consider factors such as spatiotemporal explicitness, intra-regional exchanges, and farm variability. We applied an LCA extrapolation approach to the agricultural Lieue de Grève catchment in Brittany, France. To estimate regional impacts, we first performed LCA of 25 farms in the region. In parallel, we constructed a farm typology using principal component analysis and clustering of all farms in the region with sufficient structural and operational data (114 farms: 34% of the catchment area). We ensured that each cluster included a minimum number of farms with LCA results and that their impacts per ha (for selected categories) were within  $\pm 25\%$  of each other. Next, using multiple linear regression (MLR), we estimated environmental impacts for all farms in the largest cluster (dairy farms) as a function of a set of input predictors. For this cluster, we included LCA results from other Breton dairy farms in the MLR so that the sample size was sufficiently large given the number of predictors in the each-subset regression of the MLR. We then calculated mean impacts from both LCA and MLR of all farms in each cluster and included corrections for intra-regional exchanges (balancing imports and exports of fodder and manure for all farms to determine whether the average farm had a deficit or surplus). Finally, each cluster's mean impacts were multiplied by the total area of each cluster in the region, and the impacts of centralised regional activities (e.g. communal fodder drying) were added to the extrapolated results. Conceptually, by taking characteristics of more farms in the studied region into account, this approach should estimate environmental impacts of all of its agricultural land more accurately than linear extrapolation of impacts from simple pre-defined farm types. The approach is being used to compare regional impacts before and after a series of agricultural innovations.

### MO402

#### **Bioaccessibility of PAHs in Fuel Soot Assessed by an in vitro Gastrointestinal Model Including a Third-phase Absorptive Sink: Effect of Food Ingestion**

Y. Zhang, College of Urban and Environmental Sciences; J.J. Pignatello, Connecticut Agricultural Experiment Sta. / Environmental Sciences; S. Tao, Peking University / College of Environmental Sciences; B. XING, Department of Plant, Soil and Insect Sciences / University of Massachusetts

Soot or black carbon typically contains high levels of polycyclic aromatic hydrocarbons (PAHs) and distributes widely in soil and on environmental surfaces. Soot can enter the human digestive tract via hand-to-mouth transfer of soil and other particles. Young children are especially susceptible to soil ingestion by this route. In this study, an *in vitro* digestion model was developed to estimate the bioaccessibility of PAHs in fuel soot. The model contains silicone sheet added at the small intestinal digestion stage to serve as a third-phase absorptive sink, which simulates the function of the small intestinal epithelium *in vivo* and maintains a steep concentration gradient between particles and fluids. The fraction of PAHs in the digestive fluid and silicone sheet was regarded as the apparent bioaccessibility ( $B_{app}$ ). Inclusion of silicone sheet in the model significantly increased the  $B_{app}$  of PAHs in the fuel soot. PAHs were hypothesized to exist in a labile, or potentially bioaccessible state, and a nonexchangeable, or non-bioaccessible state. The partition coefficient of the labile PAHs between digestive fluid and the digestion soot residue was positively correlated with octanol-water partition coefficient ( $K_{ow}$ ). Inclusion of the silicone sheet reduced PAH concentrations on the soot residue remaining after simulated digestion. The influence of changing physiological conditions associated with food ingestion was investigated, including pH, ionic strength, bile acids concentration, and food nutrient class, on  $B_{app}$ , toward a goal of understanding the mechanisms of their effects. While bile acids, which help solubilize PAHs via micellization, were identified as the key component, variation of the bile acid concentration from 2.0 to 10 g/L had no effect on  $B_{app}$ . The  $B_{app}$  significantly increased with pH in the range of 5.62 - 7.35. The log  $B_{app}$  was positively correlated with the lipid concentration (1 -34.5 g/L) in the digestive fluid. Food ingestion and its influence on digestive fluid chemistry is expected to modify the size and shape of bile micelles.

### MO403

#### **Whole Effluent Assessment of Offshore Discharge Waters**

K. Wadhia, Opus / Environmental

The testing programme was implemented to investigate the management of produced waters using a risk-based approach. The initiative developed by the OSPAR Intersessional Correspondence Group on the development of a Risk-Based Approach (ICG-RBA) is designed to develop a holistic approach for the management of produced water. In employing this approach, Whole Effluent Assessment (WEA) would potentially constitute an appropriate means of detection

of unknown substances and has the advantage that each unique discharge is tested, rather than relying on predictive field toxicity values. Whole Effluent Assessment (WEA) was carried out on 15 platforms in the UK Continental Shelf as part of an assessment of the applicability of WEA as part of a risk based approach for the monitoring of produced water in the offshore industry. Installations were chosen to give a broad coverage of location, type of production (oil, gas), stage of production (early, late) and characteristic of produced water (oil content, water cut, use of chemicals and complexity of produced water) based on previous biannual data submitted. The UK study was carried out in parallel with other studies in Norway, The Netherlands and Denmark. WEA testing was carried out using bioassays from three trophic levels; bacteria (MARA and LumiMARA), algae (*Skeletonema costatum*) and crustacean (*Acartia tonsa*). WEA testing was carried out on produced water samples collected offshore at the same sampling point/time as samples were collected for biannual chemical sampling. Samples were shipped onshore as quickly as possible for analysis. Samples were aged at 15°C for three weeks and WEA testing repeated. For six of the installations bacterial WEA was carried out with MARA and LumiMARA offshore at the point of sampling. Biodegradation (OECD 306) was carried out onshore on all 15 installations

#### MO404

##### Environmental Effects of Triclosan

A. Peters, D. Leverett, WCA-Environment Ltd

Triclosan is an antibacterial agent which is added to a wide range of household and personal care products. Its use in such products means that the primary route of release to the environment is via the domestic sewerage system. While EU-wide Environmental Quality Standards (EQS) have not previously been derived for triclosan, proposed EQS were derived in 2009 by the UK environmental agencies in preparation for the potential regulation of triclosan in the UK. Triclosan is an ionisable substance, having a single phenol group with a  $pK_A$  value of approximately 8.0. Both ionised and unionised forms of triclosan can be expected to be present in many natural surface waters. A significant limitation of previous assessments of the toxicity of triclosan appears to be not having taken the ionisation of the substance into account in assessments of toxicity. The possibility of an important effect of pH on triclosan toxicity, through the formation of less toxic ionised species under higher pH conditions, implies that there will be consistent differences in the sensitivity of different surface waters due to differences in local pH conditions. If the SSD is not normalised to a single pH value then there will always be some remaining uncertainty as to whether or not the resulting thresholds are likely to be protective of the most sensitive water chemistry conditions. An assessment of the potential influence of pH on triclosan toxicity, and the sensitivity of surface waters to triclosan are presented.

#### MO405

##### Evaluation of bioavailability and toxicity of grease thickeners using SPME

G.F. Whale, Shell Health / Shell Health; C.V. Eadsforth, Shell International; T. Corry, Shell Health

Grease thickeners are an intrinsic part of greases and are often formed in-situ with base oils during the grease manufacturing process. In most cases the reactions to form the grease thickener occur during the grease manufacturing process and consequently these grease thickeners generally only exist in the presence of the "blended" base oil matrix. Most greases are based on the use of metal-soap, metal-complex-soap or polyurea (PU) grease thickening agent systems. In some circumstances it is not practically feasible to generate test data for grease thickeners as isolated substances. Furthermore, the relevance of generating data on isolated thickeners for environmental risk assessments is questionable. Their chemistry is complex and interactions between the thickener and base oil do not strictly fall under the definitions of a reaction product nor do they act as a simple mixture of components due to changes which occur in the manufacturing/blending process. The hypothesis is that once blended into greases the bioavailability of the grease thickener will be reduced. To test this ecotoxicity and biomimetic screening studies have been undertaken. A biomimetic extraction technique using solid-phase microextraction (SPME) in conjunction with gas chromatography (GC) was employed to assess the level of water soluble hydrocarbons and hence the potential toxicity, as well as the bioaccumulation potential, of the water accommodated fractions (WAFs) of the test samples. In addition, the toxicity of WAFs was also monitored using an *in-vitro* Microtox™ assay, a biosensor-based measurement system. For the metal complex greases WAFs of the test samples were also taken and submitted for metal (i.e. Li and Ca) analysis. The screening ecotoxicity data (using SPME-GC and the *in-vitro* Microtox™ assay), confirm a lack of toxicity of the grease samples tested at a 1000 mg/L loading rate. Metal analyses confirm that there was no noticeable leaching of lithium or calcium ions from the grease samples. These studies provide reassurance that grease thickeners are not bioavailable once these have been blended within a grease matrix.

#### MO406

##### On the challenge to assess the exposure of organic contaminants in matrices with high partition coefficients

L. Hilber, Agroscope ART; P. Mayer, Technical University of Denmark / Department of Environmental Engineering; V. Gouliarmou, Aarhus University, Science and Technology Faculty / Environmental Chemistry and Microbiology; S.E. Hale, Norwegian Geotechnical Institute / Environmental Engineering; G.

Cornelissen, NGI; T.D. Bucheli, Agroscope ART / Analytical Chemistry Natural Resources Environmental Protection in Agriculture

To assess aqueous concentration ( $C_{free}$ ) and bioaccessibility of organic contaminants in matrices that have high solid-to-water phase partition coefficients ( $\log K_D > 5$ ) is an inherent challenge. Experiments that achieve efficient mass transfer and infinite sink conditions need to be properly designed. One key parameter controlling the (de)sorption process is the magnitude of the  $K_D$  value of the sample and the sink. Thus, the ratio of the  $K_{D, receiving\ polymer}$  over the  $K_{D, sample}$  multiplied by the  $mass_{receiving\ polymer}$  over the  $mass_{sample}$  should be at least 10 for depletive methods (bioaccessibility) and  $< 0.01$  for non-depletive methods to determine  $C_{free}$  of a pollutant. We have chosen to investigate biochar as challenging matrix due to its PAHs formed during pyrolysis, the expected high  $K_D$ , and its agglomerative and hygroscopic nature. The slowly pyrolysed elephant grass (biochar 1) and sieved coniferous wood residues (biochar 2) had total concentrations of the sum (?)16 US EPA PAHs of 63 mg/kg<sub>dw</sub> and 355 mg/kg<sub>dw</sub>, respectively. Polyoxymethylene was equilibrated with the biochars to assess the  $C_{free}$  [1], whereas Tenax [2], silicone rods [3] and activated carbon/silicone composite (1:9 mass ratio) [4] were used as sorptive sink for the determination of PAH bioaccessibility. Cyclodextrin was in some of the approaches used as diffusive carrier [3, 4] in order to enhance the PAH desorption from the biochar. The  $C_{free}$  of ?16 US EPA PAHs was 52 ng/L for biochar 1 and 71 ng/L for biochar 2, which are very low levels for a matrix containing PAHs in the mg/kg range. The reason for these low  $C_{free}$  are the very high  $\log K_D$  values that ranged from 5.7 for naphthalene in biochar 1 to 7.6 for pyrene in biochar 2. The results from the depletive methods revealed at the most 1-2% of bioaccessible PAHs. The depletive methods impressively showed the virtual absence of bioaccessibility in situations in which the contaminants are strongly sorbed or entrapped in the matrix. The results suggest that the tested biochars are rather diffusive sinks than sources for PAHs. To consolidate the findings, more biochars with different feedstocks will be tested. Additionally, depletive methods for PAHs in biochar should be adapted by e.g. using biological media such as gut fluids. Both methods shall be used to adequately and conservatively assess the exposure and the risk and thus facilitate regulatory acceptance. Future research should address the influence of biochar stability.

#### MO407

##### Comparing modelled ecotoxicity predictions using PETROTOX and SPME data on petroleum products to screen for aquatic toxicity

C.V. Eadsforth, Shell International; M. Comber; M. Pauten, ExxonMobil Petroleum and Chemicals; S. Linington, BP Castrol Technology Centre; K. den Haan, CONCAWE / Petroleum Products Safety; A.D. Redman, Exxon Mobil Biomedical Sciences; J. Butler, ExxonMobil Biomedical Sciences, Inc / Environmental Toxicology and Chemistry Laboratory; D. Letinski, ExxonMobil Biomedical Sciences

Using detailed two-dimensional chromatography (GCxGC) analysis of a set of petroleum product samples of Gas Oils, Residual Aromatic Extracts (RAE) and Bitumen categories, predictions using PETROTOX have been used to provide information to support revised category justification documents and to enable the selection of 'worst case' substances in each category for ecotoxicity testing. In addition, analysis of Water Accommodated Fractions (WAFs) of these product samples using Biomimetic Extraction (BE) with solid phase microextraction (SPME) fibres was used to confirm that (a) SPME data correlates to Toxic Units predicted by the PETROTOX model using GCxGC compositional data as input and (b) the linkage between composition, SPME data and aquatic toxicity is strengthened. This provides a technical basis for further use of SPME as a more practical characterization tool for addressing the influence of variation in substance composition on aquatic toxicity within petroleum product categories. BE-SPME is therefore shown to be a cost-effective approach to toxicity screening for petroleum substances, thereby offering an alternative method to enhance the current available ecotoxicity data sets, as well as being complementary to predicting ecotoxicity using PETROTOX.

#### MO408

##### Relating Bioavailability Parameters to the Sorbent Characteristics of PAH Polluted Soils

N. Bartolome, Agroscope Reckenholz-Tänikon Research Station ART / Analytical Chemistry Natural Resources Environmental Protection in Agriculture; I. Hilber, Agroscope ART; R. Schulin, ETH Zurich; P. Mayer, Technical University of Denmark / Department of Environmental Engineering; T.D. Bucheli, Agroscope ART / Analytical Chemistry Natural Resources Environmental Protection in Agriculture

Regulation of Hydrophobic Organic Contaminants (HOC) such as polycyclic aromatic hydrocarbons (PAHs) in soil is still based on total concentrations. However, many studies have demonstrated that not all of a pollutant's content in soil is equally available to organisms (Reichenberg & Mayer 2006). Over the last decade, intensive effort has been made to incorporate bioavailability into risk assessment (Cachada et al. 2014). Here, we compare total concentrations of PAH with two bioavailability parameters in 30 different soil samples from the archive of the standardized National and Zurich Cantonal Swiss Soil Monitoring Network (NABO and KABO). The selected samples were chosen to cover a wide range of total PAH concentrations, sources of origin, and soil types. We applied a depletive method with silicon rods for measuring bioaccessibility (Gouliarmou & Mayer,

2012) to quantify the mass of the contaminant in the soil that either are or can become mobilized, and a non-depletive method with polyoxymethylene (POM) for measuring the freely dissolved concentrations in soil pore waters (Jonker & Koelmans 2001). The measurements obtained with POM, silicon rod, and standard total extraction are related to several sorbent characteristics including organic and black carbon content. The results will provide a better understanding of bioavailability of PAHs in soils. Moreover, the outcomes will be discussed regarding to the potential application of chemical proxies in soil pollution risk assessment and legislation. References: Cachada, A., Pereira, R., Ferreira da Silva, E., Duarte, A.C. Sci. Tot. Environ. 2014, 472, 463-480 Gouliarmou, V., Mayer, P. Environ. Sci. Technol. 2012, 46, 10682-10689 Jonker, M.T.O., Koelmans, A.A. Environ. Sci. Technol. 2001, 35, 3742-3748 Reichenberg, F., Mayer, P. Environ. Toxicol. Chem. 2006, 25, 1239-1245

##### Development of Soup Tests for the Risk assessment of NER in Soil.

J. Harmsen, Alterra, Wageningen-UR / CALM; D. Hennecke, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecological chemistry; K. Hund-Rinke, Fraunhofer IME; J. Lahr, Alterra; J.W. Deneer, Alterra Wageningen University and Research Centre / ERA team

Development of Soup Tests for the Risk assessment of NER in Soil. **Joop Harmsen**, Dieter Hennecke, Kerstin Hund-Rinke, Joost Lahr, John Deneer With regard to regulation of chemicals, Non Extractable Residues (NER) are considered an increasingly important issue. Depending on the stakeholders, NER is considered in two ways, either as a chemical time bomb or as a sustainable way of detoxification. In two ECTOC reports a proper basis has been established for testing of NER. · TR 117: Understanding the Relationship between Extraction Technique and Bioavailability; · TR 118: Development of interim guidance for the inclusion of non-extractable residues (NER) in the risk assessment of chemicals. The objective of the present study is: 1) To validate the extraction regime of ECOTOC TR 117, 2) To develop a "soup test" to assess the toxicity of the different fractions of chemicals and 3) To provide a clear, mechanistically driven definition to NER and residual toxicity caused by NER. In the ECETOC reports an extraction regime is suggested that enables the measurement of a dissolved, a rapidly, slowly or very slow desorbing fraction, and of an irreversible sorbed fraction. In our approach we add more kinetic knowledge to this regime, by using methods (TENAX/cyclodextrine) that can be related to a fraction, desorbing over a specific time. For this purpose we will use model chemicals and focus on: · C14-studies in order to assess partitioning over different fractions of test soil; · Comparison of C-14 study results to standard chemical analysis of the measurable fractions; · Measurement of formation speed of NER; · Use of suitable bioassays to monitor toxicity in extracts AND extracted soils; · Translate the research results in suitable recommendations for regulators. The first results of the study will be presented.

#### MO410

##### Microbial actions on slowly-desorbing organic pollutants

J. Ortega-Calvo, Instituto de Recursos Naturales y Agrobiología / Agroquímica y Conservación del Suelo; C. Jimenez Sanchez, Inst de Recursos Naturales y Agrobiol. de Sevilla / Agroquímica y Conservación de Suelos; E. Congiu, Inst. for Natural Resources & Agrobiología de Sevilla; R. Sungthong, Instituto de Recursos Naturales y Agrobiología de Sevilla. CSIC / Agroquímica y Conservación de Suelos; M. Cantos, CSIC - Spanish National Research Council  
The occurrence of slowly desorbing fractions of hydrophobic chemicals such as PAHs is well explained today by environmental organic chemistry. The association with semisolid, NAPL-like hydrocarbon materials (e.g. creosote), black carbon, and aged residues often leads to slowly desorbing pollutants with a modified bioavailability and persistence. However, the microbial interactions with such residues are still poorly understood. Microorganisms may exhibit a unique set of activities relevant for mobilization and biodegradation, such as biosurfactant production, adhesion and behavioural responses (taxis). These microbial aspects of bioavailability are relevant not only for the improvement of bioremediation but they have also connections with the determination of bioavailable fractions of organic chemicals for risk assessment and regulation. This overview contribution will examine our recent research efforts in this issue. We used, for our studies, different experimental models to assess the bioavailability of PAHs for biodegradation, and these included Tenax extraction, dual <sup>14</sup>C/residue analysis of microcosm samples and dynamic passive dosing with O-rings and biphasic NAPL/water systems. With these approaches, we found that biodegradation of slow-desorption PAHs was enhanced by (bio)surfactants (Environ. Sci. Technol. 45:3019-3026, 2011; Environ. Sci. Technol. 48:10869-10877, 2014), the targeted fertilization of free-oil phases or NAPLs (Environ. Sci. Technol. 45:1074-1081, 2011), modulating the deposition and motility of microbial degraders in porous media (Environ. Sci. Technol. 46:6790-6797, 2012), promoting microbial availability with plants (Soil Biol. Biochem. 57:830-840, 2013), and microbial (bacterial/oomycete) interactions in the formation of biofilms at the pollutant interfaces (Environ. Sci. Technol., in prep). Taken together, our results indicate that the microbial enhancement of bioavailability should be taken into account when predicting the fate of organic pollutants present as slowly desorbing fractions in both natural and engineered environments.

#### MO411

##### Microbial motility: a behavioural approach for bioassays in toxicity assessment

C. Jimenez Sanchez, Inst de Recursos Naturales y Agrobiol. de Sevilla / Agroquímica y Conservación de Suelos; R. Sungthong, Instituto de Recursos Naturales y Agrobiología de Sevilla. CSIC / Agroquímica y Conservación de Suelos; J. Ortega-Calvo, Instituto de Recursos Naturales y Agrobiología / Agroquímica y Conservación del Suelo

The biological assessment of pollutant toxicity rarely includes behavioural responses. In this work, we aim to introduce the swimming behaviours and tactic responses of motile microbes for assessing the toxicity of pollutants (nanoparticles (NPs) and polycyclic aromatic hydrocarbons (PAHs)). Two different microbes were used in this work, i) a naphthalene-degrader bacterium, *Pseudomonas putida* G7, and ii) swimming zoospores of the rhizosphere oomycete (lower fungus) *Pythium aphanidermatum*. A computer motion analysis software (CellTrak) was used for evaluation of microbial swimming behaviours, and a chemical-in-capillary method in connection with microscopic observations and viability tests were used for evaluation of microbial tactic responses towards the pollutants. We observed that both silver and iron NPs influenced the swimming patterns of *P. putida* G7 by increasing tortuous motility. Both NPs caused a repellent effect only at a specific range of concentrations, but iron NPs showed a greater repellence possibly due to its higher toxicity to *P. putida* G7. We found also that PAHs (naphthalene and phenanthrene) influenced the tactic responses of zoospores towards a set of chemical effectors that have relevance for bioremediation. It was suggested that bioavailability of PAHs was a key factor for their toxicity effects on zoospore taxis. With these results, we propose that swimming behaviours and tactic responses of motile microbes could be a useful model to evaluate the toxicity of pollutants at environmentally relevant concentrations. In addition, the role of behavioural responses on actual pollutant exposure concentrations should be taken into account for a realistic assessment of pollutant toxicity at the microscale.

#### MO412

##### Aged spiked soils cannot resemble desorption and bioaccessibility of native PAHs in historically contaminated soils

A.P. Loibner, Boku, IFA-Tulln / Department for Agrobiotechnology IFATulln; K.E. Scherr, University of Natural Resources and Life Sciences, Vienna / IFATulln; E. Edelmann, University of Natural Resources and Applied Life Sciences / Agrobiotechnology- IFA Tulln; S. Humel, D. Kopp, BOKU / Department for Agrobiotechnology IFATulln; P. Mayer, Technical University of Denmark / Department of Environmental Engineering

In the present study, 25 Austrian soils were collected and spiked with four selected polycyclic aromatic compounds. Using the contaminant trap, PAH desorption behaviour from freshly contaminated and aged soils was monitored and then compared with three historically PAH-contaminated soils. The aim was to determine fundamental differences in desorption behaviour between spiked and native PAHs. Desorption of PAHs was determined for ground and non-ground samples of historically contaminated soils since increased desorption from ground samples would indicate physical entrapment of PAHs. Desorption experiments were repeated at high additions of toluene since increased desorption in the presence of toluene would indicate competitive binding, which is consistent with adsorption to high affinity sites. Substantial differences were observed between PAH desorption curves for historically polluted soils and spiked soils, and aging of spiked soils was not able to reduce this difference. The bioaccessible PAH-fraction was at least one order of magnitude larger in spiked soils compared to real world samples from historically contaminated sites. The observed differences could not be explained by physical entrapment of PAHs in historically contaminated soils since grinding of these soils did not enhance PAH desorption from the soils. The addition of high amounts of toluene to historically contaminated soil resulted in enhanced PAH desorption and a lower desorption resistant fraction. This observation is in line with competitive binding to high affinity sorption sites being the governing retention mechanisms of native PAHs in historically contaminated soils. These results are consistent with two sorption mechanisms occurring in the two types of soils: In historically contaminated soils, PAHs appear to be bound to high affinity sorption sites. A much lower retention in spiked soils is consistent with sorption to a much larger population of low affinity sorption sites. This has very important implications for real world situations. It challenges the significance of extrapolations of desorption and bioavailability results that were obtained with PAH spiked soils. Further, a much higher PAH retention in historically contaminated soils suggests limited mobility and exposure of native PAHs. However, the addition of co-solutes can reduce this retention and as a consequence, lead to a re-mobilisation of PAHs.

#### MO413

##### Ecological risk assessment of PAHs contaminated area - integrating bioavailability into Triad approach

A. Klimkowicz-Pawlas, Institute of Soil Science and Plant Cultivation - State Research Institute / Department of Soil Science Erosion and Land Protection; B. Maliszewska-Kordybach, Institute of Soil Science and Plant Cultivation - State Research Institute; B. Smreczak, Institute of Soil Science and Plant Cultivation / Department of Soil Science Erosion and Land Conservation

One of the main threats to soil habitat and retention function is soil contamination with chemical pollutants, including PAHs. The high level of these pollutants may

cause an adverse effect on soil organisms and decrease soil biodiversity and quality. For assessing the risk from chemical contamination the ecological risk assessment (ERA) procedures are recently applied. The first stage of ERA is often based on the comparison of soil concentrations with soil screening levels (SSL) based on the total PAHs content determinations, which may lead to overestimation of the risk. The evaluation of the fraction of these compounds available to soil organisms gives a chance for more realistic risk assessment procedure particularly in historically contaminated soils. The aim of the studies was to compare the results of ERA procedure based on three approaches: generic approach (comparison of total soil concentrations of PAHs with SSL), Triad approach based only on total PAHs and solid phase toxicity tests and Triad approach including toxicity of PAHs in soil water phase (relevant to the bioavailability of PAHs). The research area was located in the agricultural land (about 100 km<sup>2</sup>) subjected to the long time (over 100 years) PAHs anthropopressure. The total concentrations of 16 PAH compounds were determined and compared to the soil screening values (the total content of 9PAHs) according to Polish soil guidelines. Risk assessment procedure based on Triad approach included: chemical, ecotoxicological and ecological measurements. The battery of tests was applied for ecotoxicological and ecological evaluations. The results were analysed and integrated in different lines of evidence, which allowed to calculate of integrated risk indexes. ERA assessment according to the generic approach indicated that almost half of research area is under ecological risk. Application in ERA procedure of the solid toxicity tests describing habitat function led to the selection of the limited area of high risk. However, incorporation to risk procedure toxicity test relevant to PAHs bioavailability permitted on more realistic assessment and delineation only one site of high risk located in the vicinity of coke plant. The final assessment of ecological risk, after introduction of the tests describing bioavailability in risk assessment procedure, indicates on significant decrease of the area with high risk.

##### **Bioaccessibility Extraction of Hydrophobic Pollutants: Benefits of Separating Leaching Agent and Acceptor Medium**

D.J. Cocovi-Solberg; M. Miró, Universitat de les Illes Balears; A.P. Loibner, Boku, IFA-Tulln / Department for Agrobiotechnology IFATulln; P. Mayer, Technical University of Denmark / Department of Environmental Engineering  
Bioaccessibility extractions of organic pollutants from environmental solid samples are increasingly used in environmental risk assessment and management. Recent research has indicated that many bioaccessibility extraction methods have limited sink capacity for hydrophobic organic chemicals, which can lead to underestimation of bioaccessibility. Therefore, several studies have proposed to add a sink to the extraction medium, including the so called contaminant trap, the silicon rod based sorptive bioaccessibility extraction and tenax beads-assisted extractions. While these methods certainly are a step forward, they also lead to challenges related to the separation of sink and matrix and/or the subsequent quantification of the bioaccessible fraction. The present study aimed at developing a new approach for (1) enhancing the sink capacity of bioaccessibility extractions, (2) improving phase separation and (3) facilitating the measurement of the bioaccessible fraction. Cyclodextrin was used as leaching agent, ethanol as acceptor medium and a semipermeable membrane for separating these two phases. Various physical formats of this configuration were developed and tested, and the simplest and highly performing format was further optimized and validated. This new configuration was characterized in terms of mass transfer kinetics, analytical performance criteria and suitability for direct analysis by high performance liquid chromatography (HPLC) and gas chromatography (GC). Finally, the developed method was applied to PAH contaminated soils and the results compared to results obtained with other existing methods.

#### MO415

##### **PAH Composition of Clay Pigeon Target Fragments at Two Historical Skeet Range Sites**

B.H. Magee, ARCADIS; G.C. Hoeger, ARCADIS / IEST; N. Forsberg, ARCADIS US Inc / IEST

In vivo bioavailability studies have been performed to determine the relative bioavailability of PAHs in clay pigeon target fragments at two historical skeet range sites. These site-aged fragments, which are mixed with native soil, have elevated concentrations of PAHs that are expected to have reduced bioavailability compared to that seen in animal studies using pure benzo(a)pyrene in solvents added to rodent chow. The literature indicates that the clay targets are made from limestone with a binding agent such as petroleum pitch or coal tar, which serve as the source of PAHs. The literature, however, is unclear on the exact PAH mixture used in manufacturing clay pigeon targets and suggest that the binder was variable over time. Various sources have listed coal tar, coal tar pitch, bitumen, or petroleum pitch as the binding agent that may have been used in target production (ATSDR, 2002; EPA, 2003; ITRC, 2005). As part of the two bioavailability studies, PAH analyses were performed to characterize the PAH content of the fine fractions (~250 microns) of site soils containing target fragments. PAH composition data from multiple site samples will be presented and compared to the PAH composition data of coal tar, coal tar pitch, bitumen, and petroleum pitch to provide insight on the source material for the PAHs found in site soils at these range sites. The link of binding agents to specific target fragment samples will be used to evaluate data from the two individual bioavailability studies.

#### MO416

##### **Assessing mobility potential of pharmaceuticals in bank filtration, surface and ground waters.**

P. Adrian, A. BROUSSE, B. Journeil, E. Beltran, CEHTRA SARL; F. Sahigara, P. Thomas, CEHTRA SAS

Biodegradation and soil adsorption studies for pharmaceuticals are required to determine if terrestrial (including ground water) risk assessment is required. Soil adsorption studies are carried out using batch equilibrium experiments according to the OECD 106 guideline<sup>1</sup>. Additionally, the results may be used to refine the partitioning coefficients in the soil compartments and in sludge, the latter being the most important as it directly impacts partitioning in the sewage treatment plants (aqueous phase and sewage sludge). The combination between different intrinsic properties of pharmaceuticals, including ionisation potential may be useful to predict their occurrence in bank filtration, surface and ground waters. The aim of this poster is to present a simple model based on biological properties and physicochemical characteristics to predict the mobility potential of pharmaceuticals in the environment. The relevance of this model will be discussed using comparison of results with monitoring data from several countries. **Key Words:** exposure assessment; environmental risk assessment; modelling. **References:** OECD 106. OECD guideline for the testing of chemicals: Adsorption - Desorption Using a Batch Equilibrium Method. Adopted on the 21<sup>st</sup> January 2000.

#### MO417

##### **Can the Complete Tenax Model be used to assess bioaccumulation at different trophic levels?**

M.C. Archer, Southern Illinois University Carbondale / Center for Fisheries Aquaculture and Aquatic Sciences; A.D. Harwood, Southern Illinois University / Department of Natural Sciences; K. Huff Hartz, M.J. Lydy, Southern Illinois University-Carbondale / Center for Fisheries Aquaculture and Aquatic Sciences  
A major difficulty with characterizing sediment-associated hydrophobic organic contaminants is assessing the amount of compound that is available for chemical exchange with an organism. Tenax, a p-2,6-diphenylphenyleneoxide polymer, has been successfully used as an extraction tool for estimating the bioavailability of hydrophobic organic contaminants in sediment, and has been applied to laboratory-spiked sediments, field-collected sediments, laboratory-exposed organisms, field-collected organisms and studies among laboratories. A literature-based model has been developed that describes the bioaccumulation of polychlorinated biphenyls (PCBs) from independently measured field-collected sediments. The primary objective of the current study was to evaluate the distribution and bioavailability of PCBs in a southern Illinois lake and to determine if Tenax extractable concentrations could be used to estimate bioaccumulation at different trophic levels, including higher level aquatic and terrestrial species. Species tested included tetragnathid spiders, emerging insects, oligochaete worms, midges, bluegill (male and female), largemouth bass, and channel catfish. This data revealed that PCBs in the lake's sediment were bioavailable to organisms inhabiting the lake, and that there was a relationship between animal tissue concentrations and Tenax extractable concentrations, which extends the potential use of the Tenax extraction method.

#### MO418

##### **A look into the social acceptance of biochar-based soil remediation**

A.A. Arenyeka, Newcastle University / Environmental Engineering

Crude oil spills are currently a major cause of environmental devastation in Nigeria. Remediation of organic pollutants by sorbent amendment has received increased research attention particularly over the last two decades. AC amendment has been tested extensively in the laboratory and the addition of a few percent AC by soil or sediment mass has been effective in sequestering PAHs, PCBs and Organochlorine pesticides (Ghosh *et al.*, 2011). The study presented here is part of a broader interdisciplinary study which aims to investigate the viability of activated biochar as a sustainable technology solution for the remediation of oil pollution in Nigeria from a scientific as well as social point of view. The broader study involves comparing activated biochar with more traditional bioremediation technologies (biostimulation and natural attenuation) as well as subsequent risk assessment using the UK's Contaminated Land Exposure Assessment (CLEA) tool and learnings from Nigeria's risk management framework. This paper will however focus on the social aspect of the research. This commenced with an extensive desktop study which provided an understanding of the physical, social and political context of crude oil spill remediation techniques in Nigeria and helped to identify principal actors and the rules which govern their decisions. Stakeholder interactions were carried out with key oil industry stakeholders in Nigeria mainly through face-to-face semi-structured interviews. Information obtained was analysed using thematic analysis and grounded theory. Major themes observed from the interviews include remediation challenges, technical considerations, pollution typology, environmental concerns, risk considerations & regulatory concerns. One interesting point is the likely potential of biochar as a viable choice for remediation of mangrove swamp due to the sensitive nature of the Niger-Delta ecosystem. Critical analysis of results obtained will be done using an adaptation of the IAD (Institutional Analysis and Development) framework (Ostrom, 1999). Finally, results from this study will be used in the final risk analysis in conjunction with results from the laboratory. Results would hopefully provide useful information for

dissemination to stakeholders particularly regulatory decision makers and would hopefully inform changes in the manner in which risk is currently assessed in Nigeria particularly as it relates to pollutant bioavailability.

#### MO419

##### **Critical bioconcentration factor for short-term aquatic toxicity tests**

J. Kwon, Korea University / Division of Environmental Science and Ecological Engineering; S. Lee, H. Kang, Korea University; B.I. Escher, Helmholtz Centre for Environmental Research GmbH - UFZ / Cell Toxicology

According to current regulations of chemicals management world-wide, massive amount of acute toxicity data are required for evaluating hazards and risks of chemicals. Current data requirements on the registration of chemicals are primarily based on tonnage and do not consider properties of chemicals. For example, acute ecotoxicity data are required for chemicals with production volume greater than 10 ton/yr according to REACH. For highly hydrophobic chemicals, however, their internal concentration within the experimental duration might not be sufficiently high enough to cause acute effects because baseline toxicity is apparent when xenobiotic chemicals accumulate in the body greater than critical body-burden. In this work, theoretical modeling of internal chemical concentration was conducted for standard acute ecotoxicity tests at three trophic levels – algae, invertebrate, and fish. It is unlikely that acute toxicity is observed for chemicals with bioconcentration factor (BCF) or octanol-water partition coefficient (K<sub>ow</sub>) as a surrogate for biopartitioning greater than 107 in acute tests conducted following standard protocols. In order to evaluate the validity of the theoretical analysis, OECD's screening information data set (SIDS) (n= 746) was used. Without only a few exceptions, mainly organometallic substances and those with water solubility and K<sub>ow</sub> of limited reliability, critical BCF hypothesis predicted aquatic short-term toxicity cutoff very well. This indicates that current regulations about data requirements need to be revised for highly hydrophobic chemicals.

#### MO420

##### **Relationship between LI structures and their (eco-)toxicological properties in view of ionic liquid registration in REACH.**

A. Bado-Nilles, UMRI SEBIO; G. Marlair, INERIS; C. Len, UTC ESCOM; P. Pandard, INERIS; J. Porcher, INERIS / UMRI SEBIO; S. ANDRES, INERIS  
Ionic liquids (ILs), often termed as “designer” solvents due to the extreme tunability of sought functional properties, are promoted by many stakeholders as green alternatives to the conventional volatile organic solvents. Nevertheless, this qualification was stated without sufficient caution versus versatility of ILs chemical structures which could induce significant variations in hazardous properties. Moreover, this class of compounds which contained organic cations and most inorganic anions may often present a high water solubility and poor biodegradability. These specific properties could influence the environmental behavior of these ILs and implied IL potential environmental and health effects. With regards to the exponential increase of applications, publications and patent for ten years, concerning ILs without halogen atoms, we may anticipate that some ILs could attain multi-ton industrial production in the near future. In this context, according to the EC regulation 1907/2006 regarding REACH, each manufacturer or importer of a substance in quantity of minimum one ton by year should submit a registration application to the European Chemicals Agency (ECHA). In this context, a global view of some physico-chemical, toxicological and ecotoxicological data available in the literature, in accordance with the information requested by REACH regulation, is proposed here. In fact, it seems to be important to identify the relationship between LI structures and their (eco-)toxicological properties to help manufacturer for design of the more safe IL structures.

## **Ecological Risk Assessment and Sustainable Management of Contaminated Sediment: Perspectives and Experiences (P)**

#### MO421

##### **Effects of the heavy metal zinc on nematode species: Validation of the NemaSPEAR[%]-index with acute multi-species and microcosm experiments**

A. Hägerbäumer, Bielefeld University / Animal Ecology; S. Höss, Ecosa; K. Ristau, University of Bielefeld; E. Claus, Federal Institute of Hydrology BfG; C. Möhlenkamp, P. Heininger, Federal Institute of Hydrology; W. Traunspurger, University of Bielefeld

The nematode-based NemaSPEAR[%]-index was recently developed as a tool for assessing chemical induced changes of invertebrate communities in fine, adhesive freshwater sediments, that are known as hotspots for chemical exposure. In fine sediments, meiobenthic taxa (e. g. nematodes) are more abundant and species-rich than macrozoobenthos, which is commonly used for assessing the ecological quality of sediments. Thus, biomonitoring of this habitat should be increasingly based on the analysis of meiofauna to detect chemical induced effects. Based on the occurrence of nematode species in a pollution gradient, classifications in “species at risk” (NemaSPEAR) and “species not at risk” (NemaSPeNotAR) could be made. In order to validate the NemaSPEAR[%]-index, experiments were carried out to assess the response of nematode species assemblages to a model chemical, the heavy metal zinc (Zn). Acute multi-species toxicity tests were performed to observe direct toxicity of Zn (20 and 50 mg Zn/l) on relevant nematode species, isolated from reference freshwater sediments. Moreover, long-term microcosm experiments

were set up to study the effects of Zn (10 and 100 mg/kg dry weight) on nematode communities under more realistic conditions, including direct Zn toxicity and indirect food-web effects. Both results were compared to the species classifications in the NemaSPEAR[%]-index. The acute tests were only partly in line with the classifications of nematodes: in acute multi-species tests, individuals of *Monhystera paludicola* (NemaSPeNotAR) and *Achromadora terricola* (NemaSPEAR) showed highest sensitivity, while nematodes of the species *Ironus ignavus* (NemaSPEAR) and *Tripyla setifera* (NemaSPeNotAR) were tolerant towards Zn. However, over the course of the microcosm experiment, dose-dependent changes in the nematode species composition along with a significant decrease of the NemaSPEAR[%] could be detected. The results showed that the NemaSPEAR[%]-index is clearly affected by chemical stress. Effects on the nematode community structure in the microcosm and in the field, however, might not only be triggered by direct toxicity, but also by indirect effects due to interactions within the complex environment of sediments. The present study supports the suitability of microcosms with natural meiofauna communities as a useful tool to assess the impacts of pollutants in freshwater sediments and open exciting possibilities for the future use of nematodes in the ecotoxicology.

#### MO422

##### **Biodynamic modelling for contaminated sediments- a readily transferable tool to regulation?**

M. Casado-Martinez, Centre Ecotox; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; B. Ferrari, Ecotox Centre CH

Sediments have several characteristics that make them a demanding environmental compartment to study. The large heterogeneity in its nature and composition encompasses a large variability in bioavailability and toxicity, challenging the development of environmental quality standards and effect concentrations for effective risk assessment. A proposed alternative is to use as dose metrics as a measure of internal exposure such as bioaccumulation because, for a contaminant to cause toxicity, it is assumed that it must be first taken up and accumulated by the organism. For most organisms living in close contact with the sediment overlying water, pore water, sediment contact and diet all may contribute to some extent to the total load of a chemical substance in the body of the organism. Thus effective risk assessment for this environmental compartment should ideally use models that are capable of aggregating exposure through all relevant routes, taking into consideration species-specific biological features and natural history, and site-specific physico-chemical characteristics [1,2]. Biodynamic processes have been translated into conceptual and quantitative models that are capable to explaining differences in bioaccumulation patterns among species and environments for several metals [3]. It is possible to derive bioaccumulation predictions as well as estimations of the relative prevalence of exposure routes by combining the quantified constants describing physiological processes with site-specific concentrations and geochemical conditions [3]. While biodynamics has become the new paradigm for describing bioaccumulation among scientists, it is recognised among the regulatory community as a promising powerful tool for improving ecological risk assessment [2]. In the particular case of the sediment compartment, the use of biodynamic models is especially complex due to the differences in feeding and digestion strategies among benthic organisms and also due to the difficulty to determine ingestion rates and feeding preferences. The advances achieved over the last years will be reviewed to discuss on whether this level of development is enough for the implementation of this concept as a practice-oriented tool for the sediment compartment and its potential ecotoxicological and regulatory implications. [1] ECHA 2014. ECHA-14-R-13-EN. Helsinki, FI. [2] US EPA 2007. EPA 120/12-07/001. Washington, US. [3] Luoma SN, Rainbow PS. 2008. Cambridge University Press, New York.

#### MO423

##### **A protocol for assessing sediment toxicity in reservoirs before flushing**

L. Marziali, IRSA-CNR (Brugherio); L. Guzzella, Italian National Research Council Water Research Institute CNIRSA; G. Tartari, IRSACNR Brugherio / UOS Brugherio; C. Bravi, S. Castelli, A.M. Ribauda, Lombardy Region; C. Rondanini, R. Serra, Lombardy Regional Environmental Agency  
Reservoirs are often characterized by high siltation rates which impair the storage capacity. Accumulated sediments are frequently removed by flushing, causing physical-mechanical impacts on aquatic organisms in the downstream rivers. In some cases chemical compounds (organic and metals) adsorbed on sediments may induce toxic effects, mainly in a long-term perspective. PrATo is a protocol designed for assessing the toxic potential of sediments released downstream and includes methods for sampling, chemical analysis and ecotoxicological evaluation of sediments, as well as criteria for risk assessment, based on cross-interpretation of results deriving from chemical and ecotoxicological analyses. In particular, different dilution rates of flushing silt are calculated in order to prevent adverse effects. The trial of the PrATo protocol application in some Italian reservoirs will be presented. Preliminary results show that the definition of threshold concentrations may be biased by high natural background values (particularly for trace metals), by different on-site bioavailability and by synergistic effects of pollutants. Therefore, toxicity bioassays are essential to define the toxic potential of sediments. The protocol is an example of analytical approach useful for supporting decision

**MO424****Application of complementary methods in chemical and ecotoxicological monitoring of sediments under WFD in Wallonia (Belgium).**

Y. Marneffe, Inst. Scientific de Service Public / Ecotoxicology Department; M. Hemart, ISSeP / Ecotoxicology; J. Berger, M. Veschkens, Inst. Scientifique de Service Public

Sediment remains important matrix for the monitoring of certain substances with significant potential for accumulation to assess long-term impacts of anthropogenic activity and trends. The EQS Directive (2008/105 EC amended by 2013/39/EU) provides that Member States should take measures with the aim of ensuring that existing levels of contamination in sediment will not significantly increase.

Analyses of sediment can be a cost-effective approach for initial screening of areas for contamination. In using sediment as a first level screening for certain chemicals, the monitoring programme may be downscaled. Indeed, the initial screening may help to identify areas of concern and areas where additional effort is needed.

Chemical analysis of priority pollutants is often not sufficient to explain ecotoxicological effects of these complex environmental samples. Risk assessment based on concentrations, e.g. of priority pollutants in sediments or water, obviously does not reflect the risk of the actual mixture of contaminants, but only the risk of those pre-selected toxicants. Bioassays are therefore useful tools for the evaluation of sediment in which both known and unknown contaminants are present.

Effect-based monitoring is also useful for the development of investigative monitoring. Combining the three assessment methods (chemical, bioassay, ecology) in a Triad approach can give an answer that cannot be given by any of the individual methods by themselves. From 2010 to 2012, 31 monitoring stations included in the surveillance monitoring programme of the WFD in Wallonia (Belgium) were sampled for sediment. Bioassays (*Chironomus riparius*, *Heterocypris incongruens* for whole samples and *Vibrio fischeri*, *Pseudokirchneriella subcapitata* and *Brachionus calyciflorus* for pore waters) were carried out to determine the potential impact of contaminated sediment. According to their level of toxicity for the different tests, the sediments of the surveillance monitoring stations were classified from non-toxic to extremely toxic. Priority substances selected as pertinent for a monitoring in sediments and other pertinent chemicals were analysed in each sample (63 µm fraction). The link between physico-chemical and ecotoxicological parameters was assessed by multivariate statistical analysis.

**MO425****Ecological risk assessment in a riverine subtropical area (Ribeira de Iguape River, SP, Brazil) due to contamination from former Pb mining activities**

D. Abessa, Unesp / Marine Biology and Coastal Management; L.G. Morais, Universidade Estadual Paulista UNESP; F. Perina, Universidade Federal do Rio Grande / Institute of Oceanography; M.B. Davanzo, Ministry of Environment; L.M. Buruaem, São Paulo State University - UNESP Campus Experimental do Litoral Paulista; P.K. Gusso-Choueri, UFPR; F.H. Pusceddu, UNISANTA; A.C. Cruz, São Paulo State University UNESP Campus Experimental do Litoral Paulista; G. Araujo, Universidade de Aveiro / Biologia; V.G. Rodrigues, EESC USP; J.B. Sígolo, USP

The Ribeira do Iguape River (RIR) is situated between the southwest of São Paulo and northeast of Paraná states (S-SW Brazil), and formerly represented an area of lead (Pb) extraction, comprising nine mines. The river received the direct discharges of mining residues, but in the early 1990's the mining was ceased and the residues were deposited on the river banks, from where metals are still being released to the RIR. This investigation aimed to evaluate the ecological risks to the aquatic biota due to the release of metals from former mining activities into RIR. To achieve that, we used geochemistry and biological approaches. From 2009 to 2012, samples of the waters, sediments, suspended solids, bivalves (*Corbicula fluminea* and *Anadontites tenebricosus*) and mining residues were collected at six sampling sites along the RIR (P1 as reference site; P2-P6 influenced by the residues of mining). Waters and sediments were analyzed to the concentration of metals and toxicity to aquatic invertebrates. Bivalves were evaluated to bioaccumulation and biomarkers (lysosomal membrane stability and micronucleus rate). Residues and suspended solids were evaluated for chemistry. Data were combined to indicate ecological risks in RIR due to metals. Mining residues exhibited high concentrations of metals, especially Pb, Zn, Cu, Cr and Ba, thus the residues were characterized as primary sources of contaminants. Concentrations of metals were often low in the waters, excepting to Fe, Al and Mn, which are naturally high. Sediments collected downstream to the deposits of residues were sandy but showed enrichment by Pb, Ni, Cu, Cr and Zn; but only the Pb concentrations exceeded the toxic levels. The suspended solids presented high levels of Pb, Ni, Cr, Cu, Zn. Soft tissues of both bivalves presented bioaccumulation by Pb, Cr and Cu, evidencing the bioavailability of metals and characterizing the exposure. Waters and sediments did not induce acute toxicity to *Daphnia similis*, but many sediment samples caused chronic effects. The analyses of biomarkers in *C. fluminea* showed significant effects on the cell membranes and DNA, in animals from sites under influence of mining residues. These effects correlated positively to the concentrations of metals in sediments. The results indicate that the RIR is passing through a process of natural recovery, but there are still ecological risks due to the suspended solids and sediments, as bioaccumulation and chronic effects are still present.

**MO426****Methodologies and approaches for sediment characterization and ecological risk assessment based on experience gained in an Italian case study**

L. Marziali, IRSA-CNR (Brugherio); L. Guzzella, Italian National Research Council Water Research Institute CNRIRSA; m. carere; F. Scaini, Italian Institute of Health; D. Rabuffetti, Regional Agency for the Protection of the Environment of Piedmont / Department of Verbano Cusio Ossola; M. Spanò, ARPA VCO; E. Bizzotto; S. Cecon, ENSR Italia AECOM

The presentation will discuss the methodological experiences gained from an Italian case study assessed under a risk-based approach, with details on adopted methodologies for the Environmental Risk Assessment and metric selection. The case study regards historic DDT and Hg discharge on a river that inflow in a subalpine lake in Northern Italy and involves several investigations performed in collaboration with environmental agencies. Investigation design and data interpretation were based on a tiered approach to verifying at each step if it was necessary further investigations to evaluate the problem. Ecological risk assessment was the decision-making tool proposed in order to support the environmental management. Methodologies and criteria adopted in this case study are described as basis of further development of a general framework to deal such kind of comprehensive problem. The approaches illustrated below were shared in a technical board established to develop a guidance and address methodologies for Environmental Risk Assessment.

**MO427****Eurocargo Venezia Ro-Ro Cargo Ship incident: evaluation of environmental adverse effect of wasted catalyzer with bioassays and bioaccumulation test**

S. Macchia, ISPRA Institute for Environmental Protection and Research; D. Sartori; S. Giuliani, ISPRA; L. Morroni, A. Gaion, ISPRA Institute for Environmental Protection and Research; i. buttino, ISPRA / Ecotoxicology and plankton biology Lab; d. Pellegrini, ISPRA Institute for Environmental Protection and Research

On 17 December 2011, the RO-RO ferry "Eurocargo Venezia" during the crossing Catania-Genoa because of adverse sea conditions lost at sea two trailers containing 198 barrels of spent catalyst rich in heavy metal, especially nickel and molybdenum oxides, for a total of 34 tons. The research has led to the location, to a depth of 400 m, of a large number of drums off the Isle of Gorgona (Tyrrhenian Sea). The catalyst is a residue of desulfurization process in the refining of petroleum products, which can release, if comes in contact with sea water, hazardous substances to the ecosystem, as outlined in the material data safety sheet. As part of the technical advice requested by Livorno Prosecutor's office, we evaluate the possible toxicity to ecosystem of substances contained in drums. Elutriate obtained from catalyst and sea water contained in the barrels with catalyst were tested with the unicellular alga *Phaeodactylum tricornutum* and the sea urchin *Paracentrotus lividus*, furthermore bioaccumulation test with polychaete *Hediste diversicolor* were performed. Elutriates obtained from catalyst showed high toxicity, greatly inhibiting the growth of algae (EC<sub>50</sub> = 81.4) and causing a high percentage of abnormal plutei in *P. lividus* (EC<sub>50</sub> ranging from 0.71 to 3.79). Only at a dilution of 1: 100 any toxic effect was registered. A similar trend was also observed for water contained in the drum. Bioaccumulation tests with *H. diversicolor* showed that metals contained in the catalyst and released in the sediment may concentrate in the tissues of marine organisms and therefore potentially be transferred in the food web. The toxicity and bioavailability observed suggest the need to continue the monitoring activities in the abiotic and biotic environment in the medium term, in areas where the concentration of drums is still likely to be considered.

**MO428****Sustainable dredged material management and support by multi-criteria decision analysis (MCDA)**

W. Ahlf, TU Hamburg-Harburg / Environmental Technology Energy Economics; A. Scheffler, Hamburg University of Technology

The port of Lübeck is one of Germany's most important harbours for goods traffic to and from the Baltic Sea Region. Regularly maintenance dredging as well as capital dredging operations induced a chain of actions including taking the material out of the water, transport and treatment until its final destination. A range of solutions for sustainable dredged material handling exist and an assessment of these options often proves to be challenging for decision makers. MCDA provides decision support by processing different data sets and evaluating suitable options in a rational way. Using the stochastic multi-criteria acceptability analysis (SMAA)-TRI method with a modification of a previously developed computerised model for decision support in dredged material management, this study was performed to test decision support under uncertainty. The analysis endorsed that relocation to a dredged discharge pool and capping of an ammunition disposal site are viable options for Lübeck port. On the other hand, the use of dredged material from port expansion and its disposal on land are considered to be of very low sustainability under the given circumstances. The case study demonstrates capabilities as well as boundaries of computer-aided decision making under the premise of incomplete information. Despite uncertainties, sustainable decision making is possible with appropriate MCDA methodologies although minimum requirements concerning both data quality and data quantity must be fulfilled. Consequently, one possible alternative could not be integrated into the case study

due to incomplete information.

#### MO429

##### ASSESSING THE TOXICITY OF SEDIMENTS DURING DREDGING OPERATIONS IN A HARBOR FROM A SEMI-ARID REGION OF BRAZIL

L.M. Buruaem, São Paulo State University - UNESP Campus Experimental do Litoral Paulista; G. Araujo, Universidade de Aveiro / Biologia; R.V. Saes, Federal University of Ceará / Marine Sciences Institute LABOMAR; T.G. FONSECA, University of Algarve / CIMA; D. Abessa, Unesp / Marine Biology and Coastal Management

Harbors are important for the world economy; however, their activities are considered very harmful to coastal ecosystems, due to inputs of contaminants to aquatic environments. Sediments constitute the main fate for these compounds, and when contaminated, they may become a secondary source of contamination to the environment, threatening the health of ecosystems and affecting some economic activities such as dredging and disposal of dredged materials. Ecotoxicological approaches are useful to estimate the effects of contaminants in environmental compartments (or not) on non-target organisms, assisting the evaluations of exposure necessary for ecological risk characterization. Sediments from Ceará State (Northeast, Brazil) shows two distinctive compositions: organogenic and terrigenous facies. The first consists of organogenic substrates derived from calcareous algae, contributing with most of  $\text{CaCO}_3$  deposition (75 to 95%) and high contents of organic matter. The outer shelf sediments are covered by gravel, while the sediments from the inner shelf are predominantly composed of sand with bioterritic gravels and low amounts of mud. In this context, this research presents a study on Ecological Risk Assessment of sediments collected in 3 different sites besides the dredge's hopper during the dredging operations of Mucuripe Harbor, located in Ceará State by using a battery of ecotoxicity bioassays. Sediment samples were tested for whole sediment on the amphipod *Tiburonella viscana* and polychaete *Armandia agilis* (acute toxicity); and also on the copepod *Tisbe biminiensis* (chronic toxicity). The liquid phase sediment-water interface and the real elutriate from dredge's hopper were tested for acute toxicity on the mysid *Mysidopsis juniae* and chronic toxicity on embryos of the sea urchin *Lytechinus variegatus*. Samples exhibited both acute and chronic toxicity in samples affected from contamination sources, including the dredge's hopper. Also, the results presented in this study provide information concerning the knowledge of sediment quality in harbor areas in the Brazilian Coast, especially in the Ceará State.

#### MO430

##### Temporal quality evaluation of dredged sediment disposal area in the maritime terminal of mining company in Brazil through the triad (SQT) approach

T. Furley, F. Aquinoga, APLYSIA Environmental Research and Solutions; K. Chagas, Aplysia technology for the environment / Ecotoxicology Laboratory; S. AMIGO, SAMARCO MINING

The site where dredged material is disposed in the port terminal of Samarco Mining in Brazil was evaluated for sediment quality before, during and after the process of dredging. The aim of the study was to evaluate the temporal sediment quality of this area using the approach SQT. A total of 14 sampling points were selected in the disposal site within the region directly affected by the dredged material. For historical comparisons (between 2007 and 2009) of sediment quality data, the method SQT (Sediment Quality Triad) was applied (2007; 2009a; 2009b; 2010 and 2011). The sediment was analyzed for particle size, organic carbon, nitrogen, total phosphorus, metals (As, Cd, Pb, Cu, Cr, Hg, Ni and Zn) and semi-metal arsenic. Tests on ecotoxicity of total sediment were conducted for benthonic *Nitokra* copepods as proposed by Lotufo and Abessa (2002). The tests of the sediment liquid phase (interstitial water) were performed with *Echinometra lucunter* sea urchin embryos according to the ABNT 15350 (2012) of dredged material disposed; after 100% of dredged material disposed; 6 months after the completion of dredging activities and 18 months after the completion of dredging activities. At the end of the study it was observed that the arrangement of the dredged material resulted in the increase of metal concentrations at the majority of sampling points. Consequently, the sediment found in the sampling site has become more toxic, causing direct effects on the amount of female offspring of the copepod species *Nitokra* sp. Despite the fact that the test with *Echinometra lucunter* showed improvements, when 100% of the dredged material was disposed, it was observed that after 18 months of dredging the area of disposal was not fully restored. The historical data comparisons of the Triad Decision Table performed during dredging showed an increased ecotoxicological potential after the disposal of 100% of the dredged material. However, the tests showed a reduction, but not the eradication, of sediment and porewater toxicity after 18 months of cessation of dredging activities. Therefore, it is recommended the consideration of a new site for the disposal of new dredged sediments since this is an area adjacent to fishing spots.

#### MO431

##### Triad approach (SQT) application for the definition of the best disposal sites of dredged material of a maritime terminal in Brazil

T. Furley, F. Aquinoga, APLYSIA Environmental Research and Solutions; S. AMIGO, SAMARCO MINING

This study aimed to use the Triad approach (SQT) to define the best disposal site of

dredged material derived from mining activities in a maritime terminal located in Brazil. The study area consisted of a polygon measuring 12km<sup>2</sup>, located approximately 3 km from the Terminal on the nearest coastal side. This area comprised of 22 stations sampled in February 2013. At each station sediment samples were collected for chemical analysis (arsenic, cadmium, lead, mercury, nickel, zinc, chromium, iron, copper, PCBs, endrin, diendrin, DDD, DDE, DDT, HCH, chlordane, methyl naphthalene, benzo(a)anthracene, anthracene, benzo(a)pyrene, chrysene, dibenzo(a,h)anthracene, phenanthrene, naphthalene, acenaphthene, fluoranthene, fluorene, pyrene, PAHs and TBT), for ecotoxicological analysis (percentage of impairment of reproductive *Nitokra* sp in the samples compared to control) and for benthic community structure analysis (total number of organisms, diversity, evenness and species richness). For the Triad Approach evaluation the Ratio to Maximum integration method - RTM proposed by Del Valls and Chapman (1998), the Ranking Scale method proposed by Carr et al. (2000) and the Decision Table method proposed by Chapman (1990) were used. Based on the SQT evaluation methods it was observed that sampling stations 5 and 15 presented more alterations than the other stations. The sampling station number 5 presented high chemical contamination, particularly cadmium and PAHs. It was also found low benthic richness and density at station 5. On the other hand, in the sampling station 15 the found rating can be explained mainly by the ecotoxicity and the high cadmium levels. From the Decision Table it was possible to conclude that no sampling stations presented alterations in the benthic fauna assemblages. For the reasons above presented, considering sedimentary marine floor cover properties, interferences of other uses and the economic viability of the activity, it was recommended that the disposal of dredged material should be carried out in sampling station number 15.

### Impact of statistical methods used in ecotoxicological studies on regulatory decisions (P)

#### MO432

##### Challenges for Statistical Analysis of Ecotoxicology Experiments

J.W. Green, DuPont / Applied Statistics Group; T.A. Springer, Wildlife International, Ltd.; J.P. Staveley, Exponent

The conceptual advantages for ECx estimates from regression models fit to concentration-response data from toxicity experiments are clear. There is little disagreement that fitting a regression model to data and reporting a derived ECx value is advantageous for "typical" concentration-response tests. However, the amount and importance of ecotoxicity testing that is not "typical" concentration-response testing is widely unappreciated. Limitations on determining, interpreting, and applying ECx values become obvious to practitioners who are routinely confronted with "problematic" concentration-response testing situations. We present evidence that the criticisms of NOECs and the advantages of ECx estimates have both been exaggerated. While ECx estimates are certainly valuable, even preferable, under the right conditions, those conditions do not always exist and it is important to recognize such situations and bring to bear the right tools for a wide range of responses from many types of ecotoxicity experiments. There are often extreme limitations in the number of concentrations, reps per concentration, and number of subjects per rep that can be tested. Very expensive equipment of limited capacity is needed for many modern experiments and this restricts many experiments to 4-5 test concentrations plus control with 2 or sometimes 4 reps/concentration. This is a problem, since generally a larger number of test concentrations is needed for regression and ECx estimation than for NOEC determination. While in the abstract, better curves are obtained by extending the range of test concentrations, limitations arise from the low solubility common to many test chemicals, since test concentrations are restricted by the limit of solubility and, at the low end of the range, the limit of quantitation (LOQ). Further limits are imposed by the difficulty in maintaining stable test concentrations and analytical variability. Even some normally "well behaved" endpoints cannot always be fit by a model that gives meaningful results. Without NOEC, there may be no means to assess the data from such studies. Appropriate statistical models and tests demonstrate that hypothesis testing offers more than is often perceived. Responses for which no regression models have so far been proposed or accepted within the ecotoxicology community also demand a NOEC.

#### MO433

##### From NOEC to ECx: a large scale data analysis on ecotoxicological studies with pesticides

F. Marchetto, F. Galimberti, ICPS; W. de Boer, H. van der Voet, Alterra Wageningen University and Research Centre; A. Moretto, State University of Milano

Historically chronic or long-term studies performed for the authorisation of plant protection products (PPP) result in the reporting of endpoint values in terms of No-Observed Effect Concentration (NOEC). The related Test Guidelines (OECD, ISO, EPA) were designed to fulfil the data requirement for NOEC determination. NOEC values are however criticised since their values strongly depends on the experimental study design, and actually the extrapolation of Effect Concentration affecting a percentage  $x$  of the test organisms or where a percentage  $x$  of an effects is observed ( $\text{EC}_x$ ) is considered more appropriate since it takes into account the whole concentration-response curve. The new Regulation (EC) No. 1107/2009 for

the authorisation of PPPs and the related data requirements (Commission Regulation (EU) No. 283/2013 and 284/2013) require that ecotoxicological endpoint data from chronic or long-term studies provided by the Applicant are reported as EC<sub>10</sub> or EC<sub>20</sub> values together with the NOEC. However, there is no systematic comparison available to compare NOEC values to EC<sub>10</sub> and EC<sub>20</sub> values derived from the same study. In the present work, 200 long term and chronic studies on aquatic organisms, equally distributed among fish, daphnids, algae and aquatic macrophytes, are re-analysed in order to calculate NOEC, EC<sub>10</sub>, EC<sub>20</sub>, EC<sub>50</sub> and their limit of confidence (from the same study) using appropriate statistical analyses. A comparison of NOEC with EC<sub>x</sub> values and their lower limit of confidence is performed by analysing the distribution of the NOEC/EC<sub>x</sub> ratios. Considerations are made on studies based on the same organisms and on the study design (appropriately developed to calculate EC<sub>50</sub> for algae and macrophytes and NOEC for fish and daphnids).

#### MO434

##### **Does the choice of NOEC or EC10 affect consequences of ecological risk assessments?**

Y. Iwasaki, Research Center for Life and Environmental Sciences; K. Kotani, Yokohama national university / Graduate School of Environment and Information Sciences; S. Kashiwada, Toyo University / Department of Life Sciences; S. Masunaga, Yokohama national university / Faculty of Environ Information Sci No observed effect concentration (NOEC) and lowest observed effect concentration (LOEC) have been used in ecological risk assessments but strongly criticized for about 30 years by many ecotoxicologists. One of the proposed alternatives is use of EC<sub>x</sub> (the concentration that causes an effect of x%). However, few studies have investigated how the use of EC<sub>x</sub> actually affects consequences of ecological risk assessments. To address the issue, we collected chronic toxicity test data previously used for deriving species sensitivity distributions in published literature, and also obtained extensive datasets on standard chronic toxicity tests from the Ministry of the Environment of Japan (21-d reproduction test with *Daphnia magna*, growth inhibition test with *Selenastrum capricornutum*, early-life-stage toxicity test with *Oryzias latipes*). By taking EC10 as an example, we first evaluate relationships between NOECs and EC10s. Further, we investigate how the choice of NOEC or EC10 affects hazardous concentration for 5% of species (HC5) estimated using species sensitivity distribution approach.

#### MO435

##### **ECx-Values in Ecotoxicology - Defining endpoint-specific and biologically meaningful effect concentration threshold values (ECx)**

M. Caspar, BASF SE / Regulatory Ecotoxicology; E. Salinas, BASF SE; L. Peters, BASF SE

For more than 2 decades ecotoxicologists have debated replacing hypothesis testing endpoints (NOEC and LOEC) with regression-based values such as E(L)Cx. The main criticism of the NOEC-approach is the complete dependence on the chosen test concentrations and no inherent correspondence to specified no effect levels. Thus, the NOEC is widely (mis-) used as a zero-effect concentration, although it can be linked to some percent effect in the desired endpoint. This means that high control variability in an experiment may result in higher NOEC values. As a result of the growing interest within OECD member countries and the scientific community, the regression-based ECx-approach was supplemented in several regulations, guidance documents and guidelines as an alternative for the NOEC-approach for ecotoxicity test systems. It does not depend on arbitrarily chosen test concentrations and takes the whole concentration-effect relationship into account, including the calculation of confidence intervals. Until now, the REACH guidance document (R.10) suggests an EC10 as a substitute for the NOEC, whereas the regulation No. 283/2013 (in line with EC No. 1107/2009) for PPP's recommends an EC10 or EC20 for the *Daphnia magna* reproduction test (OECD TG 211). But there is no scientific reason to presume that a 10-20% effect relates to the NOEC or that this percent effect is biologically meaningful in general for all endpoints in all test organisms. The non-equivalence of statistical significance and biological relevance has long been recognized and in the best interest of environmental protection it is indispensable to detect threshold values in relation to population-level significance. Therefore, the question of what magnitude of effect is important to detect is not a statistical but rather a biological issue. The main question answered in this project is: which endpoint-specific x-value (EC<sub>x</sub>) is biologically meaningful for laboratory cultured *D. magna* populations? To answer this question we conducted a meta-analysis of a large dataset of chronic *D. magna* studies, regarding the statistical capabilities for the endpoint-specific EC<sub>x</sub>-calculations, like variability (CV%) and testpower. Together with calculated CV-values between the studies this analysis gives valuable insights of fluctuating population densities. We propose a specific range of variation around a mean which causes no population-level consequences and results in biologically meaningful x-values.

#### MO436

##### **A new approach for evaluation of reproduction count data using a Poisson model: why multiple t-tests yield unreliable results.**

R. Lehmann,

For detection of a no/lowest observed effect concentration (NOEC/LOEC) in species reproduction tests data often are evaluated using multiple statistical tests,

e.g. Williams and Dunnett t-test. While normal approximation of these data is a minor problem multiple t-tests suffer from variance heterogeneity. Assume a chemical caused a reduction of species reproductivity down to (near) zero at the highest concentration level. Thus, dispersion of the data reduced, too. Variance homogeneity does not seem a plausible assumption preventing proper application of multiple t-tests. As an alternative a Poisson model which describes the data more appropriate is proposed. Because mean rates of reproduction equal the Poisson parameter  $\mu$ , testing for differences in means implies testing for differences in  $\mu$ s. Numerous pairwise comparisons "control vs. treatment" have to be performed to detect a NOEC/LOEC using a Poisson model. Thus, we have to account for  $\alpha$ -inflation. The closure principle (CP) helps overcome this issue providing null-hypotheses which can all be tested at the same significance level  $\alpha$ . The computational approach test (CAT) is applied to test the equality of two or more Poisson-means ( $\mu$ s) simultaneously. CPCAT describes the combined approach of CP and CAT. It is demonstrated that the Poisson model in combination with CPCAT is superior to the normal distribution models of Williams and Dunnett. The new approach does neither suffer from normal approximation nor from variance heterogeneity. By application to real data it becomes apparent that CPCAT provides reliable statistical results when computing a NOEC/LOEC.

#### MO437

##### **Species sensitivity distributions: An evaluation of methods using triclosan as a case study**

T.R. Barber, M.J. Bock, ENVIRON International Corp.; J. Lyndall, ENVIRON International Corporation; M. Capdevielle, Colgate-Palmolive Company Species sensitivity distributions (SSDs) are composed of multi species toxicity data, with each data point describing a single species and its toxicity threshold. Aquatic toxicity data used to develop SSDs usually represent chronic, no-effect data from at least eight but seldom more than 20 species. SSDs are commonly used to develop water quality benchmarks for a variety of chemicals, including the medical and personal care ingredient triclosan. The 5<sup>th</sup> percentile of the distribution of chronic, no-effect aquatic toxicity data, referred to as the HC5, can be utilized as a concentration threshold that is designed to protect ecosystem function, populations and communities in the natural environment. There are many statistical methods that can be used to estimate the HC5 and the associated confidence intervals. These methods include non-linear curve fitting, linear regression, classical distribution fitting, Bayesian distribution fitting, and non-parametric bootstrapping. Given that SSDs are routinely based on a limited number of species, inferences regarding the distribution of the data are largely based on professional judgment and assumptions. In addition, these calculations are often performed using tools that were not developed by the user, insulating the user from the underlying methods and assumptions and often providing a false sense of accuracy. When comparing a fitted SSD to the experimental data, the plotting position of the experimental data is sensitive to the method used to calculate percentiles, therefore affecting the assessment of the quality of the fit. In addition to these methodological concerns, quality review of the underlying data may be more or less rigorous and certain functional groups may be over- or under-represented. These factors can significantly impact the selection of the final dataset and the calculated HC5. To illustrate these issues, SSDs and HC5s were calculated for triclosan using a variety of methods and a variety of data handling practices. Sensitivity analyses were conducted to demonstrate the significance of methodological considerations as well as the inclusion or exclusion of specific data points in altering the estimate of the HC5.

#### MO438

##### **Better by design - improving similarity in field microcosm studies**

C. Jenkins, HLS / Ecotoxicology; E. Hopkins, HLS; E. Quinton, HLS / Aquatic Ecotoxicology and Biodegradation; P. Xirogiannopoulou, Huntingdon Life Sciences Ltd

Field microcosm study designs follow well established guidelines (HARAP, CLASSIC, OECD and EFSA) with relatively standard methods for sampling and enumerating primary producers, invertebrates and emerging insects. In the current climate where the effectiveness of these studies is drawn into sharp focus by the need to highlight the power of statistical analysis to identify significant change (e.g. calculating MDD, EFSA 2013, Brock *et al* 2014), we feel there is a real need to re-examine study methodology. In particular, we need to examine the effectiveness of methods used to establish and monitor invertebrate populations and to control the similarity of experimental systems in order to improve the sensitivity and reliability of the applied statistical methods. In our studies, invertebrates are collected from field sites or un-treated reservoirs and added to shallow (30 cm deep) systems containing submerged and emergent macrophytes designed to simulate edge of field ditches. A number of methods have been introduced to achieve and subsequently control the similarity of macro-invertebrate populations during the establishment. Invertebrates such as *Asellus* and *Crangonyx* are collected by sweep-netting into a number of containers, the collection pooled, mixed and sub-samples randomly allocated to microcosms. For taxa such as *Chaoborus*, standardised collections of larvae are randomly added to microcosms directly (without sub-sampling) as are *Cloeon dipterum* nymphs. Using at least two quantitative counts of the numbers in invertebrate samplers, numbers are adjusted to improve similarity either by additional collection (for *Chaoborus* larvae) or by the exchange of invertebrate samplers between microcosms. For emerging insects, we

totally enclose each microcosm with insect-proof netting to collect all of the emerging insects to give accurate quantitative counts which we believe is important to allow the RAC for sensitive univoltine and semi-voltine species to be defined. In this presentation we describe these methods in more detail and describe some achieved MDD's and the factors affecting invertebrate population similarity during the course of a study, together with the implication of the composition of emerging insect populations on defining RACs.

#### MO439

##### **Study design and statistical analysis of regulatory community ecotoxicity studies**

A. Lawrence, Cambridge Environmental Assessments; K. Brown, Independent Consultant; G. Frampton, University of Southampton; P. van den Brink, Alterra Wageningen UR / Aquatic Ecology and Water Quality Management Group b Alterra

Ecotoxicological field studies conducted under EC Regulation 1107/2009 may be designed by industry notifiers in association with external consultants and contract research organisations (CROs). The results may then be interpreted and summarised before inclusion in a regulatory submission in support of a product or active substance registration. The submission will be reviewed by representatives from Member State (MS) Competent Authorities, in terms of both study quality and meaning. Not all parties involved may be familiar with the statistical design and interpretation requirements of such studies, which are complex. Here we discuss certain important aspects of the design and statistical analysis of such studies. These include impact of spatial scale on effects and recovery in terrestrial plots, analysis of study data by sampling method or functional group, investigation of abundance data alongside statistical analysis to aid interpretation, repeated two sample testing, and use of Principal Response Curves including analysis of reference items, amongst others. This work was funded by UK Chemicals Regulation Directorate.

## **Biodegradation and Environmental Fate of Chemicals - Regulatory Acceptance of Non-Standard Tests (P)**

#### MO440

##### **A critical evaluation of the weight of evidence approach for determining persistence in PBT assessments under REACH**

R.J. Brown, wca consulting; M. Claeussens, DuPont; I. Colombo, Solvay Specialty Polymers; M.R. Embry, ILSI Health & Environmental Sciences Institute (HE); B. Hidding, BASF SE; S. Jacobi, Albemarle Europe / HSE; M. Leon Paumen, ExxonMobil Biomedical Sciences / ExxonMobil Biomedical Sciences TES Division; N. McGrath, Euro Chlor; C. Miyata, Sumitomo Chemical Co Ltd; G.C. Roberts, ENVIRON UK Ltd / Brixham Environmental Laboratory; J.R. Snape, AstraZeneca UK Ltd. / AstraZeneca Global Environment; K.B. Woodburn, Dow Corning Corporation / HES; H. Vrijhof, ECETOC

This presentation gives a critical overview of the available tests for evaluating persistence using a weight of evidence approach under the revised Annex XIII of the EU REACH Regulation. The technical guidance for this updated regulation is currently being drafted and in support of this ECETOC produced a special report suggesting approaches for PBT assessment following the updated regulations which is used as the basis for this presentation. The limitations of the standard OECD 301 series ready biodegradation tests as screening tools for persistence will be outlined as well as potential enhancements that can be used to improve environmental realism and to evaluate if a substance is likely to require further testing. Suggestions on how inherent and marine biodegradation tests should be interpreted in the context of PBT assessment is given. Simulation studies may be required to refine the persistence assessment of a substance if the criteria for the ready and inherent biodegradation studies are not met. The relevant simulation study should be designed based on the relevant compartment of concern, the properties of the test substance and using realistic environmental temperatures. The OECD 308 test was developed as a tool for assessing spray drift for pesticide applications and is not a river simulation study and therefore is not necessarily relevant for all substances released into rivers, because the test system is static and the water to sediment ratio is very low. Alternative tests such as OECD 309 or OECD 314 may be more appropriate tests for 'down the drain' chemicals. In simulation studies the persistence of degradation products should also be considered. Some of the difficulties associated with generating and interpreting simulation studies for PBT assessment will be highlighted. Recommendations concerning non-extractable residues (NERs) are also provided. NERs are expected to be strongly bound to sediment or soil and, while adsorbed, they are protected from degradation and are not bioavailable. Therefore, in the context of the PBT/vPvB assessment, NERs should be considered as not persistent, bioaccumulative, or toxic. In conclusion, while there is a clear decision tree for conducting 'P' assessment supported by a number of validated tests, in practice the available studies are not necessarily fit for purpose and may result in chemicals being wrongly assigned as PBT or vPvB.

#### MO441

##### **Ready biodegradability of poorly water soluble substances: Impact of inoculum and bioavailability improvement methods on ready biodegradability of two chemicals**

C. Sweetlove, LOREAL SA / Research and Innovation; J. CHENELE, LOREAL; Y. BARTHEL, EUROFINS / Expertises Environnementales; F. ESCAFFRE, LOreal Research / Research and Innovation; M. BOUALAM, EUROFINS / Expertises Environnementales; G. THOUAND, University of Nantes / UMR CNRS GEPEA CBAC lab; J. L'HARIDON, LOreal Research / Research and Innovation

The biodegradation of chemicals in the bioremediation process of polluted groundwater and toxic waste sites requires a close physical contact between bacteria and the pollutant. Therefore, a low hydrosolubility may lead to underestimate the chemical's biodegradability when tests are performed in water. For example, a lipid compound with a density below 1 floats at the air/water interface in the test vessel. In this configuration, the bioavailability of the chemical to microorganisms can be limited. Only few guidance documents have suggested technical adaptations to improve the bioavailability of poorly water-soluble chemicals. Their implementation could improve the biodegradation results. The aim of this study was to define the impact of different inocula on biodegradation of two chemicals (a powder and a liquid) in a ready biodegradation test (RBT). Three inocula were selected: two specific bacteria (*Nitrosomonas europaea* and *Corynebacterium pseudodiphthericum*) and an activated sludge from a wastewater treatment plant. In addition, seven Bioavailability Improvement Methods (BIM) were compared with these three inocula. The BIM performed are dispersion with ultrasound (10 and 30 min), emulsion with 2,2,4,4,6,8,8-heptamethylnonane (HMN), silicon oil addition (two concentrations), dispersion with silicon oil associated to ultrasonic treatment (two different operating conditions) and direct addition (as reference operating condition). Experiments were performed with a screening RBT tool (Respicond VI<sup>®</sup>), which allows to compare a high number of operating conditions in the same test with the same microbial inoculum with his 95 test flasks (volume: 150 mL). This poster highlights the best inoculum to compare BIM for test chemicals (one powder and one liquid) and the best BIM to improve the biodegradation of the two test chemicals.

#### MO442

##### **Biodegradation of Triclosan during sewage treatment plant processes**

S. Pawlowski, S. Champ, BASF SE

Triclosan is an antibacterial biocide which is commonly used in various cosmetic and personal care products such as hand wash or tooth paste since decades. Due to these down-the-drain applications, the main entry part into the environment is via sewage treatment plants (STP) effluents. Thus, the removal efficiency of the STP is key to the STP effluent concentrations of Triclosan and as a consequence to the concentrations in the river. Triclosan is considered as not readily but inherently primary biodegradable based on available OECD 301 and 302 study results. Despite this test results, the discussion continues whether the removal of Triclosan during the STP process is mainly based on biodegradation or on adsorption. In order to provide more detailed information on the environmental fate profile of the substance within an STP, the results of two continuous activated sludge (CAS) studies under aerobic conditions are presented. The test concentration ranged from 40 to 2000 µg/L and 7.5 to 50 µg/L; respectively, for both studies. The overall removal efficiency ranged from 98.5 – 99.3 %. The degree of mineralization to CO<sub>2</sub> ranged from 74 – 90 %. The amount of substance being associated with the biomass (including non-extractable residues) ranged from 1.5 – 17 %. Furthermore, results from a biodegradation screening test (OECD 301B) on Methyltriclosan demonstrate that this transformation product of Triclosan is inherently biodegradable. The results clearly demonstrate that Triclosan and its transformation product are extensively biodegraded during the activated sludge process within a sewage treatment plant.

#### MO443

##### **Screening test systems for the determination of biodegradation kinetics in water, water-sediment and soil - development and applicability in the regulatory context**

T. Junker, ECT Oekotoxikologie GmbH; A. Coors, ECT Oekotoxikologie GmbH  
Biodegradation data of chemicals are needed across different regulatory frameworks, inter alia for the assessment of persistence, exposure and risk. Besides experimental data, the prediction of degradation rates, half-lives and pathways by models plays a decisive role. However, these models were mainly developed based on qualitative experimental biodegradation data (e.g. ready vs. not ready biodegradable) related to water-only test systems, whereas models based on quantitative biodegradation data for more complex environmental matrices such as soil and sediment are lacking. To overcome these shortcomings, two new screening test systems for the determination of the ready biodegradability in water-sediment systems (WSST = Water-Sediment Screening Tool) and soils (SST = Soil Screening Tool) were developed based on OECD 301C (MITI-Test). Biodegradation experiments were performed in water (MITI), water-sediment (WSST) and soil (SST) for a set of 15 compounds. The degradation curves were determined by non-linear regression models and the kinetic parameters 'mineralization at the plateau', 'duration of the lag-phase', 'mineralization half-life' and 'degradation rate constant' were determined using the regression model with the best fit. The test systems MITI, WSST and SST were evaluated for their suitability to provide quantitative biodegradation data and kinetics that can be applied in the regulatory context. The main focus was on the persistence assessment within REACH, where degradation half-lives from simulation studies shall be

directly compared to trigger values for water, sediment and soil to identify persistent compounds. However, for many substances there are no data from simulation studies available. Thus, a screening assessment for persistence is performed under REACH that is mainly based on ready biodegradability tests according to OECD 301 and extrapolation of these data to derive half-lives for water as well as soil and sediment by multiplication with default factors. In addition to experimental mineralization half-lives, alternative approaches described in literature and software packages were used in the present study to determine half-lives for the 15 test compounds in water, sediment and soil. By means of these data, a screening assessment for persistence was performed by comparing the half-lives to the persistence criteria under REACH.

#### MO444

##### **Sorption and degradation of pharmaceuticals in soil and biosolids amended soil**

M. Vilà, M. Hidalgo, University of Girona / Department of Chemistry

Pharmaceuticals are emerging contaminants which have drawn concerns about possible harmful effects in the environment or the potential entry of drugs into the human food chain. Most studies on the environmental fate of pharmaceuticals have focused on their behaviours during wastewater treatment processes, the sludge and in environmental waters. However, there is still a significant lack of knowledge of their transport and fate in agricultural soils. Sewage sludge from wastewater treatment plants (WWTPs) is commonly used as soil amendment because it contains nutrients and organic matter which can improve the soil quality. Since pharmaceuticals are routinely found in biosolids from WWTPs, once land applied they are potentially mobile and available for plant uptake and bioaccumulation. The fate of pharmaceuticals in soils is mostly determined by sorption and degradation processes. This group of contaminants consist of a wide range of compounds. Their sorption behaviours vary from compound to compound and are difficult to predict because is often controlled by interactions with specific functional groups and pH-dependent speciation. Moreover, land application of biosolids can alter the chemical and physical properties of the soil, with an increase in soil-water retention and organic matter content which can consequently affects the interaction with chemicals. In this study, laboratory experiments were performed to investigate the sorption and degradation of three anti-inflammatory (naproxen, ibuprofen and diclofenac) and five antidepressant drugs (citalopran, fluoxetine, norfluoxetine, paroxetine and sertraline), with different physicochemical characteristics, in an agricultural soil. The effect of biosolid amendment on sorption and degradation was also examined. As expected, antidepressants adsorbed very strongly to the soil with and without addition of biosolids. Adsorption tests using a batch equilibrium method showed that adsorption of all tested pharmaceuticals could be well described with Freundlich equation. Competitive sorption was observed when the pharmaceuticals coexisted. This cosolute effect was no observed for anti-inflammatory drugs in absence of antidepressants. Biosolids amendment increased the sorptive strength for all the compound studied and, in general, had also an effect on degradation under the conditions of this study.

#### MO445

##### **Bioremediation of Hydrocarbons with Microorganisms**

S. Ashraf, Environmental studies Center- QU; M.Y. Al-Sulaiti, ExxonMobil Research Qatar / Water Reuse; C.S. Warren, ExxonMobil Research Qatar / Advanced Environmental Scientist; I.M. Al-Shaikh, Environmental Studies Center-QU

Bioremediation or the use of microorganisms for environmental cleanup is usually the preferred and major route of PAH removal from contaminated environments because it is cost effectiveness and complete cleanup (Pothuluri and Cerniglia, 1994). Several isolated microorganisms have been successfully utilized in major hazardous waste cleanup processes such as, in industrial process streams and effluents (Levinson *et al.*, 1994 and Al-Wasify and Hamed, 2014). Unfortunately, most of these studies were carried out in Western countries, to a limited extent in South America and Asia (Prantera *et al.*, 2002). In Qatar, there is limited information on microbial degradation of polycyclic aromatic hydrocarbons (Al-Thani *et al.*, 2009). In this work, we reported the isolation and characterization of some bacterial and yeast species from soils and industrial wastewater (IWW) collected from a native plant experiment conducted at Environmental Studies Center (ESC) of Qatar University. The native plant experiment project had two phases. Sand samples were collected in sterile containers after mixing the soil-sand culture and before and after irrigating with IWW. Samples were collected every 15 days according to the project plan. Water samples were collected from the first and second IWW deliveries. The same procedure was repeated for the second phase of the project. After using the serial dilution method for the microbial total count, preparation of several media such as (nutrient agar, Pseudomonas Agar Base, Cetrimide Agar, Trypticase Soy Agar, yeast extract agar & Czapek-Dox Agar) was done to promote the bacterial and yeast growth. After isolation and purification of bacterial species, identification was done using **API 20NE & API Coryne** as an identification system from **bioMérieux** then, confirmation was done using **VITEK 2 Systems Version: 04.02 MIC Interpretation Guideline** to some selected strains. Our results showed that, twenty nine species belonged to twenty genera were isolated from the IWW and Soil samples. Isolation and screening cultures on mineral salts medium and enrichment medium were done. The effect of different diesel concentration on the growth of these species was studied. **API 20 AUX** as a

**yeast identification system from bioMérieux** was used to identify the most common yeast isolates which show thirteen species which were belonged to eight different genera. The most common were *Candida spp.*, *Trichosporon mucoides* and *Cryptococcus spp.*

#### MO446

##### **Effects of HP-β-CD concentrations and repeated exposures to diesel on biodegradation of benzo[a]pyrene in soil**

I.S. Obuekwe, University of Benin Benin City Nigeria; O. Adebisi, UNIVERSITY OF ILORIN NIGERIA; K.T. Semple, University of Lancaster / Lancaster Environment Centre

**Aim:** It is well-known that low aqueous solubility and poor microbial catabolic activity limit benzo[a]pyrene biodegradation in soil. Used as a solubility-enhancement agent, the effect of increasing hydroxypropyl-β-cyclodextrin (HP-β-CD) concentrations (0, 12.5, 25 and 50 mM) on benzo[a]pyrene mineralisation was assessed in soil. The effect of repeated exposures over 150 d to diesel oil (1x500, 1x5000, 2x250, 2x2500, 5x100 and 5x1000 mg<sub>oil-C</sub> kg<sup>-1</sup> soil) on the development of benzo[a]pyrene catabolic activity was also assessed. **Materials and Methods:** Sequential aqueous, HP-β-CD and alkaline extractions were used to quantify benzo[a]pyrene bioavailability and partitioning in soil. Standard radiorespirometric assays were used to measure catabolic activity and mineralisation of <sup>14</sup>C-benzo[a]pyrene in soil. **Results:** Indigenous catabolic activity towards benzo[a]pyrene was low in control soil (mineralisation extent < 1%). However, pre-exposure to diesel oil significantly enhanced (11–55times) catabolic activity; this being greatest in soils repeatedly exposed to lower diesel concentrations. Overall, whilst the presence of 50 mM HP-β-CD significantly increased (26–67times) benzo[a]pyrene bioavailability in soil, it failed to enhance benzo[a]pyrene mineralisation; however, lower HP-β-CD concentrations appeared to have some impact on mineralisation. **Conclusion:** Increasing HP-β-CD concentration significantly increased the apparent aqueous dissolution of benzo[a]pyrene from soil matrices, but failed to further enhance <sup>14</sup>C-benzo[a]pyrene mineralisation in diesel-contaminated soil. These findings are important in assessing the fate of benzo[a]pyrene and designing bespoke remediation strategies for soils chronically exposed to petroleum-derived oils.

#### MO447

##### **Humic acids of Patagonian soils. Isolation and kinetic study of the photochemical action in the natural degradation of environmental pollutants**

M.M. Bregliani, J. ESCALADA, UNIVERSIDAD NACIONAL DE LAPATAGONIA AUSTRAL; A. Pajares, UNPATAGONIA; N.A. GARCIA, UNIVERSIDAD NACIONAL RIO CUARTO

Humic substances, among which humic acids (HAs) constitute a relevant fraction, are natural mixtures of organic compounds, abundant in terrestrial and aquatic ecosystems [1][2]. In some sense, the same can be said about riboflavin (Rf, vitamin B<sub>2</sub>) which is also present in waters of rivers, lakes and seas. This contribution presents a systematic kinetic and mechanistic study on the photosensitizing properties of the mixture HA plus Rf, in order to determine potential synergistic or inhibitory effects of the photosensitizers. As compounds models for Ar-OH contaminants, phenol (PhOH) and 3-hydroxypyridine (3-OHP) were employed. The HA used was isolated from a forest soil near El Chalten, Santa Cruz, Argentina. The fraction was obtained by sequential dialysis using hydrochloric acid, sodium hydroxide and hydrofluoric acid and purified by dialysis in cellulose tube Sigma D-7884.[3] A solution of 50µg/ml of HA plus 0.04 mM Rf was used as sensitizer. As an overall result, it was determined that the visible-light-mediated photooxidation of 3-OHP at pH 7, sensitized by low Rf and HA concentrations, and standardized by comparison to the photooxidation rate of the known oxidizable target FFA, is an efficient process. It should be mentioned that the experiments of oxygen uptake for 3-OHP and FFA were made under identical experimental conditions, including the concentration of the oxidizable substrates. On the other hand, the degradation of PhOH only operates in the alkaline pH range. A moderate decrease in the rate of oxygen consumption by 3-OHP upon Rf + HA sensitization was observed as compared to the simple addition of the oxygen uptake rates for 3-OHP upon individual Rf and HA sensitization. It is attributed to a catalytic decomposition of O<sub>2</sub>•- by HA, which competes with 3-OHP by the oxidative species. <br clear="all" /> [1] J.I. Edges, J.M. ## **Engineering in vivo fish models for advancing environmental hazard and risk assessment (P)**

#### MO448

##### **Dynamic and differential expression of the gonadal aromatase during the process of sexual differentiation in a novel transgenic cyp19a1a-GFP zebrafish line**

n. Infray, INERIS / Ecotoxicology Unit; E. Chadili, INERIS; B. Piccini, m.

caulier, INERIS / Ecotoxicology Unit; J. Porcher, INERIS / UMRI SEBIO; y. guiguen, INRA / LPGP; F. Brion, INERIS / Ecotoxicology Unit

In most gonochoristic fish species, aromatase, the enzyme responsible for the synthesis of estrogens, has been shown to play a critical role in the process of sexual differentiation (SD). In zebrafish, that undergoes a juvenile intersex stage, there is still a lack of knowledge regarding the precise localization and pattern of expression of gonadal aromatase (Cyp19a1a) impeding the formal characterization of the role of *cyp19a1a* in this process. To fulfill this gap, the spatio-temporal expression of *cyp19a1a* was analyzed in a novel transgenic zebrafish model expressing Green Fluorescent Protein (GFP) under the control of the zebrafish *cyp19a1a* gene promoter. First, we showed a perfect co-expression of GFP and endogenous Cyp19a1a protein in adult gonads that was localized in the cytoplasm of oögonia, young oocytes and peri-follicular cells of the ovary and in the cytoplasm of Leydig and germ cells in the testis. Then, the spatio-temporal expression pattern of *cyp19a1a* was studied during SD using GFP fluorescence imaging in gonads at 20, 30, 35 and 40 day post-fertilisation (dpf). Our data showed that GFP was expressed in all undifferentiated gonads of 20 dpf-old zebrafish. At later stages of development, GFP expression increased in early differentiated female at 30 and 35 dpf to reach high GFP intensity in well-differentiated ovaries at 40 dpf. This pattern of gonadal GFP expression markedly differed from that of males which consistently displayed low GFP expression as compared to female whatever their stage of development, resulting in a clear dimorphic expression between males and females. Interestingly, fish that undergoes ovary-to-testis transition (35 and 40 dpf) presented an intermediary GFP level as compared to those measured in males and females. Our results suggest that (1) *cyp19a1a* is expressed early during gonadal development before the histological process of SD, (2) the down-regulation of *cyp19a1a* expression is critical for the testicular differentiation, (3) although *cyp19a1a* expression exhibit a clear dimorphic expression in gonads during SD, its expression persists whatever the sex suggesting that estradiol synthesis is important for gonadal development in both male and female. Monitoring the expression of the GFP in control and exposed-fish will help to identify the interest of this model to study the mechanisms of action of endocrine disrupting chemicals on critical physiological processes such as SD.

#### MO449

##### **Application of transgenic zebrafish to enable adverse outcome pathway analysis for endocrine disrupting mechanisms**

A. Brown, Exeter University / Safety Health Environment; J. Green, University of Exeter; M.J. Hetheridge, University of Exeter / Biosciences; R. Currie, Syngenta; C.R. Tyler, Biosciences College of Life and Environmental Sciences

Around 800 chemicals are known, or suspected, to interact with hormone receptors, and/or to affect hormone metabolism, with the theoretical potential to affect physiological function, if exposures exceed thresholds for activation of molecular initiating events (MIEs). However, only a small fraction of these chemicals have been investigated in tests capable of identifying overt endocrine disrupting adverse effects in intact organisms or their progeny or (sub)populations (Weybridge, 1996, WHO/UNEP, 2012). Whilst *in silico* and *in vitro* tools may provide some indication of the potential endocrine activity of chemicals, reliable *in vivo* systems are required to assess for potential adverse effects, ideally in a high through-put/high content manner. Transgenic animal models (e.g. zebrafish) offer systems whereby MIEs that trigger adverse outcome pathways (AOPs) can be identified and quantified by fluorescent protein reporters linked to specific receptors or enzymes. Spatial resolution of receptor or enzyme responses at the organ and tissue levels potentially enables targeted assessment of downstream molecular events and subsequent pathological, physiological and functional responses. Temporal resolution is also possible in individual fish, enabling the identification of latent responses in organs and tissues. Quantification of MIEs and other key events and their calibration against adverse outcomes are crucial next steps for moving the application of AOPs from basic hazard assessment to intelligent risk assessment. Using the 'ERE-Casper' zebrafish as an illustrative model, we present a scheme for the application of transgenic zebrafish in chemical hazard and risk assessment and, at a more mechanistic level, show how they can serve to enable adverse outcome pathway analysis. The ERE-Casper zebrafish possesses a green fluorescent protein (GFP) reporter activated by estrogen response elements (ERE) and amplified via a two plasmid system, making it highly sensitive for detecting environmentally realistic exposure concentrations of selected estrogens (Lee et al., 2012). Furthermore, this model lacks skin pigmentation, making detection of the GFP response possible in both larval and juvenile life-stages and allowing for direct comparisons against adverse effects on development and function of targeted organs for these life-stages.

#### MO450

##### **A newly cyp11c1-GFP transgenic zebrafish model to study the expression and the perturbation of corticosteroidogenesis by endocrine active substances at early developmental stages.**

C. Garoche; M. Picot, INERIS; n. hinfray, INERIS / Ecotoxicology Unit; E. Chadili, INERIS; B. Piccini, INERIS / Ecotoxicology Unit; C. Turies, INERIS; J. Porcher, INERIS / UMRI SEBIO; S. Ait-Aissa, INERIS / Ecotoxicology Unit; O. Kah, IRSET; F. Brion, INERIS / Ecotoxicology Unit

The 11 $\beta$ -hydroxylase (11 $\beta$ H) is the enzyme responsible for the biosynthesis of cortisol, the main corticosteroid in fish, which is implicated in the regulation of

multiple physiological processes including energy metabolism, hydromineral balance, reproduction and the immune system. In fish, the gene coding for 11 $\beta$ H, namely *cyp11c1*, is expressed early in interrenal cells during the development participating to the emergence of the corticosteroid axis. To further investigate the expression *cyp11c1* and its potential deregulation by stressors and pharmaceutical ligands, we established a transgenic zebrafish line that expresses Green Fluorescent Protein (GFP) under the control of the zebrafish *cyp11c1* promoter. Using *in vivo* fluorescence imaging techniques on whole larvae, we showed a weak expression of the reporter gene from 4 to 7 days post-fertilization (dpf) in an anatomical region where interrenal cells are known to be present. Tissue sections and immunostaining with specific 11 $\beta$ H antibodies revealed that GFP is co-localized with the endogenous cyp11c1 protein in interrenal cells. This well agrees with the expression and localization of other steroidogenic interrenal marker genes such as *star* and *cyp11a1* in wild-type zebrafish at this stage of development (To *et al.* 2007). To further characterize the *cyp11c1*-GFP zebrafish model, GFP was quantified in 6-dpf old zebrafish after osmotic stress or exposure to glucocorticoids receptor (GR) agonists (Dexamethasone, DEX) and antagonists (Mifepristone, MIF). Exposure to salt water led to a rapid induction of GFP, showing that *cyp11c1* responds to an osmotic shock. Exposure to MIF (1 $\mu$ M from 5 to 6 dpf) decreases GFP intensity, suggesting that GR is involved in the transcriptional regulation of *cyp11c1* during development. In DEX-exposed larvae (10 $\mu$ M, 5-6dpf), GFP intensity was inhibited as compared to controls, this effect being abolished when zebrafish larvae were co-exposed with MIF. These data agree with the known negative feedback of DEX on pituitary expression of Pro-opiomelanocortin (POMC), leading in turn to a down-regulation of genes involved in corticosteroidogenesis (Sun *et al.*, 2010). Altogether, these data suggest that the newly developed transgenic *cyp11c1*-GFP zebrafish is an interesting model to study the expression of 11 $\beta$ -hydroxylase gene in interrenal cells and its perturbation by endocrine active compounds acting on the Hypothalamic-Pituitary-Interrenal axis, which is critical for cortisol homeostasis.

## **Ecotoxicology of amphibians and reptiles. Resolving uncertainties about the impact of pollutants on individuals, populations and communities (P)**

#### TU001

##### **Pesticide risk assessment needed for amphibians and reptiles?**

F. Streissl, EFSA / Pesticides Unit; A. Ippolito, EFSA - European Food Safety Authority / Institute for Environment and Sustainability IES; M. Arena, EFSA - European Food Safety Authority / Pesticides; D. Auteri, Auteri / Pesticides Unit; R. Sharp, EFSA - European Food Safety Authority / Pesticides Unit; C. Szentcs, Pesticides Unit; J. Tarazona, EFSA

Many amphibians and reptile species are globally in decline and it is hypothesized that one of the causes for their decline is exposure to xenobiotic chemicals and complex interactions with other environmental stressors [1] [2] [3] [4]. Many amphibian and reptile species occur in agricultural landscapes and can be exposed to pesticides in the aquatic and the terrestrial environment. Exposure to pesticides could potentially lead to severe impacts on amphibians [5]. The EU regulation EU 1107/2009 requires for approval of plant protection products no unacceptable effects on the environment, by considering particularly their impacts on non-target species including on the ongoing behaviour of those species and their impacts on biodiversity and the ecosystem. The data requirements for active substances (Regulation EU 283 / 2013) and formulations (Regulation EU 284 / 2013) ask for information on effects on terrestrial wildlife including amphibians and reptiles as well as for consideration of endocrine mediated effects. Information is available on the toxicity of aquatic life stages of amphibians which enabled a comparison of acute toxicity endpoints with other aquatic organisms. It is concluded in the aquatic guidance document [8] that the acute risk to aquatic life stages of amphibians is covered by the standard first tier risk assessment for fish. It would need to be investigated further whether this covers also the risk to amphibians which develop in shallow non-permanent water bodies since exposure may be different than in the currently assessed FOCUS scenarios (i.e. permanent water bodies with a depth of 30 cm). Dermal exposure to pesticides is likely to be a major route of exposure for amphibians. In particular movements through treated fields could present a worst case exposure situation. EFSA has recently published a guidance document on non-dietary human exposure covering in-field and edge-of-field assessments, some elements could serve as a basis for future developments to address the dermal and inhalation exposure of other terrestrial vertebrates. In order to draw conclusions on what is covered by the current risk assessments more information on exposure estimates for shallow non-permanent water bodies, toxicity data (dermal and oral), feeding patterns and potential coverage of the risk by human health non-dietary risk assessments is needed.

#### TU002

##### **Challenges facing terrestrial amphibian risk assessment**

J.M. Bausch, BASF Corporation; P. Dohmen, BASF SE / Landw Versuchsstation APDRO

Risk assessment processes for agricultural chemicals are generally well developed for protecting aquatic species; however, there is currently no risk assessment

process to analyze potential exposure and/or effects to terrestrial phase amphibians. Many uncertainties regarding exposure and effect remain, and need to be addressed in order to develop a comprehensive risk assessment procedure for terrestrial amphibians. This poster seeks to highlight some of these issues and to stimulate discussion of how they can be addressed moving forward. Terrestrial stage amphibian exposure to agricultural chemicals is highly variable and poorly understood. It is known that amphibians can be exposed to agricultural compounds during routine applications, but many mitigating factors such as amphibian behavior, amphibian life-stage (metamorphs vs. adults), application timing, crop stage, etc. can substantially alter exposure. These factors are critical to understand, and are vital for producing a realistic exposure framework. In addition to the uncertainties regarding exposure to agricultural compounds, limited information is available on effects as well. Due to the multitude of species, ecotoxicological testing is generally constrained to a certain number of surrogate species, with the assumption that surrogate species sensitivity is representative and protective of others. In addition, ecotoxicological assessment of agricultural products does not include specific testing of amphibians and reptiles. Instead, data from fish, birds, and mammals are used. Although fish data are generally protective of aquatic life stages of amphibians, there are indications that terrestrial life stages of amphibians may not necessarily be covered by bird and mammal toxicity data. Yet, some studies indicate that only certain products may be harmful to amphibians while others do not indicate any cause for concern. Therefore, it is important to first develop models or triggers to identify which compounds would eventually need further attention or actual testing. By understanding realistic exposure, as well as when toxicity is not already accounted for using surrogate species, a more well defined risk assessment approach can be developed.

#### TU003

##### **Standardized toxicity test method development for Northern Leopard Frog (*Lithobates pipiens*): A road to including amphibians in contaminated site assessment and chemical evaluation in Canada**

L.A. Van der Vliet, Environment Canada / Ecotoxicology and Wildlife Health Division; B. Lo; J.R. Elphick, Nautilus Environmental; J.A. Miller; P.M. Jackman, Environment Canada / Atlantic Laboratory for Environmental Testing; L.N. Taylor, Environment Canada / Ecotoxicology and Wildlife Health Division; R.P. Scroggins, Environment Canada / Biological Methods

Although there is growing evidence of their sensitivity to contaminants, amphibian toxicity data are currently under-represented in risk assessments. Few standardized methods are available, which contributes to this under-representation, and none of the available methods pair whole-organism chronic endpoints with species that are relevant to Canadian environments. Environment Canada has sponsored research for the standardization of an amphibian toxicity test method using *Lithobates pipiens* (leopard frog, formerly *Rana pipiens*), with a focus on sublethal, chronic effects (growth, development) which manifest as a result of whole-organism, aqueous exposure. A review of all method development results revealed several data gaps, and Environment Canada identified two priority issues: supply of test organisms and test duration. While research and discussion of pragmatic options continue to address data gaps, method writing has begun and a first draft of the standardized method will be available in 2015. Once released, this standardized amphibian toxicity test method can be used to assess contaminated sites, and in pesticide regulation and registration. Additionally, results from chemical-specific tests can be incorporated into Canadian water quality guidelines.

#### TU004

##### **Comparison of exposure routes in toxicity assessment of pesticides to common frog juveniles**

M.E. Ortiz Santalieu, Institute for Environmental Sciences University of Koblenz-Landau / Institute for Environmental Sciences; C.A. Bruehl, University of Landau, Institute for Environmental Sciences / Institute for Environmental Sciences The European legislation on plant protection products has recently introduced the requirement of considering relevant data for terrestrial amphibian stages when evaluating potential risks of pesticides. One of the main uncertainties that remains in the terrestrial amphibian pesticide risk assessment is the relevance of dermal exposures, since only oral uptakes have been considered so far in vertebrate surrogate taxa. In this study we compare the results of oral and dermal exposures of common frog (*Rana temporaria*) juveniles to three currently used pesticide formulations. Animals were collected as eggs and grown until metamorphosis. Post-metamorphic individuals were assigned to one of the three formulations (i.e. Folpan® 80WDG – active ingredient folpet -, Basta® - a.i. glufosinate ammonium-, and Kiron® - a.i. fenpyroximate), one exposure route (dermal or oral) and one of the five dosage levels (100-6.25% of the formulation application rate). Exposure lasted for 14 days. Folpet caused no effects and no lethality was detected in any treatment. Glufosinate ammonium exposure through food caused higher effects than dermal exposure in terms of body mass gain. No differences among treatments were detected in prey consumption, which indicates that effects on mass gain were not due to food avoidance. Spiking prey items with fenpyroximate caused a reduction of food ingestion relative to non-spiked prey, which in turn resulted in a higher growth rate of frogs exposed dermally to the insecticide. Dermal exposure to the highest level of fenpyroximate significantly increased the production of TBARS in the liver. Our results show that dermal is a very important route of exposure of amphibians to pesticides. With regards to oral routes, the relevance of food

exposure scenarios in the field needs to be addressed to elucidate how pesticide application affect terrestrial amphibians and their food. The concentrations mirroring recommended application rates caused negative effects on juvenile common frogs, which claims for the necessity of further studies on the real risk of terrestrial amphibians to become exposed to these concentrations

#### TU005

##### **Temporal coincidence of amphibian migration and pesticide applications on arable fields in spring**

C.A. Bruehl, University of Landau, Institute for Environmental Sciences / Institute for Environmental Sciences; G. Berger, Leibniz Centre for Agricultural Landscapes Research / Institute of Land Use Systems; P.P. Lenhardt, Institute for Environmental Sciences

Pesticide management may differ between crop species and farm type, particularly with regard to type, number, amount and date of pesticide applications. Such variations in pesticide application strategies entail different temporal coincidence with amphibian species and with species' population proportions. For the first time, we assessed the presence of *Bombina orientalis*, *Rana arvalis*, *Pelobates fuscus* and *Triturus cristatus* in agricultural fields. We quantified the temporal coincidence of pesticide applications with the breeding migrations of adult amphibians and evaluated a realistic exposure to pesticides, including the interception by various crops at different growth stages. The level of species-specific coincidence depended on the performed pesticide management, determined by the timing, crop, number and type of pesticide applications. Late migrating species, such as *B. orientalis* and *P. fuscus*, overlapped more with pesticide applications than early migrating species, such as *R. arvalis*. Up to 86% of the reproducing population proportion of *P. fuscus* experienced a temporal coincidence with a single pesticide application during stem elongation in winter rape (80% interception). In maize, up to 17% of the reproducing population proportion of *B. orientalis* encountered a single herbicide application during bare soil/emergence (no interception). Local monitoring of amphibian migration combined with adjusted pesticide management is recommended to reduce temporal coincidence and thus potential risk of pesticide exposure of amphibians.

#### TU006

##### **Are pesticides a factor for genetic differentiation of amphibian populations?**

P.P. Lenhardt, Institute for Environmental Sciences; C.A. Bruehl, University of Landau, Institute for Environmental Sciences / Institute for Environmental Sciences; K. Theissinger, Institute for Environmental Science

Decreasing habitat availability as well as habitat fragmentation and environmental pollution by agricultural chemicals are among the major causes for the observed global amphibian decline. It is necessary to understand how anthropogenic land use influences habitat suitability and amphibian migration. This includes migration between different terrestrial and aquatic habitat patches as part of the natural life cycle of amphibian species as well as genetic exchange between populations and colonization of new habitat patches through dispersal. During migrations over arable land exposure to agro chemicals, such as fertilizers and pesticides, is likely. Due to their skin properties, amphibians are highly susceptible for chemical uptake, which can cause lethal or sub lethal effects. We sampled eight breeding sites of *Rana temporaria* in the winegrowing area of Palatine and adjacent forest (Rhineland-Palatine, Germany). Genetic differentiations (pairwise  $F_{ST}$  values) were calculated based on ten microsatellites. Pairwise  $F_{ST}$  values between agricultural breeding sites were significantly higher ( $0.059 \pm 0.019$ ) than forest populations ( $0.028 \pm 0.009$ ). Our statistical analysis showed no significant correlation of the pairwise  $F_{ST}$  values between agricultural breeding sites with established factors for genetic differentiation, like geographic distance and traffic intensity on roads between populations, neither solely nor in combination. Pesticides might therefore be an additional factor causing the fragmentation of breeding sites. Recent laboratory studies showed high toxicity of commonly used pesticides to terrestrial amphibians at field application rates. Therefore, field cultivation and in particular pesticide applications may create a sink for populations during terrestrial activity. In combination with reproduction failure and decreased connectivity between habitats as well as populations, pesticides may promote local amphibian extinction.

#### TU007

##### **Histological changes on the epithelium of *Pelophylax perezi* (Seoane, 1885) from agropesticide contaminated areas**

N.M. Costa, Biology department; F.H. Caetano, B.F. Pereira, Universidade Estadual Paulista Júlio Mesquita Filho / Biology; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; I. Lopes, University of Aveiro / CESAM Biology Department

Agropesticide are one of the major contaminants of aquatic ecosystems. Surface water runoffs contaminate lagoons and temporary ponds, affecting aquatic organisms, particularly amphibians in early development life stages. Amphibian skin contains two types of exocrine glands: a granular gland and a mucous gland, widely distributed and responsible for the production of a polysaccharide mucous. Scientific data confirm that mucous glands play an important role in transepithelial transport and osmoregulation with the mucous functioning as a mechanism for evaporative water loss. Alterations in skin morphology such as excessive melanin production or reduction of the keratinized layer have already been reported for other amphibian species exposed to pesticide-contaminated sites. The purpose of this

study was to evaluate differences in the area/volume ratio of mucous glands of natural populations of *Pelophylax perezi* exposed to agropesticides within contaminated sites. Seven adult females from four sampling areas were collected. Adults were euthanized with MS222. Morphometric parameters were determined and skin was removed for posterior histological analysis. Pieces of skin were fixed in Bouin solution and then processed for paraffin-wax embedding using routine protocols. Subsequently, 6 µm sections were cut and stained with several colorations (e.g. H&E, Alcian Blue and PAS). Sections were analyzed at the fluorescence microscope and the measure of each gland was carried out to observe differences between sites. Preliminary data analysis shows that there is a significant increase ( $p < 0.05$ ) in gland area ratio in organisms from a contaminated area when compared with the control site. Keywords: Agropesticides, histology analysis, mucous glands, osmoregulation, *P. perezi*.

#### TU008

##### Exposure of spotted salamander (*Ambystoma maculatum*) egg masses to a PSII inhibitor throughout embryonic development

L.R. Baxter, University of Guelph / School of Environmental Science; R. Brain, Syngenta Crop Protection, Inc. / Department of Environmental Risk Characterization; A.J. Hosmer, Syngenta Crop Protection, Inc.; K.R. Solomon, University of Guelph / School of Environmental Sciences; M.L. Hanson, University of Manitoba / Department of Environment and Geography  
The North American yellow-spotted salamander (*Ambystoma maculatum*) produces gelatinous egg masses that are colonized by a green alga (*Chlorophyceae*) commonly referred to as *Oophila amblystomatis*. This has been reported as a mutualistic relationship, indicating that embryos may be indirectly impacted if algal growth is reduced. Since the wide distribution of this salamander includes major agricultural regions, the question of how herbicides might impair this relationship has been raised. After previously assessing sensitivity of *Oophila* sp. in laboratory cultures to the PSII-inhibitor atrazine, we examined impacts of this herbicide on algal growth and salamander development in whole egg masses. The primary goal of this study was to examine hatching success, size and stage of *A. maculatum* larvae at hatching following exposure to atrazine throughout embryonic development. *A. maculatum* egg masses were collected in Algonquin Provincial Park, Ontario, Canada in May 2014, and exposed to technical-grade atrazine at nominal concentrations of 0, 3, 10, 30, 100 and 300 µg/L ( $n=5$  for controls;  $n=3$  for treatments) until hatching was complete (up to 66 d). Controls (untreated) and exposures to atrazine occurred in a controlled environmental chamber under field-like conditions of light and aeration. Responses were measured simultaneously in untreated egg masses in 24-h dark with and without aeration, and in the light without aeration ( $n=3$ ). In addition, algae was isolated from a reserved egg mass, cultured in the laboratory and assessed for growth inhibition over 96-h exposure and recovery periods. No statistically significant differences in stage at hatch were observed for any treatment (Kruskal-Wallis ANOVA on ranks). Treatment with atrazine did not significantly affect average days to hatch, length at hatch or hatching success (MANOVA; Approx.  $F_{15,42} = 1.02$ ,  $p = 0.455$ ). In toxicity testing of cultured algae, responses were similar to those observed previously, with an EC50 for 96-h growth rate of 284 µg/L. Overall, the development of *A. maculatum* embryos as measured in this study was not impacted by exposure of egg masses to technical-grade atrazine at concentrations and durations exceeding those commonly found in the environment. Growth of the algae *Oophila* sp. appears to be less sensitive to atrazine in the natural egg environment than in laboratory culture.

#### TU009

##### Differential and short-term effects of three maize herbicides (linuron, S-metolachlor, dicamba) to Perez's frog embryos

V. Galhano, Department of Biology & CESAM - University of Aveiro / Biology dBio; C. Quintaneiro; M.S. Monteiro, Aveiro University / Biology; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM  
In Portugal, many surface waters and groundwater are vulnerable to anthropogenic contamination owing to intensive agricultural practices. Effectively, herbicide residues are frequently detected in many rural areas, like for example in maize fields adjacent streams and water abstraction wells, causing significant costs for water purification and concomitant loss of biodiversity. Therefore, it is necessary to adopt appropriate environmental risk assessment strategies to protect local populations of amphibians, whose numbers are in decline due to extensive use of herbicides. In this context, the aim of this study was to investigate the effects of increasing concentrations of three maize herbicides, viz. linuron (5-25 mg/L), S-metolachlor (10-50 mg/L), and dicamba (250-350 mg/L) on embryos of the Perez's frog [*Pelophylax perezi* (Seoane)] during 168h, following the current Frog Embryo Teratogenesis Assay-Xenopus (FETAX) guidelines. The following apical endpoints were determined for each herbicide: mortality, hatching rate and malformations and. At the end of the experiment, surviving embryos exposed to linuron and S-metolachlor presented LC<sub>50</sub> of 21 mg/L and 37.5 mg/L, respectively, and pronounced malformations (e.g., abdominal edemas, spinal curvature and deformation, blistering of the tail fin, microphthalmia), whereas no frog embryos survived at dicamba concentrations higher than 296 mg/L. Notwithstanding, at 168h the surviving embryos exposed to lower concentrations of dicamba exhibited marked malformations, namely prominent edemas and considerable tail degradation. These results suggest higher toxicity of linuron to Perez's frog embryos. Obtained results are useful to understanding the toxic effects of common

used herbicides in anuran embryos. Moreover, the monitored apical endpoints assessed in this work will be further complemented with effects at biochemical level in embryos exposed to herbicide concentrations below the LC<sub>10</sub> in order to unravel the mechanisms involved in their toxicity. Keywords: embryonic stages, FETAX, herbicides, *Pelophylax perezi*

#### TU010

##### Effects of temperature on the toxicity of sulfentrazone in tadpoles of *Eupemphix nattereri* (Leptodactylidae): oxidative stress biomarkers

J.S. Freitas, Chemistry; E.A. Almeida, Chemistry and Environmental Sciences  
The increase in temperature and other environmental effects influenced by global climate changes (GCC) have documented several impacts on global amphibian populations. Changes in environmental variables can potentially alter the chemical toxicokinetics and therefore one current challenge is to predict the risks established by the interactions between nonchemical and chemical stressors at biological level. In Brazil, many species of amphibians are distributed in common agriculture areas and they mainly breed during the rainy season, which is the period of greatest environmental pesticides contamination. Sulfentrazone is a potent herbicide used on crops of sugar cane and soy in the southeastern Brazil with a long residual effect in the soil and high potential for contamination. In this study, we evaluated the effects of temperature on the toxicity of sulfentrazone (commercial formulation Boral®SC) in tadpoles of *Eupemphix nattereri* by analysis of oxidative stress biomarkers. Tadpoles at stage 29-32 were exposed to 0.01, 0.05 and 0.1 mg/L to temperatures of 28°C, 32°C, and 35°C during 3 and 8 days. Results from antioxidant enzymes show alterations in tadpoles exposed to combined treatment with temperature and sulfentrazone in both experimental periods. Tadpoles exposed to 0.1 mg/L at 28°C had the catalase (CAT) increased after 3 days and the ones exposed to 0.01 mg/L at 36°C had a decrease of this enzyme after 8 days. Glutathione-S transferase (GST) activity increased at different concentrations at 28°C and 32°C after 3 days. After 8 days, GST was induced by sulfentrazone concentrations at 32°C and 36°C. Activity of glucose-6-phosphate dehydrogenase (G6PDH) was increased by all concentrations at 32°C and 36°C in both experimental periods. Lipid peroxidation (MDA) was also induced by the treatments. MDA increased in animals exposed to 0.5 and 0.1 mg/L at 28°C and 32°C after 3 days. Exposition to 0.01 and 0.1 mg/L also increased MDA after 8 days at 32°C and 36°C. The comparison among control groups also showed that tadpoles maintained in 36°C had the highest antioxidant enzymes activities and MDA levels. The results show that temperature is an important environmental stressor influencing the toxicity of sulfentrazone in tadpoles and the changes in oxidative stress biomarkers are probably a result of physiological adaptation to stress conditions established by the interaction between chemicals and different temperatures.

#### TU011

##### The oral toxicity of several rodenticides and herbicides to the western fence lizard (*Sceloporus occidentalis*)

S.M. Weir, Savannah River Ecology Laboratory / Savannah River Ecology Laboratory; S. Yu, Syngenta Crop Protection / Department of Environmental Toxicology; J. Monks, New Zealand Department of Conservation; L.G. Talent, Oklahoma State University; C.J. Salice, Towson University / Biological Sciences Environmental Science

The effect of invasive species on island ecosystems has been well established. On the islands of New Zealand invasive mammals have had detrimental effects on native species including reptiles. Pesticides may be an important tool in the control of invasive species, but the use of pesticides may itself affect native species. Here we provide oral toxicity data for 5 rodenticides and 5 herbicides used in New Zealand to the western fence lizard (*Sceloporus occidentalis*) as a surrogate for native New Zealand reptiles. We quantified toxicity using a standard up-and-down method (UDM) with few minor changes. Reptiles were observed for 14 days following single oral doses. Doses followed the standard UDM guidelines: 5.5, 17.5, 55, 175, 550, and 1750 µg/g. Reptiles were dosed with pure pesticides using gelatin capsules, no carrier solvents were used. Only one rodenticide (pindone, LD50 = 550 µg/g) and one herbicide (triclopyr, LD50 = 550 µg/g) were found to be toxic to reptiles at doses tested. The remaining compounds were not toxic up to 1750 µg/g. Our data suggests little risk of these pesticides to native reptiles. We have not yet investigated the effects of formulated products, or the likelihood of exposure under natural scenarios. Understanding potential pesticide exposure as well as the toxicity of formulations is an important next step to understanding risk of these pesticides to reptiles.

#### TU012

##### Effect of cadmium contaminated soils on reproductive fitness and offspring survival of the wall lizard *Podarcis sicula*

R. Scudiero, Department of Biology; P. Simoniello, GSI Helmholtz Center for Heavy Ion Research / Department of Biophysics; F. Trinchella, C.M. Motta, University Federico II of Naples / Department of Biology  
Animal species are under extinction risk due to several factors (habitat loss, global warming, introduction of exotic species, emerging pathologies). Environmental pollution is one of the most relevant extinction causes for animals such as amphibians, while terrestrial oviparous vertebrates are considered more resistant to soil contaminants. Their embryos are considered well protected by shells from the

external environment; the presence of contaminants in eggs or developing embryos is attributed to maternal transfer during vitellogenesis and oviductal egg retention. Recently, it has been demonstrated that metals present in soil may cross the parchment-like shell of reptilian eggs. So, we decided to investigate cadmium effects on reproduction and development in *Podarcis siculus*, a lizard inhabiting both pristine and urbanized areas. Our data demonstrate that both adults and embryos are highly susceptible to Cd effects. In adults, oral Cd administration, consistent with a transfer via food chain, gives rise to the accumulation of the metal in tissues. The accumulation in liver is accompanied by severe damage at multiple levels interfering with tissue structure and function, in ovary is accompanied by stimulation of oögonial proliferation, oocyte recruitment and follicular atresia. The effects exerted by Cd in *Podarcis* ovary are not typically estrogenic as expected but rather FSH-like, and strongly reduce fecundity and reproductive performance. In embryos, incubation in Cd contaminated soil causes damage to forebrain vesicles and eyes. In addition, Cd is able to interfere with gene regulation, affecting the expression of genes associated with pathways such as membrane trafficking, signal transduction, neuronal transmission and regulation of gene transcription. The dysregulation in the expression of these genes could explain many of the morphological alterations displayed by embryos. Although no in ovo mortality was observed, the severe malformations may be incompatible with adult survival. Since almost all reptilian species lay their eggs in subterranean nests, the rapid decline in many reptilian populations observed in recent years might be partly ascribed to developmental failures in offspring in the increasingly polluted environments, and partly ascribed to the impaired fecundity of Cd contaminated females, leading to a loss of reproductive performance and a likely decline in the number of individuals for wild populations living in polluted areas.

#### TU013

##### **Does thermal stress affect lizard embryonic development in the same way of chemical stress?**

R. Scudiero, Department of Biology; M.G. Esposito, University Federico II of Naples; P. Simoniello, GSI Helmholtz Center for Heavy Ion Research / Department of Biophysics; C.M. Motta, University Federico II of Naples / Department of Biology

Species distribution across geographic regions is greatly controlled by environmental temperature, especially when the animals are ectothermic. The current models of climate change predict the increase of the average global temperature and the frequency and intensity of periods with extreme temperatures. These changes may have pronounced effects on ectothermic species capacities, survival and distribution. Growing evidence demonstrates that environmental temperature is a particularly important factor in determining developmental rates, morphological-, behavioural-, and performance-related traits as well as final size of organisms. In reptiles, temperatures experienced by developing embryos determine offspring sex. The incubation temperature also affects the duration of the incubation and the hatchling size, locomotion and growth. Females of egg-retaining squamates lay eggs only when thermal environments are optimal for developing embryos. We examined the effects of thermal stress (both cold and warm stresses) on the development of the oviparous lizard *Podarcis siculus*. The results showed a severe negative impact of constant thermal stress on the viability of embryos, resulting in lethality, reduced survivorship and abnormal development. A preliminary analysis on gene expression demonstrated changes in the embryos transcriptome in response to cold shock. These findings demonstrate that lizard embryos show a very narrow temperature ranges and that thermal stress during embryonic development may be a critical factor for offspring adverse effects. This higher sensitivity of embryos also suggests that many lizard populations will be most affected by global climate change, with severe reductions in hatchling production. Interestingly, similar morphological alterations (in particular, anencephaly, brain and eye malformations), such as the dysregulation of gene expression were observed even when *P. siculus* embryos were incubated in cadmium contaminated soils. Thus, we can speculate that in *P. siculus*, and possibly in many other organisms, different environmental stressors bring comparable effects both at morphological and molecular levels. More studies are needed to elucidate the potential harm of the interactions between temperature and cadmium on the developmental stages of ectothermic vertebrate species and to reach to an accurate prediction of pollutants toxicity, taking into account other variables that act in concert with the toxicants.

#### TU014

##### **Effects of cadmium on maturation, fertilization and development of *Xenopus laevis* oocyte**

S. Slaby, University of Lille / Lille Sciences et Technologies Equipe Régulation des Signaux de Division UGSF UMR Cité scientifique SN Villeneuve d'Ascq France; S. Lemièrre, Fonctionnement des Ecosystèmes Anthropisés; A. Lescuyer, University of Lille / Lille Sciences et Technologies Equipe Régulation des Signaux de Division UGSF UMR Cité scientifique SN Villeneuve d'Ascq France; S. Demuyneck, LGCgE - EA 4515; J. Bodart, University of Lille / Lille Sciences et Technologies Equipe Régulation des Signaux de Division UGSF UMR Cité scientifique SN Villeneuve d'Ascq France; M. Marin, University of Lille / Biology

Through their activities, humans contaminate their environment, by discharging intentionally or not organic or inorganic pollutants. The latter cause adverse effects on the ecosystems and this pollution contribute to the major causes of the global

decline of biodiversity, including amphibians. Indeed, the aquatic compartments are particularly affected by anthropogenic contaminations. The aim of this work was to highlight the effect of metallic environmental exposure on *Xenopus laevis* oocytes. Cadmium (CdCl<sub>2</sub>), an inorganic compound with natural and mainly anthropogenic sources, such as metallurgy, was chosen. We first focused on cell survival with phenotypical (morphology, pigmentation), physiological (maturation ability) and electrophysiological (resting potential) approaches. Then, maturation was assessed *in vitro*, with morphological (migration and breakdown of the germinal vesicle – GVBD), biochemical (activation of MAPK – Mitogen Activated Protein Kinase – and MPF – M-phase Promoting Factor – pathways) and histological (meiotic spindle formation, polar body extrusion) aspects. Finally, fertilization and early stages of development (up to one week) were studied. In another work, we demonstrated that chloride metal exposure affects oocyte survival with both morphological and electrophysiological methods. Here, oocytes survival was considered by a new physiological method: the ability to undergo maturation after hormonal (progesterone) stimulation *i.e.* the gain for the oocytes to be competent for fertilization. In a second set of experiments, after cadmium exposures, we demonstrated that MPF pathway (associated with oocyte maturation) is deregulated. Fertilization was then assessed when male and female gametes were, together or separately, exposed to cadmium. Our data showed that cadmium exposure was responsible for adverse effects in a dose dependent manner on *in vitro* fertilization rates, development and organogenesis. In addition, our results showed that cadmium preferentially targeted the female gamete rather than spermatozoon, and prevented them to be fertilized. Taken together, our results demonstrated that early stages of amphibians could be critical windows of exposure to cadmium.

#### TU015

##### **Combined toxicity of zinc, copper and cadmium on the tadpoles *Lithobates catesbeianus*: acute and chronic effects on liver antioxidant system**

M.N. Fernandes, Universidade Federal de São Carlos / Ciências Fisiológicas; H. Utsonomiya, Universidade Federal de São Carlos; T. Pasquoto, Universidade Federal de São Carlos; M.J. Costa, Federal University of São Carlos (UFSCar) - Soroca / Department of Biology; M.M. Sakuragui, Federal University of São Carlos / Department of Physiological Sciences; C.S. Carvalho, Universidade Federal de São Carlos

The effect of metals (Zn+Cd, Cu+Cd and Zn+Cu+Cd, 1 µg L<sup>-1</sup>) on the antioxidant system in the liver of *Lithobates catesbeianus* was analyzed after for 2 and 16 days exposure. After 2 days, all metals increased in the liver (50-300%) and after 16 days exposure, the concentration of Zn (240%), Cu (138%), Cd (690%), and in all groups associated to Zn (100-430%) increased. Cd concentration decreased when associated to Zn and Cu (20-80%). After 16 days to exposure to isolated metals, metal accumulation decreased (30-100%), and in Cu+Cd (96%) and Zn+Cu+Cd (50-90%) groups, but increased in exposure to Cu (185%), Zn+Cu (100%), Zn+Cd (120%). The activities of SOD, CAT, GPx and GST increased in most groups after 2 days exposure to isolated and associated metals. After 16 days exposure, the activities of SOD, CAT and GST decreased and GPx increased. The enzymes activities increased in the controls after 16 days compared to 2 days exposure and, SOD, CAT and GPx increased after 16 days in relation to 2 days. However, GST activity decreased after 16 days exposure to Cu (60%), Cd (70%), Zn+Cu (60%), Zn+Cd (50%), Cu+Cd (57%) and Zn+Cd+Cd (35%). The levels of MT and GSH decreased after 2 days, but increased after 16 days. LPO levels increased after 2 days and decreased after 16 days. The levels of GSH and LPO decreased in controls after 16 days of exposure compared to 2 days, and MT levels decreased in fish exposed to Cd (54%) and Zn+Cu+Cd (41%), but increased after exposure to Cu (87%). GSH levels increased in fish exposed to Cu (38%), Zn+Cu (106%), Zn+Cd (144%) and Zn+Cu+Cd (61%). LPO levels decreased in all groups exposed to isolated and associated metals after 16 days compared to 2 days. The high levels of metals in the liver of tadpoles demonstrated that, although the metal concentrations in the present study are below the maximum concentration considered environmental safe to the Brazilian Environmental Council (CONAMA, res 350/2005), they cause acute or chronic effects on bullfrog tadpoles. The process of metal uptake is influenced by several factors, such as their chemical form in water (soluble or particulated), the physical and chemical conditions of the aquatic environment (temperature, pH, salinity, dissolved O<sub>2</sub>), and the animal physiological condition (stage development, age and size, activity period of the reproductive cycle). The antioxidant system showed protects liver against oxidative stress. Financial support: FAPESP Proc. 2011/50752-3.

#### TU016

##### **Ecotoxicity of carbon-based nanoparticles in *Xenopus laevis* larvae**

L. Lagier, F. Mouchet, ECOLAB UMR5245 CNRS UPS INPT / Ecotoxicology and Environmental Health; A. Mottier, Université de Caen; S. CADARSI, ECOLAB UMR 5245 CNRS UPS INPT / Ecotoxicology and Environmental Health; E. Flahaut, CIRIMAT/NAUTILE; C. SARRIEU, CIRIMAT/LCME UMR CNRS 5085; E. VAZQUEZ, UCLM; J. Boutonnet, ARKEMA France; E. PINELLI, L. GAUTHIER, ECOLAB UMR CNRS UPS INPT

Because of their unique properties, carbon-based nanoparticles (CNPs) such as multi-walled nanotubes (MW) and double-walled nanotubes (DW), few layer graphene (FLG) and graphène oxyde (GO) are or will be widely produced and used around the world. Faced with this increasing development, anticipate environmental risks associated with these emerging contaminants is a necessity.

Aquatic environment may be particularly affected by the release and the transfer of these materials. However, few ecotoxicological data are currently available. The objective of the present work is to assess the ecotoxicity of well characterized CNPs on amphibian larvae (*Xenopus laevis*) using standardized tests (ISO, 2006) [1]. The exposure concentrations ranged from 0.1 to 50 mg/L. Various endpoints were studied, ie (i) acute toxicity (mortality), (ii) chronic toxicity (growth inhibition), and (iii) genotoxicity (induction of micronucleated erythrocytes). Moreover, the effects of CNPs were compared with each other. The results depend on the type of CNPs. No mortality was recorded for all CNPs whatever the concentration. By contrast, significant growth inhibition was observed from 10 mg/L of DW and at 50 mg/L of MW and GO. No growth inhibition was observed for FLG. The chronic toxicity observed in larvae exposed to high concentrations of CNPs could be limited to physical effects (gill clogging and/or abrasive effects and or nutrients deprivation). Genotoxicity has been only observed in larvae exposed to GO. This work has been carried out in the frame of the European FP7 FET program Graphene Flagship and the French joint laboratory NAUTILE. [1] ISO. 2006. ISO International Standard. Water quality - Evaluation of genotoxicity by measurement of the induction of micronuclei - Part 1: Evaluation of genotoxicity using amphibian larvae. ##### **Assessing Risk to Amphibians on Contaminated Sites in Canada - Ecological Risk Assessment Guidance for the Federal Contaminated Sites Action Plan**

U. Pott, Environment Canada / Federal Contaminated Sites Action Plan; E. Liu, University of British Columbia/Environment Canada  
In Canada, the Federal Contaminated Sites Action Plan (FCSAP) supports site managers in reducing human health risks, ecological risks and financial liabilities associated with federal contaminated sites. FCSAP provides guidance for ecological risk assessment that promotes applying a comprehensive weight of evidence approach to assess risk from contaminants to all receptors, including amphibians. Risk Assessors may investigate risk to receptors at federal contaminated sites through different lines of evidence: 1) conducting site-specific toxicity tests; 2) comparing exposure at the contaminated site to literature-based toxicity data; 3) conducting site-specific biological field studies; and 4) comparing site-specific exposure to biological field studies reported in the scientific literature (FCSAP 2012). Until recently, amphibians have often been excluded from risk assessments because site-specific methods or literature data are either not available or not easily accessible. In order to facilitate risk assessments for amphibians, Environment Canada is developing practical guidance for amphibian risk assessments for the four different lines of evidence. For site-specific toxicity and biological testing, available methods are being evaluated and provided to the risk assessor. For comparing site-specific contaminant concentrations to concentrations in laboratory-based toxicity studies, amphibian toxicity concentration-response data is being compiled for metals that are particularly toxic to amphibians (Birge 1978). The toxicity data covering multiple endpoints is illustrated as a multi-species concentration-response relationship. This allows the risk assessor to go beyond point-estimate based hazard quotients and evaluate risk in context of effect magnitude and uncertainty across a range of concentrations present at federal contaminated sites. The concentration-response data compilations also confirm whether contaminated sites water quality guidelines, which are typically developed without specific amphibian considerations, are providing adequate protection for this sensitive group of receptors.

## **Interpreting Biological Effects of Metals and Their Mixtures (P)**

#### TU018

##### **Developing sentinel mollusc species for toxicity assessment: Metal exposure, dose and response - laboratory versus field**

W.A. Maher, University of Canberra / Institute of Applied Ecology; A.M. Taylor, C.P. Marasinghe Wadige, University of Canberra / Institute for Applied Ecology  
Sentinel species can be used to detect ecological risks by providing advanced warning of environmental hazards before loss of species and ecosystems occur. When assessing the suitability of a species for this purpose, establishing relationships between exposure, internal dose and associated biological response is necessary, to understand the organism's interaction with a contaminant in its environment. Benthic bivalves are useful biomonitors of environmental metal contamination as they accumulate biologically available metals and can give a time-integrated measure of contamination. Biomarker measurements provide evidence that organisms have been exposed to contaminants at levels that exceed their detoxification and repair capacity, establishing the link between contaminant exposure and ecologically relevant effects. Controlled laboratory exposures, using previously unexposed organisms, are routinely used in the development of toxicological effects tests. Metal accumulation is influenced by bioavailability via water, sediment and dietary pathways. This may be influenced by the mode of exposure, which in turn may affect biological responses. Relationships between tissue dose and biological responses of the benthic marine bivalve *Anadara trapezia* to metal contaminated estuarine sediment from Lake Macquarie, NSW, and of the freshwater bivalve *Hyridella australis* to metal contaminated river sediments from the Molonglo River NSW were evaluated. A comparison of metal accumulation and effects was made between organisms exposed to the sediments in

laboratory aquaria and caged *in-situ* in the Lake and River. Dose included total metal tissue burden and subcellular metal distribution to determine metabolically available metal. Effects biomarkers of oxidative stress, total antioxidant scavenging capacity of cells and lipid peroxidation along with the cellular integrity biomarker lysosomal membrane stability were used to examine organism response. Using laboratory and field comparisons to identify contaminant exposure and effects relationships in potential sentinel organisms is required to improve their predictive capability for ecological risk assessment.

#### TU019

##### **Toxicity of a mixture of metal contaminated sediments on the freshwater bivalve *Hyridella australis*: linking exposure-dose-response**

W.A. Maher, University of Canberra / Institute of Applied Ecology; A.M. Taylor, C.P. Marasinghe Wadige, University of Canberra / Institute for Applied Ecology  
Sediment in aquatic environments acts as a major sink of metal contaminants and has the potential to be released into the water column through dredging, changes of physicochemical conditions and feeding and burrowing activities of benthic biota, leading to continuous contamination of aquatic systems. To evaluate fate and effects of sediment bound metals, sediment toxicity tests are increasingly being used in laboratory and field conditions. The exposure-dose-response (EDR) approach has been proposed as prognostic tool in sediment toxicology studies as it integrates the chemistry of abiotic matrices with bioaccumulation and impairment of biological systems. In this study, the freshwater bivalve *Hyridella australis* was selected as sentinel organism to use within this frame work. Previous studies showed clear EDR relationships of *H. australis* to single metal spiked sediments under laboratory conditions. In the environment metals are present as mixtures, therefore, toxic effects are not a result of a single metal exposure, but is rather a results of exposure to mixtures of metals due and their toxicological interactions. In this context, exposure-dose-response relationships of *H. australis* to a mixed metal contaminated sediment was investigated. This study is being conducted in parallel to *H. australis* caged experiments in the Molonglo River to further understand differences of cause and effects of the same mixed metal contaminated sediments under environmentally realistic and laboratory conditions. *H. australis* were exposed for 28 days to four different concentrations of mixed metal contaminated sediments collected from the bivalve caged sites at the Molonglo River. After 28 days of exposure, metal dose was measured as in whole body and individual tissues. Sub-cellular analysis is conducted in hepatopancreas tissues to examine the biologically available and detoxified metal content. Enzymatic and cellular biomarkers are measured as responses to metal toxicity in hepatopancreas tissues.

#### TU020

##### **The effect of waterborne silver on survival, ionoregulatory function, metallothionein and *nkx 2.5* inductions in zebrafish (*Danio rerio*) embryos**

S.M. Bakir, Plymouth University / Biological Sci; R.D. Handy, Ecotoxicology Research and Innovation Centre; T.B. Henry, Heriot-Watt University / School of Life Sciences  
Natural leaching from silver sites and anthropogenic activities, as well as Ag-NPs that are used as an antimicrobial, lead to elevation of silver concentrations in the aquatic environment. Silver salts such as AgNO<sub>3</sub> are soluble and dissociates to yield free silver ions (Ag<sup>+</sup>) which are known to cause ionoregulatory toxicity in adult fishes. However, the effects on fish embryos and their development are less well understood. The objectives of this study were to investigate the effects of dissolved silver on the survival and hatching success of zebrafishes, and then to understand the sublethal responses that relate to defences against toxic metals (metallothionein expression), osmoregulatory disturbance (Na<sup>+</sup>K<sup>+</sup>-ATPase, electrolyte levels), oxidative stress (total glutathione), and cardiac development (*nkx 2.5* gene). Embryos < 1hpf were exposed to silver 0 (no added Ag), 2.5, 5, 7.5, 10, and 15 µg l<sup>-1</sup> Ag as AgNO<sub>3</sub> for up to 72 h. Although, the survival was not affected by increasing concentrations of total silver, a decrease in hatching and increase in heart beat was observed (ANOVA, p < 0.05). Live and dead embryos were collected at 24 and 72 hpf for silver determination and biochemistry. A significant (ANOVA p < 0.05) increase in embryonic silver accumulation in both live 24 and 72 hpf and dead embryos, also it was observed more significant accumulation (two way ANOVA, p < 0.05) in 24 hpf live embryos. Dead embryos and live embryos at 72 h exposed to Ag had lower Na<sup>+</sup> and K<sup>+</sup> concentrations (two way ANOVA, p < 0.05). Live embryos also showed a transient increase in Ca<sup>2+</sup> concentration at 24 h (two way ANOVA, p < 0.05). A 4, 4, 8, and 16 fold increase (two way ANOVA, P < 0.05) in Na<sup>+</sup>K<sup>+</sup>-ATPase activity, *Mt2*, total glutathione, and protein concentration respectively were seen in embryos after 72 h of exposure to AgNO<sub>3</sub> compared to controls. In contrast, *nkx 2.5* gene expression significantly decreased (two way ANOVA, P < 0.05) by 3 fold in 24 h aged embryos exposed to silver compared to controls. Silver toxicity is consistent with ionoregulatory toxicant in embryos that also affects gene involved in development.

#### TU021

##### **Concentration addition in mixtures with increasing number of metals**

J. Hammer, University of Utrecht / IRAS; W. Bartstra, J. Dalmijn, N. van der Does, B. van Kuijk, S. te Wierik, University of Amsterdam / IBED; M. Kraak, University of Amsterdam

The majority of research on the toxicity of metals consists of single metal experiments. However, contaminated ecosystems are often exposed to a mixture of

compounds. Therefore, it is important to investigate the toxicity of metals when present in a mixture. Mixtures of dissolved metals can exhibit a different (higher or lower) toxicity than predicted based on the toxicity of the individual metals. Such a deviation from additive may, however, become less pronounced when more metals are added to the mixture. Therefore, this study aimed to analyze the effect of increasing numbers of metals in a mixture on the toxicity to *Daphnia magna*. To this purpose we performed 48h acute *Daphnia magna* immobilization tests according to OECD guideline nr. 202. The selected metals were Ni, Cd, Zn and Cu, tested individually and in mixtures. Binary, tertiary and quaternary equitoxic mixtures were composed using the Toxic Unit (TU) concept. There were 5 concentrations per test, 4 replicates per concentration and 5 daphnids per replicate. EC<sub>50</sub> values and the corresponding 95% confidence limits were calculated applying a log-logistic response model. The results showed strong more-than-additive as well as less-than-additive effects of the metals in binary mixtures. When the number of metals in the mixture was increased from two to three, deviations from additivity decreased. No deviation from additivity was observed when the mixture consisted of four metals. Thus, decreased deviation from additivity was observed in a mixture of three metals, which remained apparent in the mixture of four metals. It is therefore concluded that in complexly polluted ecosystems, where mixtures with even higher numbers of metals are typically present, concentration additivity might be the rule rather than the exception. **Keywords:** complex metal mixtures; concentration addition; aquatic ecotoxicity, *Daphnia magna*

## TU022

### Mixture toxicity of zinc and copper on the growth of the diatom *Navicula pelliculosa* and comparisons with concentration additive and independent action predictions

T. Nagai, National Institute for Agro-Environmental Sciences; K.A. De Schampelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit  
Metal mixture effects on algal growth have not often been investigated, especially for species other than green algae. Moreover, the applicability of conventional mixture toxicity prediction models, concentration additive (CA) and independent action (IA), has also not sufficiently been investigated. Here, we investigated the mixture toxicity of zinc and copper on the growth of a diatom, *Navicula pelliculosa*. A toxicity test was conducted using 96-well microplates for 72 h, and the algal growth was monitored using a fluorescence microplate reader. A 7×7 full factorial experimental design was used for the mixture test (49 combinations) in total. Tested concentrations were EC<sub>10</sub>/4, EC<sub>10</sub>/2, EC<sub>10</sub>, EC<sub>30</sub>, EC<sub>50</sub>, and EC<sub>70</sub>, which were determined by preliminary single metal toxicity tests. Free ion activities in test solutions were calculated using chemical equilibrium speciation software WHAM6. Mixture effects were predicted by CA and IA models based on free metal ion activity-response relationships of both single metals. CA prediction was conservative at all effect level and IA was a better predictor than CA. However, the deviation of IA predictions from experimental results increased with increasing effect levels. Synergistic effects relative to IA were observed at higher effect levels. These results suggest that the toxic mode of action of metal mixtures may vary depending on the effect level.

## TU023

### Evaluation of chronic Interspecies Correlation Extrapolation (ICE) models using metals

D. Leverett, A. Peters, Wca Environment Ltd.  
Interspecies Correlation Models (ICE) allow the prediction of toxicity of a substance to an untested species based on the known toxicity of the substance to a single surrogate species. ICE models are generally log-linear least squares regressions based on the known toxicities of two species to a range of different substances. The regression of the differential toxicity for the two species therefore allows an extrapolation of the toxicity for a substance where only one of the two species has been tested. The USEPA has developed a series of ICE databases (covering aquatic animals, algae and wildlife) which utilises approximately 2400 models to predict toxicity, and which also includes extrapolations for Species Sensitivity Distributions (SSDs). However, the USEPA models are all based on acute toxicity endpoints, and the technique is therefore of limited use in assisting in increasing the species complement for the chronic SSDs. Under the majority of EU chemicals regulations (e.g. WFD), toxicity results (NOEC/ EC<sub>10</sub>S) covering a minimum of 10 species are required before an SSD approach can be considered for the derivation of long-term quality values. For substances with smaller datasets, a deterministic approach is therefore the only option in deriving such standards, with associated large assessment factors. In this poster we present an initial attempt at developing ICE for chronic endpoints for invertebrates, algae/ plants and fish using the large chronic aquatic toxicity datasets which are available for some metals (e.g. zinc, copper, nickel, and silver), and discuss the potential for this approach to be utilised in deriving estimates for chronic toxicity to untested species in order to supplement chronic toxicity datasets, and to assist in developing SSDs for other, less data rich, metals.

## TU024

### INFLUENCE OF pH AND DISSOLVED ORGANIC CARBON CONCENTRATION ON URANIUM TOXICITY TO DAPHNIA MAGNA: IMPLICATIONS FOR ACID MINE DRAINAGE TREATMENT AND

## CATCHMENT PROTECTIVE WATER QUALITY STANDARDS

S.K. Kalule, USK Consulting / ENVIRONMENT WASTE ENGINEERING;  
S.J. Klaine, Clemson University / Institute of Environmental Toxicology  
CUENTOX

In an earlier study, pH variations due to acid mine drainage and organic matter loading from point source discharges of domestic wastewater treatment plants, appeared to dictate the toxicity profile of the Wonderfontein Spruit, a mine tailings dominated catchment in the Witwatersrand Gold Basin of South Africa. In this catchment where dissolved Uranium concentrations range between 20-250 µg/L, both acute and chronic toxicities to *D. magna*, in this catchment were attributable to dissolved uranium concentrations alone. A significant reduction in toxicity was observed at sites located just downstream of wastewater treatment discharge into the river. DOC concentrations increased at sites downstream of the wastewater discharges into the river, and this resulted in significant reductions in both survival and reproduction of *D. magna*. These results suggest that stream segments downstream of WWTW discharges were healthier and that the reason was the increase in pH and dissolved organic carbon in the stream. In this paper follow-on study, the influence of dissolve organic carbon (DOC) and pH on the toxicity of uranium to *D. magna* was assessed using a multifactorial test design. Exposures were conducted in moderately hard water reconstituted with pH (4.5 - 9.5), DOC (0 - 10 mg/L) in the form of natural organic matter (NOM) standard Suwannee River Fulvic Acid (FA). Organisms were exposed to a range of U concentrations ranging from (1.375 - 22 mg/L). Results revealed that DOC concentration and pH had a significant effect on Uranium toxicity. In general, an increase in pH and DOC resulted in a linear increase of LC<sub>50</sub> and EC<sub>50</sub> values. U toxicity was significantly less in tests with 10 mg/L DOC, relative to tests with 0 and 2 mg/L DOC. Tests also revealed that DOC concentration was the most important factor in influencing effects of Uranium toxicity to *D. magna*, explaining above 64% of the observed effects as compared to pH. Speciation predictions of Uranium in moderately hard water performed using Visual Minteq could also explain some of these results, where model output accounted for reduction in toxicity due to complexing of uranyl species, such as UO<sub>2</sub>+2, UO<sub>2</sub>OH+ and other positively charged species by DOC. These results could be used to predict concentration of DOC and pH that would significantly reduce toxicity in a system. Further this research can become a first simple tool for establishing biotic ligand model derived catchment protective water quality standards.

## TU025

### Nickel toxicity in soft waters

A. Peters, Wca Environment Ltd.; G. Merrington, Environment Agency; C. Schlegel, NiPERA, Inc.; A.J. Harford, Dept. of the Environment / ERISS  
Environmental Research Institute of the Supervising Scientist Division; R.A. van Dam, ERISS / Australian Government Department of the Environment  
The chronic nickel Biotic Ligand Models (BLMs) developed for application in Europe show limitations when applied to results of toxicity tests using Australian test species in Australian waters. Specifically, the models were unable to decrease intra-species variability to a factor of < 2. One possible explanation for these results is the applicability limit of the model in soft-waters. The lower validation limit of the European nickel BLMs is at a calcium concentration of 2 mg l<sup>-1</sup>. However, a potentially significant proportion of Australian waters show water hardness below this value. Previous acute and chronic toxicity modelling studies with Ni indicate that soft water organisms exhibit an increased protective effect of calcium and magnesium on nickel toxicity than is observed in hard water organisms. This study aims to establish the degree of competition from calcium and magnesium in calculating the accumulation of nickel at a hypothetical "biotic ligand" in an Australian invertebrate species which is able to tolerate very soft water chemistry conditions. Chronic nickel toxicity testing on *Hydra viridissima* was performed in a very soft water, which will be amended with increasing concentrations of calcium and magnesium to identify their effect of nickel toxicity. The findings of the study will be used to refine the application of bioavailability models for nickel in soft Australian waters.

## TU026

### ARSENIC TOXICITY ISOLATED AND ASSOCIATED WITH IRON TO THE TROPICAL CLADOCERAN *Ceriodaphnia silvestrii*

S.C. Sales, Federal University of Minas Gerais / Department of Zootechnia; A.C. Rietzler, M.M. Martins Ribeiro, Department of General Biology  
Arsenic is an ametal widely distributed, and its occurrence is associated with oxides and hydroxides of iron and manganese or organic matter. Evaluating arsenic toxicity to aquatic organisms is critical to preserve these ecosystems and to prevent human contamination. Cladocerans can be considered an essential group to transfer metals through the trophic chain being used in ecotoxicological studies. The aim of this study was to evaluate arsenic toxicity isolated and associated with iron to *Ceriodaphnia silvestrii*. Three experiments were conducted: (1) evaluation of arsenate and arsenite EC<sub>50</sub>; (2) evaluation of arsenate IC<sub>25</sub>, considering surface waters containing predominantly the pentavalent form; and (3) evaluate arsenate EC<sub>50</sub> in the presence of Fe (III). Among the results, the EC<sub>50</sub> ranged value between 0.69 mg L<sup>-1</sup> (As V) and 0.44 mg L<sup>-1</sup> (As III). Furthermore, in the presence of iron at concentrations 0.02 e 2.00 mg L<sup>-1</sup> EC<sub>50</sub> was significantly reduced (0.37 mg L<sup>-1</sup>) demonstrating a synergistic effect. However, the IC<sub>25</sub> mean value was 0.59 mg L<sup>-1</sup> (As V), indicating detoxification mechanisms reducing arsenic toxicity. The

arsenite showed higher toxicity than its pentavalent form, but this variation was lower than expected from the literature. The toxicity of arsenic significantly increased associated with iron. These results demonstrated the need for monitoring and reduction of arsenic in aquatic environments, especially in places where the geological matrix is composed of iron ore.

#### TU027

##### Effect of copper contamination on *Tribolium castaneum*: large differences in sensitivity between life history traits

A.J. Bednarska, Jagiellonian University / Institute of Environmental Sciences; R. Laskowski, Jagiellonian University / Ecotoxicology Stress Ecology Group; W. Makarowski, K. Stepień, P. Gibas, Jagiellonian University / Institute of Environmental Sciences

Effects of toxicants on animals are most frequently evaluated in short term experiments with mortality as the only endpoint. It is known, however that sensitivity of particular life history traits to toxicants can differ, and prolonged exposure may cause delayed effects. Moreover, detailed quantitative information about effects of toxicants on individual life-history traits is necessary for better understanding and mechanistic explanation of underlying processes. This is particularly important for holometabolic insects with their complex lifestyles and a number of life stages, each of which can differ in sensitivity to toxicants. To compare sensitivity to a toxicant of all life history traits of a holometabolic insect we performed an experiment on the red flour beetle *Tribolium castaneum* (Coleoptera: Tenebrionidae) exposed to Cu at 0, 1000, 2000 or 4000 mg/kg for 90 days. The following life history traits were recorded: hatching, growth rate, duration of larval and pupal stages, larvae and pupae size, adult emergence, sex ratio, adult body mass, fecundity (in randomly mated pairs) and survival. Each individual was followed separately from the egg stage. Larvae survival was high in all treatments with no significant Cu effect, even if the highest survival, 96%, was found in control and the lowest, 80%, in the highest Cu treatment. The growth rate of *T. castaneum* larvae was best described by the logistic function, with body mass increasing exponentially at the beginning and levelling-out before the pupation. The growth rate at the two highest concentrations was significantly slower and the larvae pupated later than in control, but no significant difference in the final body mass was found between treatments. Consequently, there was no Cu effect on pupae mass. All insects that reached the pupal stage emerged. Copper affected time from hatching to adult: the higher the concentration the later the adults emerged. The fecundity dramatically decreased with increasing Cu concentration, from 502 to 42 eggs per female. Only at 1000 mg/kg the fecundity did not differ significantly from control. No effect of Cu was observed in sex ratio or survival of emerged adults. The experiment clearly shows that mortality-based bioassays may not detect toxic effects of chemicals while they actually seriously affect other life history traits. *The project was financed by the National Science Centre project HARMONIA (No.2012/06/M/NZ4/00137) and Jagiellonian University (DS 758).*

#### TU028

##### Regulation of internal copper concentration by the red flour beetle *Tribolium castaneum*

A.J. Bednarska, K. Stepień, Jagiellonian University / Institute of Environmental Sciences

In order to predict internal metal concentrations in animals under specific environmental concentrations (pollution levels), the relationship between exposure concentrations and values of toxicokinetic parameters must be known. Our previous studies have shown that the assimilation ( $k_A$ ) and elimination ( $k_E$ ) rate constants are actually constant only at certain conditions, such as specific metal concentration. For example, crickets exposed to metals in food regulated internal body concentration of Zn by changing simultaneously  $k_A$  and  $k_E$ , whereas Cd was regulated almost exclusively through increasing  $k_E$ . Whether other nutritional and xenobiotic metals are regulated in a similar manner, even if with different efficiency, it is not known. At high exposure concentrations, availability of the carriers by which metal ions are transported through membranes may become limited, and thus assimilation rates may decrease. Moreover, the higher the metal concentration in food the higher the damage to the gut and the lower the assimilation efficiency and/or the higher the elimination rate (mostly due to shedding damaged epithelial cells). Thus, the assimilation rates should decrease and elimination rates should increase with increasing metal concentrations in food. Indeed, our toxicokinetics study on the red flour beetle *Tribolium castaneum* (Coleoptera: Tenebrionidae) exposed to Cu at four different concentrations (500, 1000, 2000 and 4000 mg kg<sup>-1</sup> dry flour) showed that with increasing Cu concentration in exposure medium,  $k_A$  decreased from 0.0032 day<sup>-1</sup> at 500 mg kg<sup>-1</sup> to 0.0017 day<sup>-1</sup> at 4000 mg kg<sup>-1</sup>, and  $k_E$  increased from 0.019 to 0.043 day<sup>-1</sup>. No differences between sexes in kinetics parameters were observed. Although a clear increase in body Cu concentration with increasing exposure was found, Cu was regulated by *T. castaneum* efficiently: an 8-fold increase in exposure concentration (from 500 to 4000 mg Cu kg<sup>-1</sup>) resulted in only 1.7-fold increase of internal concentration. There was no effect of Cu exposure on respiratory metabolism of *T. castaneum* measured during toxicokinetics study. The project was financed by the National Science Centre project HARMONIA (No. 2012/06/M/NZ4/00137) and Jagiellonian University in Kraków (DS 758).

##### Soil Enzyme Activity Index vs. heavy metals Pollution Load Index. An ecotoxicological study in irrigated mixed farming in Morocco i.e. a common situation under semi-arid Mediterranean climate.

J. Thoisy, F. Elsass, INRA; J. Duplay, Strasbourg University; N. Rais, Fes University; V. Grondin, INRA; N. El Ghachtouli, A. Kouchou, Fes University; N. Cheviron, INRA

Mediterranean soils with relatively high pH and carbonate, and low organic matter contents under semi-arid climate conditions, often exhibit low metal mobility and increased metal accumulation at the soil's surface (Lafuente *et al.*, 2008). Thus, they may be considered as the most vulnerable soils (Batjes, 2000). Extracellular enzyme activities are good sensors for long-term soil metal anthropogenic contamination and recognized as more sensitive bioindicators than plants and animals (Hinojosa *et al.*, 2004; K?z?lkaya *et al.*, 2004). In Europe, many studies on microbial disturbance by metals refer to Northern countries, compared to Mediterranean area (de Santiago-Martin *et al.*, 2013). We focused on disruption study of biological parameters (impacts of exposure of microorganisms to heavy metal mixtures), by metal pollutants of the iron transition group (Cr, Ni, Cu, Zn) in calcareous agricultural soils (Saiss plain, North Morocco). We selected 5 multi-element-contaminated plots on identical soils: 1) maximum contamination along Oued Fez downtown Fez city; 2) at the confluence of Oued Fez and Oued Sebou; 3-4) downstream the confluence; 5) uncontaminated reference sample (along Oued Sebou upstream the confluence). We focused on soil hydrolase activities because of their wide use in assessment of biochemical disruption by metals: phosphatase, arylsulfatase, urease, arylamidase, b-galactosidase and glucosidase. Indexes were calculated for metal pollution loads (PLI) and soil enzyme activity (EAI), by a similar computing of metal concentration factors and intensity factors of enzyme activities. PLI and AEI profiles showed strongly identical tendencies. The strong correlations between hydrolase activities suggested coexistence, if not an interdependency of key biological processes, such as nitrogen mineralization/transformation, cellulose degradation together with organic phosphorus and sulfur turnover. Life Cycle Assessment is currently conducted to assess impacts of industrial effluents on water and soil in this area. The terrestrial ecotoxicity is assessed for each metal separately. It would be interesting to use these calculated indexes to characterize terrestrial ecotoxicity of mixtures by simpler Life Cycle Impact Assessment taking into account the local responses of soil and microorganisms. The efficiency of the EAI, an economic approach for predicting the ecotoxicity of metal mixtures, needs further investigation on microscale mechanisms.

#### TU030

##### Diet quality influences chronic toxicity of copper to the freshwater snail *Lymnaea stagnalis*

o.h. berteloot, GhEnToxLab (Ghent University) / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; K.A. De Schampelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit  
*Lymnaea stagnalis* is a very widespread organism in Europe and frequently inhabits systems impacted by urban and agricultural activities, which suggests that they might be relatively insensitive to chemicals, including metals. However, based on laboratory ecotoxicity data, *L. stagnalis* is amongst the most sensitive organisms to Cu, Pb and Ni. Thus *L. stagnalis* chronic toxicity data are an important determining factor in chronic Species Sensitivity Distributions (SSD) that are used to derive estimates of hazardous concentrations for 5% of the organisms (HC<sub>5</sub>). However most chronic toxicity studies with freshwater snails are 14-day to 28-day juvenile growth studies in which lettuce is used as a food source. Lettuce may be a sub-optimal food source for juvenile snails because early juvenile life stages might have an incompletely developed feeding apparatus making these juveniles insufficiently proficient to feed on lettuce. In this regard we tested the effect of food source (lettuce vs. fish flakes) on copper toxicity in a fully randomized 28-day juvenile growth test with *L. stagnalis* using an artificial water with semi-static renewal. Endpoints measured were: survival, shell length and dry blotted weight. Growth rates ( $\mu$ ) for all individuals were calculated as the slope of LN(length) in function of time. Dose response curves were generated for all endpoints and EC<sub>x</sub> values were calculated. Results of this experiment demonstrate that food source plays an important role in size-related endpoints such as shell length, dry blotted weight and growth rate. Fish flake fed individuals in control conditions had a >60% larger shell than lettuce fed individuals in control conditions after 28 days. For dry blotted weight a 10-fold difference in 28-day EC<sub>10</sub> values was found, with an EC<sub>10</sub> of 7  $\mu$ g/L for lettuce fed snails and an EC<sub>10</sub> of 78  $\mu$ g/L for fish flake fed snails. Also for growth rate a 4-fold increase in EC<sub>10</sub>'s was found between lettuce and fish flake fed individuals. Thus lettuce fed individuals were more sensitive for copper based on size related endpoints than fish flake fed individuals. However there was no difference in survival between snails fed with fish flakes and snails fed with lettuce exposed to copper. We hypothesize that the difference in sensitivity of *L. stagnalis* individuals to copper between the two food treatments is likely due to the high protein content and softness of the fish flakes making it a better food source for juvenile snails than lettuce.

#### TU031

##### Effects of arsenic compounds on freshwater microalgae from different phyla

#### under suboptimal conditions

G. Giménez Papiol; N. Roig, Universitat Rovira i Virgili; J. Sierra, Universitat Rovira i Virgili / Soil Science Unit; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering

Algal growth inhibition assay is extensively used in aquatic ecotoxicology. The standardized protocol accepts a varied array of microalgae species, nevertheless, it requires optimal culturing conditions and specific growth stages for a correct performance. It is also time consuming, since it lasts between 48 and 96h. Several biosensors based on microalgae have been developed, many of them relying on dead microalgae containing active enzymes. The living microalgae attached to a biosensor usually are in suboptimal conditions, compared to those provided in laboratory or in the growth inhibition assay, because they must be immobilized or managed in order to be part of the sensor. Moreover, for commercial purposes, preservation for storage conditions must be also taken into account. The general objective of this work is to study the performance of microalgae maintained in suboptimal conditions when exposed to a known contaminant, in order to evaluate their suitability as the biological part of a commercial biosensor. To achieve it, *Navicula pelliculosa* (Bacillariophyceae), *Chlorella vulgaris* (Chlorophyta), *Raphidocelis subcapitata* (Chlorophyta) and *Synechococcus leopoliensis* (Cyanobacteria), purchased from the Sammlung von Algenkulturen (SAG, Goettingen University), were chosen as representative of freshwater microalgae phyla and microalgae models. Arsenic compounds were chosen as representative of heavy metal contamination in Catalan rivers. The standard growth inhibition assay was compared to suboptimal conditions (stationary growth stage, pre-manipulation for preservation, etc.) results when exposed to pure solutions of selected arsenic compounds. Microalgae species are ranked according to their sensitivity/resistance to arsenic compounds, and to the variations of the standard growth inhibition assay.

#### TU032

##### Insights to neurosensory toxicity of mercury in fish eyes provided by accumulated levels, oxidative stress and acetylcholinesterase profiles

R.J. Pereira, University of Aveiro / Biology; S. Guilherme, Universidade de Aveiro / Biology; F. Brandão, Biology Department of Aveiro University / CESAM Department of Biology; M.A. Santos, CESAM & Department of Biology, University of Aveiro, 3810-193 Aveiro, Portugal / Chemistry; M. Pacheco, University of Aveiro / Dept of Biology; P. Pereira, Department of Biology and CESAM

In general, animals use the eyes to monitor the surrounding environment and maintain homeostasis. Mercury (Hg) (including methylmercury - MeHg) is a pernicious and ubiquitous contaminant in natural waters but the assessment of its potential to interfere with fish eyes is an almost unexplored issue. This study contributes to fill this knowledge gap by the evaluation of Hg accumulation in the eye wall of wild grey mullet (*Liza aurata*) together with the assessment of biochemical endpoints related with the oxidative stress status and neurotransmission. This approach was complemented by the characterisation of environmental contamination profiles (both in water and sediment). Sampling was conducted in two sites of a Portuguese coastal lagoon (Aveiro lagoon): (i) Largo do Laranjo (LAR) located in an Hg contaminated confined area, and (ii) São Jacinto (SJ) closer to the lagoon inlet and selected as reference site. Winter and summer conditions were considered. Eye wall was analysed for total Hg (tHg) and methylmercury (MeHg) levels, as well as for antioxidant responses (CAT, SOD, GPx, GR, GST), peroxidative damage and acetylcholinesterase (AChE). Inorganic mercury levels (iHg) were estimated by the difference between tHg and MeHg levels. tHg, iHg and MeHg in eye wall were higher at LAR than SJ in winter and summer, reflecting environmental spatial differences of water column and surface sediments. Moreover, fish caught at LAR in winter showed a significant decrease of CAT and SOD, in line with the occurrence of peroxidative damage. A different spatial pattern was recorded for those biological endpoints in summer, being characterised by the increment of GR and GPx at LAR, eventually preventing the occurrence of lipid peroxidation. The PCA analysis allowed discerning a cause-effect relationship between accumulated iHg and MeHg with GPx and LPO, particularly at LAR. Current data pointed out the vulnerability of fish eyes to environmental contamination by Hg. This neurotoxicant can be accumulated in eye wall leading to alterations in the cellular protection against oxidative stress. Such repercussions could eventually compromise fish visual capacity.

#### TU033

##### Toxicity of Molybdenum to the aquatic macrophytes and the effect of growth medium

D. Bowes, P.K. Sibley, University of Guelph / School of Environmental Sciences; J. Rodriguez Gil, University of Guelph; R.S. Prosser, Environment Canada / Canada Centre for Inland Waters

Mining in Canada's northern and sub-Arctic regions is increasing raising concerns about potential contamination of aquatic habitats. As part of a larger project to investigate remediation options for a metal-contaminated uranium mine site in northern Saskatchewan, we are investigating the toxicity of molybdenum (Mo), which has been detected at elevated concentrations (>1 mg/L) in run-off and leachates from the mine waste piles, on the aquatic macrophytes *Lemna minor* and *Myriophyllum spicatum*. At present, there is little information on the toxicity of Mo toward aquatic plants. We assessed Mo toxicity to *L. minor* in standard 7-day

growth tests in relation to concentration (ranging from 0.1 to 1000 mg/L) and hardness (soft, medium, hard, very hard) using wet/dry mass, growth rate, and photosynthetic activity. We also compared responses in two recommended media: Hutner's and AAP. In tests conducted in Hutner's media, EC50 values for inhibition of these endpoints were, respectively, 73.6, 167.9, 372.7, and 407.8 mg/L for the four endpoints at the greatest hardness. Toxicity increased by up to 4-fold with decreasing hardness. In tests conducted in the AAP media, EC50 estimates were comparable across endpoints (< 20% variation) compared to Hutner's but relative growth was significantly greater. Preliminary tests with *Myriophyllum* indicate comparable sensitivity (+/- 25%) and enhanced growth performance relative to medium type compared to *L. minor*. Using the most sensitive EC25 value (*L. minor* wet mass) and the highest concentration of Mo detected at the mine site (6.1 mg/L), a HQ value of 0.32 was estimated. These data indicate that Mo likely poses minimal risk to aquatic macrophytes exposed to the typical range of concentrations of Mo (< 0.1 mg/L) found in aquatic habitats at the mine site. Our data also suggest that AAP media performs consistently better compared to Hutner's, even though both are recommended for use in toxicity testing with aquatic macrophytes.

#### TU034

##### Population dependent mixture toxicity: intraspecies differences matter

D. Deruyter, University Ghent / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; K.A. De Schamphelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; N. Nevejan, Ghent University / Laboratory of Aquaculture and ARC; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

The Baltic Sea - one of the largest brackish water bodies in the world - harbours a limited numbers of species among which is the blue mussel *Mytilus edulis*. This species can survive and reproduce at salinities down to 6 psu, although previous research has indicated that low salinity does impair growth and decreases the metabolic rate of settled mussels. Given this potential reduced 'fitness' of this mussel potential, the question arises if mussel larvae from a Baltic sea population are more or less sensitive to metal pollution and if mixture interactions are similar to their North Sea (living at 32 psu) counterparts. To assess the influence of binary mixtures of Cu, Zn and Ni on mussel larvae development, several full factorial experiments (between 6\*6 and 7\*11) were performed. The effect of each binary mixture was assessed on mussel larvae originating from both a North Sea population (32 psu) and a Baltic Sea population (6 psu). Each experiment was conducted according to the ASTM E 724-98 guideline. For the Baltic population, a deviation from this protocol was required as none of the embryos developed into the D-larvae stage after 48h; therefore these experiments were extended to 60h. Each experiment was performed at least twice to ensure reproducibility of the results. R statistics was used to analyse the results, calculate the EC50s and determine if synergistic, additive or antagonistic mixture toxicity could be established. The slower development and smaller size of the Baltic Sea larvae indicates that the larvae, similar to the adult mussels, have a lower growth rate and metabolism. The results of this study indicate that the Baltic population might be more sensitive towards metals compared to the North Sea population. The binary mixture results were reproducible between within each population but were not similar between populations. For example, when mussel larvae are exposed to a Cu/Ni mixture significant deviations from concentration addition were found for the North Sea population but not for the Baltic Sea population. At the moment it is unknown if the observed differences between the two populations are the result of differences in the environment (lower salinity), due to local adaptation, or the differences in the experiment. Further experiments should (e.g. at identical salinities) be performed to clarify this.

#### TU035

##### Why Are There Perceptions That Tissue Quality Benchmarks For Metals Cannot Work For Aquatic Biota?

B.K. Shephard, U.S. EPA / Office of Env Assessment OEA

Tissue screening benchmarks, calculated as the product of a USEPA chronic water quality criterion and a bioaccumulation factor, are increasingly utilized in screening level ecological risk assessments to define whole body tissue residues of chemicals potentially posing unacceptable risks to aquatic life. While the utility of tissue screening benchmarks is generally accepted for organics, there is a reluctance to accept their utility for evaluating ecological risks to aquatic species from bioaccumulated metals. A review of the available residue-effects literature for bioaccumulated chemicals indicates that as a group, whole body tissue screening benchmarks for metals perform marginally better (97% accuracy) than whole body organic chemical benchmarks (94% accuracy) in identifying tissue residues which, if exceeded, may pose unacceptable risks on survival, reproduction and growth of aquatic species. The reluctance to accept metal tissue benchmarks may be due in part to the success of organic tissue benchmarks that define a relatively constant tissue residue associated with toxicity (e.g. LR<sub>50</sub> of 2 - 8 mmol/kg for nonpolar organics). This success may have led to an expectation that metal benchmarks should also define relatively constant tissue residues associated with toxicity. However, for many reasons, including metals having multiple sites and mechanisms of toxic action, a single metal residue is unlikely to be associated with all possible toxic endpoints in all species. In this regard, metal tissue residue

benchmarks are no different than water or sediment quality benchmarks, for which there is no expectation that a single water or sediment concentration affects all species equally. Thus, as is the case for water and sediment quality benchmarks, a reasonable expectation for screening level ecological risk assessment tissue benchmarks for metals is that they represent residues that, if not exceeded, are protective of a large proportion (i.e. 90 or 95%) of the aquatic species present in a community. The more detailed and species specific evaluations of metal tissue residues associated with toxicity, such as measures of biologically active metals as opposed to whole body residues, are more appropriately performed during baseline ecological risk assessments, not during screening level risk assessments.

#### TU036

##### **Effect of Ni, Zn and their mixtures on different morphological variables of duckweed**

s. martinez, Universidad Nacional de Lujan; W.D. Di Marzio, Universidad Nacional de Lujan-CONICET; J. Alberdi, UNLU; S. Curieses; m. saenz, Universidad Nacional de Lujan CONICET  
*Lemna* sp., commonly called duckweed, is a floating macrophyte commonly used in environmental risk assessment. Macrophytes are important in oxygen production, controlling water quality, sediment stabilization, providing habitat and shelter for aquatic life and wildlife and are primary energy sources for most aquatic ecosystems. Fresh water systems contaminated with heavy metals of thousands of industrial and natural chemical compounds is one of the major environmental and human health problems worldwide. In this work we evaluated the toxicity of two heavy metals (Zn and Ni) to duckweed. The aim of this study is to provide phytotoxicity data for the environmental hazard assessment process by comparing the effect on morphological and growth parameters of plants exposed to different concentration of metals. For this, monocultures of plants were exposed to different concentrations of Zn and Ni, in the form of ZnCl<sub>2</sub> and NiSO<sub>4</sub>. Controls consisted in culture medium without metal addition. Plant were grown in an Erlenmeyer containing 100 ml of culture medium with (treated) or without (controls) metal for 7 days under a mean light intensity of 5000 lux. Different variables were measured: growth rates, frond and colony number, total frond area, fresh and dry weight and longitudinal and transverse axes average. Total area of fronds was calculated by an image analysis program (ImageJ). Growth rates, calculated by frond number, were affected by both metals. IC50 values derived from frond number were 1.51 and 123.89 mg/L for Ni and Zn, respectively. IC50 values based upon average fresh weight, were the lowest between all assessed variables, for both metals. All Ni concentrations evaluated differed significantly from controls when assessed by total area, frond number, colony number and fresh weight. While only the highest concentration showed significant difference from control in dry weight and longitudinal axis average measurements. The statistical comparisons of transverse axis average of fronds exposed to Ni showed no differences between treatments and controls. None Zn assay concentrations showed significant differences with controls on colony number and longitudinal and transverse axes average measurements. For dry weight and total area, only the two highest concentrations were different from controls. When frond number was evaluated, all Zn concentrations differed from control except the lowest. Fresh weight parameter was significantly affected at all assay Zn concentrations.

#### TU037

##### **Mixture toxicity of copper and cadmium in the zebrafish (*Danio rerio*)**

K.I. Cordery, Universiteit Antwerpen / Biology; S. Husson, University of Antwerp; E.E. Smolders, Katholieke Universiteit Leuven / Division Soil and Water Management; K.A. De Schampelaere, Ghent University (UGent) / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; R. Blust, University of Antwerp / Systemic Physiological and Ecotoxicological Research Department of Biology  
 The uptake and toxicity of metals is well characterized for a number of aquatic species and this information is used to develop environmental quality standards. Most studies performed so far have focussed on single metal exposures, however in the environment exposure is often more complex including multi-metal exposures. In this study we have investigated the uptake and toxicity (mortality) of copper (Cu) and cadmium (Cd) in adult zebrafish (*Danio rerio*) on the basis of 10-day single compound and binary mixture exposure experiments. The experiments were conducted according to a partial factorial design covering a wide range of exposure concentrations and different water types ranging from very soft to very hard. In the single metal exposure the zebrafish were generally much more sensitive to Cu than to Cd and the toxic effects showed a strong dependence on water chemistry. Exposure of the fish to binary mixtures of the metals resulted in a very strong increase in metal toxicity, which was much higher than expected on the basis of classical mixture toxicity models such as concentration addition, i.e. Cu and Cd interacted synergistically. The body concentrations of Cu and Cd in zebrafish also strongly depended on the exposure scenario but there was no evidence of a strong Cu-Cd interaction for uptake. As a result expression of metal toxicity in terms of internal metal loading only partially explained the observed toxic effects. These results demonstrate that metal interactions can have strong toxicological impact and that the observed mixture effects must imply synergistic interactions at the level of the homeostatic regulation and internal processing of the metals. More research is needed to identify if such interactions occur at low levels.

#### TU038

##### **Subcellular partitioning of metals in the mealworm beetle (*Tenebrio molitor*) larvae**

Z.M. Swiatek, Institute of Environmental Sciences, Jagiellonian University / Institute of Environmental Sciences; A.J. Bednarska, Jagiellonian University / Institute of Environmental Sciences  
 Metals assimilated by organisms are sequestered in various compartments and some forms are more stable than other. Sequestration mechanisms used by invertebrates to detoxify metals and prevent interaction with important biomolecules include metal binding to proteins and other ligands, and storage in inorganic granules. Different time may be needed to initiate specific physiological processes of metal regulation in an organism, which may additionally change over the exposure period and differ among metals and/or their concentrations. We performed an experiment on the mealworm beetle (*Tenebrio molitor*) larvae by breeding them in the medium (flour) contaminated with Cd at 100, 300 and 600 mg/kg, Zn at 1000 and 2000 mg/kg or control. Subcellular compartmentalization of the metals into organelles, heat-sensitive and heat-stable proteins (the first supernatant, S1 fraction), cellular debris (the second supernatant, S2 fraction) and metal-rich granules (G fraction) was checked after 7, 14 and 21 days of exposure using different centrifugation steps. In control animals the granular fraction represented 52% of the total accumulated Cd, and the percentage of Cd in fractions S1 and S2 was almost equal, ca. 24% each. Total Cd concentration (sum of all fractions) increased significantly with increasing exposure concentration. The percentage of Cd in the G fraction was similar (30-40%) in all Cd treatments. At the lowest Cd concentration, the percentage of Cd in the S1 fraction, which represents metal trophically available to predators, was 1.7 times higher than at 600 mg/kg. With increasing Cd exposure from 100 to 600 mg/kg the percentage of the metal retained in S2 increased by a factor of 1.7. Cellular debris (S2) was the dominant fraction for Cd binding (46.5%) at the highest Cd concentration. Cadmium distribution in the mealworm larvae will be compared with that of Zn for better understanding of sequestration processes of xenobiotic and nutritional metals and their possible transfer along trophic chains. The project was financed by the Foundation for Polish Science project HOMING PLUS (No HOMING PLUS/2013-8/1).

#### TU039

##### **Searching for associations between mercury sediment loads, accumulated levels in gills and liver of the clam *Venerupis philippinarum* and oxidative stress profiles**

O. Araujo, DIVOA; A.M. Marques, CESAM e Departamento de Biologia; D. Piló, F. Pereira, IPMA Portuguese Institute for the Sea and Atmosphere; S. Guilherme, Universidade de Aveiro / Biology; S. Carvalho, King Abdullah University of Science and Technology - KAUST / Red Sea Research Center; M. Pacheco, University of Aveiro / Dept of Biology; P. Pereira, Department of Biology and CESAM

One of the main challenges in Ecotoxicology is to establish comprehensible associations between environmental availability of trace elements and their accumulation in aquatic organisms, as well as between accumulated levels and biological effects. This is due to several confounding factors mainly related to the co-existence of numerous trace elements in environmental matrices, their bioavailability and the organisms' physiological condition. The current work was designed to search relationships between those three lines of evidence (environmental quality – accumulated metals – biological effects) in a chronically contaminated estuary by mercury (Hg) [Tagus estuary, Portugal]. In autumn 2013, a field campaign was performed at two sampling sites, one located in the most contaminated area of the estuary (Barreiro - BAR) and another in a low contaminated area (Alcochete - ALC) situated in the estuarine natural reserve. Surface sediments were collected at both sites, as well as the clam *Venerupis philippinarum*. Gills and digestive gland of the clams were analysed for total Hg levels and the oxidative stress profile (enzymatic antioxidants, GSH content and lipid peroxidation - LPO) was characterized. Surface sediments and interstitial water were also collected in both sites for Hg determinations. Environmental levels of Hg corroborated that Barreiro basin is a highly contaminated area. Despite that, accumulated levels of Hg both in gills and digestive gland of clams were significantly higher in specimens collected at the low contaminated area. Such incongruence between environment Hg levels and those accumulated in clams' tissues was previously reported in other estuaries, which can fit in the "Hg accumulation paradox". An inhibition of CAT activity was observed in the gills at BAR compared with the ALC site, while SOD and GR activities increased. The enhancement of those antioxidant defenses probably prevented the occurrence of lipid peroxidation in gills of clams from BAR. Moreover, a significant increase of SOD activity and GSH content were recorded in digestive gland of clams from BAR. Such antioxidant protection couldn't prevent the occurrence of LPO. Organ-specific patterns were found regarding oxidative stress being the digestive gland a vulnerable organ to peroxidative damage. The current puzzling data reinforces the need of an integrated approach to an accurate diagnosis within the environmental health assessment.

#### TU040

##### **Determining detection limits for uptake of metals in mixtures from soils using PRSTM and DGT probes.**

A.E. Laird, University of Guelph / School of Environmental Sciences; S.D. Siciliano, University of Saskatchewan / Toxicology Group and Department of Soil Science; B.A. Hale, University of Guelph / School of Environmental Sciences

Metal contamination in soils most often occurs as mixtures of more than one metal. Although there have been numerous studies on how single metals are taken up by plants from soil, the accumulation and toxicity of metal mixtures remains largely unstudied and unknown. Furthermore, tools for risk assessment of mixtures of metals in soils are lacking. One possible addition to the toolkit is the use of ion exchange resins as proxies for plant root accumulation of metals from soil. Plant root simulator (PRS<sup>TM</sup>) probes have their origins in testing for soil nutrient bioavailability, but have been adapted for use in metal bioavailability. Diffusive gradients in thin film (DGT) were originally created for measuring bioavailability of metals in water, but were soon adapted for use in soil. The application of these methods to metals in soil is not yet universal, and the implications of the multiple metals for these tools are yet to be investigated. If these tools are applicable for use in determining bioavailability of metals in soil, they may be applied as a screening tool for use in risk assessment when more than one metal of concern is present. In order to evaluate the usefulness of these tools for risk assessment of metals in mixtures, we must first determine if the probes are as sensitive as plants are in detecting the presence of metals at elevated concentrations, especially when there is more than one metal of concern. To this end, the detection limits of PRS<sup>TM</sup> and DGT probes are being determined. The probes are deployed into soils with a known range of metals in combination (Ni, Cu and Co), including field soils collected from around Ni mining and smelting activities. The uptake of these metals by the resin devices will be compared to the total and bioaccessible metal concentrations in the soil. From this study, we will determine detection limits for PRS<sup>TM</sup> and DGT relative to total and bioaccessible soil metals. This information will be critical in determining if these tools may be applied to risk assessment of metals mixtures in soil.

##### **Differentiation between intrinsic toxicity and other effects - the question of causation**

R. Wess, Harlan Laboratories Ltd / Global Registration and Strategic consulting

Iron salts exist dry in the oxidation stages +2 (ferrous salts) and +3 (ferric salts), but rapid hydrolysis and in the case of ferrous salts additionally oxidation processes start in aerobic aqueous solutions. Such processes may cause death of test organisms by oxygen depletion, fouling effects and due to ingestion of flocculated matter. The initially good soluble salts speciate to much less soluble hydroxides in equilibrium. Nonetheless these substances were used in a number of studies for aquatic toxicity, which were available from the overview publications of Johnson et al. (2007) and Vangheluwe & Versonnen (2004). The Hill criteria, published 1965 in the context of effect causation of pharmaceuticals, were adapted in order to differentiate between intrinsic effects and other reasons for the observed effects as in the regulatory context (e.g. REACH) only intrinsic toxicity matters. In result a scheme is presented, which is proposed for application in the evaluation process of metal salts tending to hydroxide formation and/or oxidation or generally formation of less soluble reaction products. Hill AB (1965). The environment and disease: association or causation? Proceedings of the Royal Society of Medicine 58:295-300. Johnson I, Sorokin N, Atkinson C, Rule K, Hope S-J (2007). ##### **Linking inorganic mercury accumulation in *Diplodus sargus* blood with the induction of erythrocytic nuclear abnormalities**

A.M. Marques, CESAM e Departamento de Biologia; P. Pereira, Department of Biology and CESAM; J. Raimundo, IPMA / DIVOA; O. Araújo; S. Guilherme, Universidade de Aveiro / Biology; P. Pousão-Ferreira, M. Barata, Portuguese Institute for the Sea and Atmosphere; M.A. Santos, CESAM & Department of Biology, University of Aveiro, 3810-193 Aveiro, Portugal / Chemistry; M. Pacheco, University of Aveiro / Dept of Biology

Despite the large knowledge and concern regarding the impact of mercury (Hg) compounds to the aquatic ecosystems, there is an evident scarcity of studies linking the bioaccumulation pattern of inorganic mercury and its genotoxic potential to fish. To address this issue, the present study aimed to assess the genotoxic effect of inorganic Hg in fish blood. Thus, *Diplodus sargus* (n=8) was exposed to realistic levels of inorganic Hg (2 µg L<sup>-1</sup>) in water during 3 (E3) and 14 days (E14). Following this period, fish were transferred and kept in Hg-free water during 28 days (PE28), aiming to simulate the cessation of exposure that might happen in natural environment due to fish mobility or contaminant input ending. In parallel, control groups of fish were maintained in clean water during the whole experiment. At each sampling moment, total Hg (Hg<sub>t</sub>) was quantified in fish blood and the genotoxic potential assessed through the erythrocytic nuclear abnormalities (ENA) assay in mature peripheral erythrocytes. Levels of Hg<sub>t</sub> in blood were significantly

higher in exposed fish in relation to control, during both exposure and post-exposure periods, reaching its maximum value at E14. After 28 days of permanence in Hg-free water (PE28), Hg<sub>t</sub> blood levels decreased to values similar with those found at E3, despite still significantly higher than the respective control. The frequency of ENA observed in exposed fish was significantly higher in relation to control and these levels were maintained during the entire experiment, revealing the genotoxicity of inorganic Hg. Overall, the prominent Hg<sub>t</sub> levels in *D. sargus* blood along the experiment, including at the post-exposure period, resulted in a non-recovery in what concerns the cytogenetic damage evaluated. These facts point out the environmental risk of the inorganic Hg to fish, underlying its genotoxic potential and long-lasting effect.

##### **Predicting the chemical and biological effects of tertiary metal mixture (Ni, Cu, Cd) to aquatic plant, *Lemna minor***

B.A. Hale, Y. Gopalapillai, University of Guelph / School of Environmental Sciences

In nature, contamination of aquatic environments may be a mixture of metals and this is particularly true of natural waters contaminated by mining effluents since mineral deposits are commonly an association of multiple metals. For example, nickel mineral deposits mined from Sudbury (Ontario, Canada) are often associated with copper and cadmium. However, water quality guidelines (WQGs) for protection of aquatic life are not designed for multiple contaminants or multiple forms of the same contaminant that co-occur. Rather, WQGs are overwhelmingly based on dose-response studies of single contaminants. Resolving the inability to predict risk from metal mixtures in waters surrounding Canada's many current and legacy extractive mining sites is a high priority for Environment Canada, Health Canada, as well as base metal mining companies. Mixtures of forms of the same metal and mixtures of different metals may have toxicity that would not be predicted additively. Our study aimed to validate the 'concentration addition' approach to predicting the toxicity of a tertiary metal mixture (Ni, Cu, Cd) to *Lemna minor* (one of Environment Canada's recommended test plant species for bio-monitoring of mining effluents) using a central composite design (CCD). The CCD is an efficient experimental approach that uses a rotatable incomplete factorial design to model a response surface, without requiring a complete three-level factorial, which is very resource intensive for conducting toxicity studies. Preliminary results show that toxicity of Ni, Cu, plus Cd is not concentration additive, likely due to competition amongst the metals for uptake into plant.

##### **Periphyton ecology and ecotoxicology: how much complexity and reproducibility are required to connect both perspectives? (P)**

##### **Risk assessment of chemical pollution in Mediterranean rivers based on classical periphyton bioindicators and new biomarkers**

N. Corcoll, Department of Biological and Environmental Science; M. Kuzmanovic; L. Ponsati, Water Institute for Water Research (ICRA); E. Tornés, Catalan Institute for Water Research ICRA; B. Bonet, Institute of Aquatic Ecology / Institute of Aquatic Ecology; T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; M. Petrovic, ICRA; A. Ginebreda, CSIC - Spanish National Research Council / Department of Environmental Sciences; D. Barcelo, IIQAB-CSIC / Institute for Environmental Assessment and Water Research; H. Guasch, Institute of Aquatic Ecology; s. sabater, Universitat de Girona

Environmental risk of chemical pollution in Mediterranean basins is of special concern due to high emissions faced with low dilution capacities. The aim of this study is to evaluate the risk of chemical pollution in Mediterranean rivers using periphyton responses as a model to assess chemical impact. The study also aims to compare classical periphyton indicators of water quality (e.g. diatoms diversity) with new biomarkers of toxic stress (e.g chl-a fluorescence parameters and antioxidant enzymatic activities). Nineteen sites in four Iberian rivers (Llobregat, Ebro, Júcar and Guadalquivir) were sampled in autumns 2010 and 2011. A total of 116 organic compounds were detected in surface waters (60 pharmaceuticals and hormones compounds, 11 personal care products and industrial compounds, 36 pesticides and 9 perfluorinated compounds), and 6 metals in periphyton matrix. The potential risk of this cocktail of pollutants was estimated based on the "Toxic Units (TUs)" approach for algae. Results of TUs indicate that the Llobregat and Júcar rivers were those with the highest environmental risk for algae. TUs based on metals bioaccumulation in biofilm were two orders of magnitude higher than those based on organic compounds, being Zn and Cu the metals with the highest risk. Results from diatoms community composition allowed to identify sites with high environmental risk. Communities in these sites presented an altered diatoms composition, where sensitive species to pollution were replaced by tolerant ones. Biomarkers, based on antioxidant enzymatic activities (catalase, glutathione reductase and superoxide dismutase) and chl-a fluorescence parameters (photosynthetic activity and non-photochemical quenching), tended to show a less consistent pattern. Overall, results indicate that in all the Mediterranean basins studied there are many sites with an environmental risk from chemical pollution,

and that the current use of periphyton biondicators and biomarkers allow to identify sites presenting high levels of pollution, however, new tools are required to evaluate "in situ" situations of moderate and low chemical pollution.

#### TU045

##### **Metal contamination under high surveillance: The case of small streams in Nunavik, Northern Quebec, Canada**

L. Paris, INRS Centre Eau Terre Environnement; I. Lavoie, INRS - Eau, Terre et Environnement / INRS-ETE; S. Leguay, INRS-ETE; C. Fortin, University of Quebec / Centre Eau Terre Environnement

The fragile and pristine ecosystems of Northern Quebec (Canada) are under pressure from the ongoing and expected development of mining activities. Despite tight governmental regulations for environmental protection and restoration, metallic contamination is likely to occur and aquatic ecosystems are particularly at risk. Monitoring metal contamination in streams is complex: trace metals in the water column show marked fluctuations in concentrations over time, bioavailable concentrations are difficult to estimate, and commonly measured parameters do not necessarily provide adequate information about the exposure and response of the biota. Combining chemistry measurements and biomonitoring is an appropriate approach for adequate water quality assessment. As primary producers, algae are particularly efficient for assessing the level of metal bioaccumulation and potential transfer to higher organisms. Studies have shown clear relationships between free metal concentrations ( $[M^{+}]$ ) in the water and intracellular metal concentrations in biofilms, suggesting that metal content in biofilm cells represents a robust indicator of metal exposure and is a good proxy for  $[M^{+}]$  in water. Diatoms (microscopic algae) have also proved to be an excellent tool for assessing the effects of metal contamination, with responses noticeable at the assemblage level (changes in taxonomic composition, low diversity) and at the individual level (morphological abnormalities, smaller-size cells). Following the promising results obtained in previous studies, 16 watercourses were sampled in a Nunavik mining area for water and biofilm. The goals of this project were (1) to assess metal levels in water and biofilms at sites where mining activities have already started and sites where mining development is planned in order to have a reference for future investigations following mining intensification or restoration, (2) to compare the relationship between  $[M^{+}]$  and biofilm metal concentrations obtained in a northern environment with existing data to evaluate the consistency and reliability of biofilm metal content as a proxy for bioavailable metal concentrations, and (3) to study the response of diatom assemblages to high metal levels. The data will ultimately be used for the development of a multimetric index of metallic contamination.

#### TU046

##### **Periphytic diatoms responses to a short-term arsenic exposure**

L. Barral, University of Girona / Environment; S. Morin, Irstea / UR EABX; H. Guasch, Institute of Aquatic Ecology

Diatoms are cosmopolitan aquatic organisms and are a major component of periphyton. They are also the basis of the trophic chain, thus they can respond quickly to environmental changes such as water metal contamination. Effects of metals on diatom communities have been extensively studied in field and laboratory experiments, underlying their high potential for metal contamination assessment. Arsenic pollution is a global problem. Water (surface and groundwater) is the main route of arsenic contamination. We conducted an experiment by combining ecological and ecotoxicological descriptors to investigate the effects of arsenate ( $130 \mu\text{g/L}$  during 13 days) on functional and structural descriptors. Specifically, we analysed changes in photosynthesis-related endpoints and diatom community structure (species relative abundances) and species cell size. Arsenic exposure caused inhibition of periphytic algal growth and diatom community adaptation. We identified 52 diatom taxa of which *Achnanthes minutissimum* was the most abundant species, representing almost the 77% of the total abundance of diatoms: 75% in control and 79% in arsenic exposure, showing a tolerance to arsenic. Moreover, arsenic reduced diatom species richness ( $p=0.051$ ). Diatom average cell biovolume was clearly reduced by arsenic ( $p=0.003$ ). Individual cell biovolume (or cell size) in some species (*i.e.*, *Nitzschia fonticola*) also changed with arsenic exposure. A general trend in biovolume decrease was observed (*Amphipleura pellucida*, *Nitzschia dissipata* var. *dissipata* and *Navicula reichardtiana* var. *reichardtiana*), but *Fragilaria* species biovolume increased under arsenic exposure, due to greater cell and/or higher cell numbers in the arsenic treatment. Measured biovolumes were compared with theoretical biovolume data for each species and were poorly correlated, suggesting that the real measurements are recommended to better assess real impacts. In conclusion, both functional and structural algal parameters were affected by arsenic exposure. The strongest effect of arsenic on diatom community is the decrease in real cell biovolume, but arsenic also selected for species like *Achnanthes minutissimum* (tolerant to metal exposure) and reduced diatom species richness. Considering how low is the arsenic concentration and exposure time in this experiment compared with reality, the results call into question the limits of arsenic concentration established to environmental quality, which are higher.

#### TU047

##### **LINKING NUTRIENTS, PHYTOPIGMENTS AND MICROFLORA IN RIVER BED SEDIMENTS: A CASE STUDY IN THE ANLLÓNS RIVER (SPAIN)**

D.M. Prieto, University of Santiago de Compostela / Soil Chemistry; R. Devesa-Rey, University of Vigo; R. Paradelo, University of Vigo / Departamento de Biología Vegetal y Ciencia del Suelo Facultad de Ciencias Universidad de Vigo Campus de Ourense; M. Penalta, University of Santiago de Compostela; F. Díaz-Fierros Viqueira, University of Santiago de Compostela / Departamento de Edafología y Química Agrícola Facultad de Farmacia; M. Barral, University of Santiago de Compostela / Departamento de Edafología y Química Agrícola Facultad de Farmacia

In the Anllóns River (NW Spain) several areas have been identified as affected by diffuse pollution due to agricultural runoff and industrial activities, as well as by past mining activities which originated elevated As concentrations in the bed sediments, downstream Au-As mineralized areas [1,2,3]. The Anllóns riverbed sediments were analyzed to evaluate the presence of benthic epipsammic microflora and to identify the influence of nutrients and pollutants on the biofilm formation. Sediment samples were collected at four points along the river course. The study included the characterization of the pore waters: pH, electrical conductivity (EC) and total and soluble P, as well as the determination of the main chemical properties of the sediments: particle size, total and bioavailable P, total C, N and As, as well as toxicity, evaluated by TCLP extraction and Microtox® test. Biological properties were assessed by means of biochemical properties: phytopigments, and dehydrogenase (DHA) and phosphatase (MPE) activity), and by means of a taxonomic study, requiring a specific sampling, to identify the main autotrophic species forming the biofilm. The main autotrophic taxa belonged to divisions: Cyanophyta, Heterokontophyta, Euglenophyta and Chlorophyta. Bacillariophyceae (Heterokontophyta), and namely the genera *Navicula*, was the predominant class throughout the river bed sediments. Site 4, located at the river mouth, exhibited the highest values of nutrients, EC and biological properties ( $\text{Chl } a = 34.6 \mu\text{g g}^{-1}$ ,  $\text{DHA} = 3075 \text{ mg TPF kg}^{-1} \text{ d}^{-1}$ ,  $\text{MPE} = 62.9 \text{ mg p-nitrofenol kg}^{-1} \text{ hora}^{-1}$ ), as well as total abundances ( $265,504 \text{ abundances cm}^{-2}$ ) and species richness (17.8), and the lowest toxicity. Statistical analysis revealed significant, positive correlations ( $p < 0.05$ ) between the chemical (except sand content and toxicity) and the biological properties of the sediments, evidencing the effect of the environmental conditions on the development of biofilm. [1] Devesa-Rey et al. 2008. *Water Air Soil Poll* 195 (1-4):189-199 [2] Devesa-Rey et al. 2010a. *J Environ Manage* 91 (12):2471-2477. [3] Devesa-Rey et al. 2010b. *Environ Earth Sci* 61 (7): 1401-1417.

#### TU048

##### **Development of a dual radiolabel incorporation assay for simultaneous detection of toxicity to photosynthesis and bacterial protein synthesis in marine periphyton communities**

M.M. Eriksson, Chalmers Technical University / Department of Shipping and Marine Technology; V. Fihlman, T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; H. Blanck, Goteborg University / Department of Biological and Environmental Sciences

Short-term toxicity assays are used to detect Pollution-Induced Community Tolerance (PICT) in microbial communities. In this context, they hence detect long-term effects of toxicants that have exerted a selection pressure on natural communities in the field or in experimental ecosystems. Various short-term metabolic endpoints have been used to detect PICT, but so far they have only studied effects on metabolic processes in a specific part of microbial communities, such as enzymatic activity in bacteria or photosynthesis in phototrophs. Here we present a methodology that simultaneously detect effects on bacterial protein synthesis and algal and cyanobacterial photosynthesis by incorporation of  $^3\text{H}$ -labelled leucine and  $^{14}\text{C}$ -labelled bicarbonate, respectively. Since the decays of  $^3\text{H}$  and  $^{14}\text{C}$  have different energy spectra, liquid scintillation counting can simultaneously measure decays of these isotopes, and hence estimate both the amount of incorporated  $^3\text{H}$  and that of  $^{14}\text{C}$  in one sample. We tested incorporation of both  $^3\text{H}$ -labelled leucine and  $^3\text{H}$ -labelled thymidine, representing bacterial protein and DNA synthesis respectively, simultaneous to the incorporation of  $^{14}\text{C}$ -bicarbonate into photosynthetic products. All three isotopes were linearly incorporated over the studied time of 8 hours, and neither  $^3\text{H}$ -labelled leucine nor  $^3\text{H}$ -labelled thymidine interfered with the counting of  $^{14}\text{C}$ -bicarbonate, and vice versa. Dark incubations revealed that leucine incorporation, but not thymidine incorporation, was independent of light. Incorporation of bicarbonate and leucine seemed to be specific for protein synthesis in bacteria and photosynthesis in cyanobacteria and algae, respectively. During initial toxicity testing, incubation times of two, three and four hours were tested. The two endpoints of the assay responded differently to toxicants with specific mechanisms of action. For example, toxicity of a photosystem-II-inhibiting herbicide to photosynthesis was detected, but toxicity of this herbicide to bacterial protein synthesis was not detected. Moreover, toxicity of a protein synthesis-inhibiting antibiotic was detected to bacterial protein synthesis, but not to photosynthesis. Hence, the dual assay could detect specific toxic effects on processes in the two organism groups, simultaneously. However, effects of more chronically acting compounds, such as the herbicide metazachlor and the antibacterial sulfamethoxazole, could not be detected over the studied incubation times.

#### TU049

##### **Periphyton metaproteomics, from community ecotoxicology to environmental assessment in aquatic environment**

J. Kuruville, Linköping University / Department of Clinical and Experimental Medicine; B. Mathew, Linköping University / Department of Clinical and Experimental Medicine Cell Biology; M. Matzke, Centre for Ecology & Hydrology (NERC) / Molecular Ecotoxicology; M.M. Eriksson, Chalmers Technical University / Department of Shipping and Marine Technology; T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; S. Cristobal, Linköping University / Department of Cl and Exp Medicine Cell Biology

Periphyton ecology and ecotoxicology has been studied and established in biomonitoring programmes. However, it is a difficult task to define effects of exposure to pollutants in such a complex and highly variable community and to evaluate the impact of stressors as beneficial or detrimental. Current metaproteomics techniques could provide a wide resolution of proteins from a complex ecosystem biological or environmental. The qualitative and quantitative metaproteomic analysis provides a functional overview over several level of complexity: at the community level, how the communities respond to the exposure, stress or disease; at the molecular level, which protein families have been expressed; and at the biochemical level, which enzymatic reaction or macromolecular machines have acquired a relevant role to maintain the community in equilibrium. Thus, metaproteomics analysis could offer a molecular snap shot of the eukaryote or prokaryote communities at a certain time and place. However, metaproteomic analysis has not yet explored to implement traditional environmental assessment in aquatic communities. Periphyton could be used to exploring this methodology in both, fresh water and marine environment. The fundamental goal of a metaproteomic environmental assessment is to deliver a robust evaluation the environmental impact at population, individual, cellular and molecular level from one single, comprehensive and cost-efficient methodology. We presented the metaproteomic analysis of a periphyton and we evaluate the importance of protein extraction in the reproducibility. The biofilm were prepared in specific running system for 3 weeks. The proteins were extracted with the three different extraction methods, separated by SDS-PAGE. The gel was divided in slides and the protein mixtures were in-gel trypsin digested. The peptides were analysed on a linear trapping quadrupole-Orbitrap-MS. The LC-MS (2)-spectra were then searched using a combination of two different search engines: Unipept or MEGAN against different database and computational analysis. We compared a sequential citrate phenol extraction, guanidine hydrochloride method and a detergent extraction method and the latest gives the highest number of identified taxa as well as the highest reproducibility. We tested if metaproteomic analysis from periphyton is reproducible and if the method can estimate: i) variation in the abundance of protein families, ii) changes in biodiversity.

## Plastics in the Aquatic Environment: Mechanisms and Implications (P)

### TU050

#### Towards a definition of microplastics

A.J. Verschoor, RIVM / Centre for Safety of Substances and Products; J. Herremans, RIVM / National Institute for Public Health and the Environment / Centre for Safety of Substances and Products; W.J. Peijnenburg, RIVM / Center for Safety of Substances and Products

Microplastics are identified by the UNEP as a global environmental problem, originating from many sources. The concerns of microplastics in the environment mainly relate to their persistence, their consumption by aquatic organisms and birds, and their potential to act as a vector for other contaminants present in water. Under the Marine Framework Directive and OSPAR, strategies are being developed to reduce the emissions of microplastics to the environment. Before (legal) emission reducing measures on microplastics can be implemented, a clear definition of microplastics is of utmost importance. Such definition should preferably be a generic definition; useful and valid for the identification of microplastics in all types of products. Microplastics are now generally described by the following characteristics: made from plastics solid particles smaller than 5 mm insoluble in water not degradable. A definition of microplastics for policy purposes should be crystal clear. The problem is that the above mentioned criteria have not been translated into quantifiable units. On our poster we will propose quantitative, measurable threshold values or more specified descriptions for each element of the definition of microplastics.

### TU051

#### Can microlitter in field-collected sediment and biota be quantified?

T.M. Karlsson, Örebro University / MTM; D. Vethaak, DELTARES; M.v. Velzen, Vrije Universiteit Amsterdam / Institute for Environmental Studies IVM; F. Arie, Vrije Universiteit Amsterdam; B. Carney Almroth, Göteborg University; C. Schönlaui, MTM Research centre Örebro University; H. Grahn, Corpus Data Mining; P. Geladi, Swedish University of Agricultural Sciences / Unit of Biomass Technology and Chemistry; M. Engwall, Örebro University / MTM research center Department of Science and Technology; A. Kärrman, Örebro Universitet / SCHOOL OF SCIENCE AND TECHNOLOGY; B.v. Bavel, MTM Research centre Örebro University; H. Leslie, IVM- VU University / Chem Biol Microlitter such as fibers, rubber and plastic is observed in pelagic samples all over the world. This has raised increasing concern from the scientific community as well

as the general public since it is associated with ecological, societal and economic problems. Pioneering analytical methods have been applied to investigate this emerging contaminant. Still there is uncertainty as to the baseline values for the level of microlitter in marine environments, which is important for being able to assess trends. Furthermore we have only begun understanding its sources and sinks. To address these and other research questions robust, validated and comparable analytical methods are needed. In this project current methodologies were tested and modified for analyzing microlitter in sediment and invertebrate biota from different aquatic environments. Recovery in the modified method for particles in sediment increased by 18 % to 82%. For biota the optimized method gave an increase in recovery of 63% to a total of 97%. Raman spectroscopy showed promise for identifying microlitter from environmental samples, but certain obstacles were identified that will have to be considered for future investigations. The environmental measurements performed showed that microlitter was present in 85% of the biota samples investigated. It also indicated an accumulation of microlitter higher up in the foodchain and show a significantly higher amount in filter-feeders compared to other functional groups. In mussels the concentration was a thousand times higher than in surrounding water and sediment. These overall promising results with method developments are of high importance in developing monitoring strategies of microlitter. The method for biota analysis also provides the possibility to analyse whole-body residues and tissue concentrations of particles in organisms, but may also be applied to stomach microplastic content-analysis for particles as small as 1 µm. Variations between subsamples are however still high and fit-for-purpose experimental design and statistical methods are also needed to create robust, comparable datasets for monitoring microlitter. Furthermore there is an urgent need to develop faster and more objective approaches to identifying and quantifying microlitter in environmental samples. We are currently working with several spectroscopic techniques to understand their potentials and limitations for environmental sampling and analysis of microlitter.

### TU052

#### A comparison of microscopic and spectroscopic identification methods for microplastic analysis

Y. Song, Oil and POPs research group; W. Shim, S. Hong, Korea Institute of Ocean Science and Technology / Oil and POPs research group; M. Jang, Korea Institute of Ocean Science and Technology / oil and POPs research group OPRG; G. Han, Oil and POPs research group; M. Rani, Korea Institute of Ocean Science and Technology

The analysis of microplastics in various environmental samples requires the identification of microplastics from natural materials. The identification technique lacks a standardized protocol. Herein, stereomicroscope and Fourier transform infrared spectroscopy (FT-IR) identification methods for microplastics (< 1 mm) were compared using the same samples from the sea surface microlayer (SML) and beach sediment. Fragmented microplastics were significantly ( $p < 0.05$ ) underestimated and fiber was significantly overestimated using the stereomicroscope both in the SML and beach samples. In the fragment, many transparent or white fragments were identified as synthetic polymers, such as polyethylene (PE) and polypropylene (PP) by FT-IR, but were not counted as microplastics using the microscope. And less than 1 mm sized fragment had a limitation of identification by microscope. In the fiber, plastic-like fibers such as sea grass and cotton were apparently miscounted as microplastics. The total abundance by FT-IR was higher than by microscope both in the SML and beach samples, but they were not significantly different because of the offset of the fragments and fiber in abundance. Depending on the number of samples and the microplastic size range of interest, the appropriate identification method should be determined; selecting a suitable identification method for microplastics is crucial for evaluating microplastic pollution. **Keywords: microplastics, identification, stereomicroscope, FT-IR microscope**

#### Mitigation of microplastics impact caused by textile washing processes. MERMAIDS project

M. Escamilla, LEITAT / Sustainability Unit; R. Villalba, Leitat Technological Center / Sustainability Unit; L. Piñol, L. Rodriguez, Leitat Technological Center / Maritim Division; R. Escudero, Leitat Technological Center / FMCG Home Personal Care; M. Brouta-Agnés, Leitat Technological Center / RD Textile Technologies; M. Avella, CNR Institute for Polymers Composites and Biomaterials / ICTP; J. Lancharro, Polysistec S.L.; J. Dagevos, Plastic Soup Foundation / Programs

European oceans are contaminated by marine litter, mainly by plastics. Microplastics are particularly worrying because water treatment plants do not take them into account in their management processes and they are deposited in waterways and sewage sludge. The European Marine Strategy Framework Directive (2008/56/EC) establishes a framework in order for Member States to contribute to create a Good Environmental Status (GES) in the marine environment by 2020 through the monitoring of different indicators, among them microplastics. Microplastic particles of synthetic clothes coming from laundry wastewater have been encountered in marine sediments, ecosystems and runoff and sewage waters. The "Accumulation of Microplastic on Shorelines Worldwide: Sources and sinks" study states that "the source of the microplastic fibres in the sewage treatment plants is most likely to be from washing machine wastewater as the mixture of fibres

found in synthetic textiles is similar to the mixture of microplastic fibres found in beaches at disposal sites and in the wastewater of sewage treatment plants.”. On average, more than 1900 fibres of microplastics can be released by a synthetic garment during one wash [1]. Microplastics concentrate Persistent Organic Pollutants via partitioning and they can be ingested by marine biota entering in the food web [2]. The main objective of MERMAIDS is to contribute to the mitigation of the impact caused by micro and/or nanoplastic particles resulting from laundry wastewater on European seas’ ecosystems, by demonstrating and implementing innovative technologies and additives for laundry processes and textile finishing treatments. A reduction of at least 70% of the total amount of microplastic fibres that is currently discharged in laundry wastewater is sought by means of the improvements achieved. Policy recommendations will be set in order to promote the widespread implementation of technologies which promote garments’ microplastics retention in washing processes contributing to reach a GES by 2020. With the same aim in view, good practices guidelines on microplastic retaining for plastic fibres manufacturers, textile industry, detergent manufacturers and households will be elaborated. [1] Science for Environmental Policy. DG Env, new alerts issue 272. 9 Feb 2012 [2] Teuten, E. et al 2007. Potential for plastics to transport hydrophobic contaminants. #### TU054

##### Characterisation of Microplastics in Personal Care Products

K. Renner, Institute for the Environment, Health and Societies Brunel University / Institute for the Environment; M.D. Scrimshaw, Brunel University / Institute for the Environment

Microplastics are synthetic contaminants which have a global distribution and are present in the aquatic environment. Studies on plastic contamination in the aquatic environment have focused largely on macroplastics which are greater than 5mm in size, but recent research is focusing on microplastics which are less than 5mm in size. This shift in research focus is partly due to microplastics being used as ingredients in personal care products. Today, the frequent use of facial scrubs or toothpaste which contain microplastics especially polyethylene, release unknown quantities of microplastics through waste treatment plants to the aquatic environment. Waste treatment plants which have fine and coarse screens do not remove these microplastics from waste waters effectively, before discharge to the aquatic environment. The lack of a standardised protocol for the characterisation of microplastics has hindered progress in determining the concentration and impact on the aquatic environment. Polyethylene microplastics in two brands of toothpaste and facial cleansers were extracted using a density separation method and viewed using binocular microscope equipped with QCapture Pro 5.1 imaging software, at 40X magnification on a Sedgewick-Rafter cell. The microplastics analysed in all products were less than 1mm in diameter. Microplastics in toothpastes showed similar size range of 80 – 433.3 µm and 80 – 431.7 µm; and facial scrubs showed size ranges of 170 – 495 µm and 91.67 – 253.3 µm respectively. However, the analysis of variance carried out showed that there was a significant difference ( $p < 0.05$ ) in the mean size of microplastics for the four personal care products [ $F(3, 1596) = 494.93, p = 2.5736E-227$ ]. In addition, final results showed that one of the facial scrubs had a total count of 969.6 microplastics per ml of product, while one of the toothpastes had a total count of 145.2 microplastics per ml of the product. These were the highest and lowest microplastics count per ml of the products respectively.

#### TU055

##### Microplastics in a biological wastewater treatment plant and the receiving freshwater environment in Flanders, Belgium

L. Van Cauwenberghe, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology; W. Van Echelpoel, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; K. De Gussem, G. De Guldre, Aquafin NV; M.B. Vandeghechuchte, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

The vast majority of studies dealing with microplastic pollution focus on the marine environment as it is regarded as the ultimate sink for all littered plastic. Rivers are often considered continuous suppliers of this waste, and sewage treatment plants (STPs) as major sources of microplastics. Domestic sewage is polluted with microplastics as they are used in personal care products (microbeads) and are formed during the washing of synthetic clothes. Due to their small sizes, microplastics are believed to pass through the STP without being retained. In order to describe the removal of microplastic from sewage, influent, effluent and sewage sludge were sampled and analysed for plastic content. The receiving brook and river (Scheldt) were also monitored. Sample processing involved oxidation of organic matter ( $H_2O_2$ ), density separation using a high density salt (NaI) and filtration. STP influent samples had an average microplastic concentration of  $17 \pm 7$  plastics.L<sup>-1</sup>. A decrease in the microplastic load was observed in the effluent which had on average  $5 \pm 1$  plastics.L<sup>-1</sup>. This corresponds to a removal efficiency of 47%. Microplastics are removed from the sewage as a result of (co-)sedimentation with the activated sludge. As such, very high microplastic concentrations were detected here:  $20.2 \pm 6.7$  plastics.g<sup>-1</sup> ww. We calculated that this single STP has a daily discharge of  $21.4 \cdot 10^8$  plastics.d<sup>-1</sup> ( $1.4 \cdot 10^5$  plastics.inhabitant<sup>-1</sup>.d<sup>-1</sup>). Using these figures, a daily discharge of roughly 14.6 billion plastics.d<sup>-1</sup> is derived for the whole

of Flanders ( $6.5 \cdot 10^6$  inhabitants). This high discharge is reflected in the microplastic abundance detected in the surrounding freshwater environment, i.e the receiving brook and Scheldt river: here, on average  $6 \pm 2$  and  $7 \pm 2$  plastics.L<sup>-1</sup> were detected. In freshwater sediments, the lowest abundances observed (ranging from 4,148 plastics.kg<sup>-1</sup> to 15,111 plastics.kg<sup>-1</sup>) were higher than those reported for marine sediments. Here, we demonstrated that STPs play an important role in the discharge of microplastics into the aquatic environment. Even though almost 50% of the particles are retained during the sewage treatment process, discharges into the environment remain high, with billions of particles being released on a daily basis. Since microplastics do not belong in sewage tackling their input into the environment at the source (e.g. a ban on microbeads or improved technologies for laundry washing) is the sustainable way to go.

#### TU056

##### Presence and Abundance of Microplastics in the Thames River Basin, UK.

A.A. Horton, Centre for Ecology and Hydrology; E. Lahive, Centre for Ecology & Hydrology (NERC); C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology; D. Read, NERC, Centre for Ecology and Hydrology / Hails Section; D. Spurgeon, Centre for Ecology & Hydrology

The global increase in plastic production has led to growing concern about the environmental impacts of plastics and their degradation products. Microplastics have been extensively observed and studied in the marine environment but little is known about their presence and abundance in freshwater environments. Although rivers are recognised as a significant source of microplastics to the oceans, they are seldom considered in studies of the environmental presence of microplastics and there are no data reported to date on microplastics in UK rivers (or indeed any freshwater bodies). This study aimed to identify and quantify the abundance and types of plastics in the Thames Basin where population densities and sewage inputs are well described. Ten sampling sites on the River Thames and its tributaries were selected, ranging from densely populated, urban areas to sparsely populated, rural areas. Sites are all downstream of sewage treatment works (STWs) serving known populations, allowing correlation between population density with plastic types and abundances found. In addition samples were collected from sites at known distances downstream of STW outfalls, as well as the effluent itself, to try and establish the proportion of plastics directly entering from STWs and its fate and transport pathways. River sediment and water samples were collected at all sites. Sediment samples were initially searched by eye, followed by flotation and overflowing using ZnCl<sub>2</sub> solution. Plastics collected from the sediments were subsequently identified by Raman spectroscopy. Initial observations indicate that coloured and manmade particles are obviously visible in sediments from sites with high population densities compared to few evident manmade particles in sediments from areas with low population densities. Further analysis will allow for correlation of the plastic types and abundance with population density and sewage inputs to understand the distribution of plastics in river systems.

#### TU057

##### Occurrence of microplastic in the river Rhine and Meuse delta

E. Besseling, Wageningen University & Research Centre / Aquatic Ecology and Water Quality Management Group; E. Foekema, Wageningen IMARES; K.L. De Hoon, Prinsentuin College Breda & IMARES / Natuur Milieu en Ruimte; A. Wegner, Wageningen University; R. Gylstra, Waterschap Rivierenland / Kennis en Advies; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group

Microplastics are traced, hypothesized to be transported and thought to affect organisms in several freshwater and marine systems nowadays. Little is known about the distribution of microplastic along river deltas. Here we report the first inventory of the occurrence of microplastics that includes fresh, estuarine and marine surface water locations of the main river delta in The Netherlands. Sediment samples from sixteen locations were taken using a Van Veen grab or spade and water was sampled at five locations by filtering 10 m<sup>3</sup> in triplicate. In a laminar flow cabin, the samples were treated by density separation, organic matter degradation and filtration. Subsequent microscopy analysis indicates maximum concentrations of 0.06 particles / g dry weight sediment and 0.3 particles / m<sup>3</sup> water, with no apparent spatial pattern present. These concentrations are in line with concentrations found for fresh water elsewhere in Europe. The relatively low concentrations may point to a high retention and burial of microplastic particles in river systems upstream of The Netherlands.

#### TU058

##### Microplastic sampling in the Mediterranean Sea

F.J. Bignagwa, Department of Environmental Social and Spatial Change; B.M. Sosthenes, K. Syberg, Roskilde University / Department of Environmental Social and Spatial Change; H.B. Pedersen, C. Sick, Plastic Change; M. Eriksen, 5 Gyres Institute; Y. Shashoua, The National Museum of Denmark; F.R. Khan, Roskilde University / ENSPAC

The extent of microplastic pollution in the Southwestern Mediterranean Sea is not yet known, although on Northwestern part has been previously studied. Plastic samples were collected at 7 transects during a 10 day expedition from Sicily (Italy) to Malaga (Spain) in September 2014. A 330 µm mesh manta trawl was used for surface water sampling. Physical and chemical characterization of plastic particles was performed with regard to size ( $1 < 5$  and  $> 5$ mm), shape (fragment, line, thin

film, foam and pellets), color (transparent, white, black and colored), density and chemical composition according to 5 Gyres protocol. Microplastics (< 5mm) were more abundant than macroplastics (>5mm) across all sites. Abundance decreased with increasing distance from the coast of Palermo to the open sea, with the highest abundance (20717 particles per Km<sup>3</sup>) observed at the Sicilian coast. Fragments were the dominant shape of plastics with 86% and 75% of < 5mm and >5mm sizes, respectively. Transparent plastics comprised the majority of total plastic particles obtained with 65% and 56% of < 5mm and >5mm sizes, respectively. Despite their small number, plastics of >5mm weighed more than particles < 1mm. This is the first study to assess plastic pollution levels in SW Mediterranean Sea.

#### TU059

##### **Microplastics in marine and freshwater environments of northern Scotland**

N.A. James, Environmental Research Institute / Environmental Research Institute; B. Gordon, K. Boyd, University of the Highlands and Islands / Environmental Research Institute

As plastics have become more widely used, their presence in the environment has increased. Microplastics, small pieces of plastic measuring less than 5 mm in two of their dimensions, may have detrimental effects on the environment and its inhabitants. Sediment samples were collected from five marine beaches and two freshwater lochs in Caithness in the far north of Scotland. Microplastics were separated from sediments on the basis of density and enumerated visually using microscopy. Microplastic particles were found in all samples. The samples ranged from 0.07 to 37.89 pieces of plastic per 100 g. The greatest number of microplastic pieces (440 000 per m<sup>3</sup> sediment) was found at Scrabster Beach, whilst the fewest (166 667 per m<sup>3</sup>) were at Loch Calder. Four of the five saltwater samples and one of the two freshwater samples had significantly more plastic particles than in control samples. A wide range of different coloured plastics were found with clear being the most common, and predominantly rope fragments or fibres. In order to determine if such materials could be a vector for polycyclic aromatic hydrocarbons (PAHs) samples of rope from five beaches were extracted and analysed for the presence of phenanthrene and anthracene using high performance liquid chromatography with fluorescence detection. Extracts contained PAHs in concentrations over 200 times that of the control samples. The presence of microplastics, combined with their ability to adsorb PAHs in the environment highlights the importance of understanding their source and fate in remote areas such as Caithness, Scotland.

#### TU060

##### **Plastic Pollution in the Baltic Sea - Outcomes and Observations of the Baltic Sea Expedition 2014**

C. Schoenlau, Institute for Environmental Research / MTM research center Department of Science and Technology; T.M. Karlsson, Orebro University / MTM; P. Geladi, Swedish University of Agricultural Sciences / Unit of Biomass Technology and Chemistry; H. Grahm, Corpus Data Mining; M. Engwall, Orebro University / MTM research center Department of Science and Technology; B. van Bavel, MTM Orebro University; A. Kärrman, Örebro Universitet / SCHOOL OF SCIENCE AND TECHNOLOGY

During the last decades scientists have proven that plastic in the marine system poses a threat to several aquatic species via entanglement, ingestion and so called "ghost fishing". The worldwide production and consumption of plastic is constantly growing and is about 280 million tonnes per annum. Considering surface runoff and the lack of waste water treatment, it is very likely that some of this plastic will end up in the aquatic system. One of the goals of the Marine Strategy Framework Directive (MSFD), initialized by the European Union in 2008, is to reduce marine litter that negatively affects or is likely to negatively affect marine organisms by 2020. Thus, it is crucial to evaluate the current status of marine pollution at different sites, as well as identify and characterize the material. The Baltic Sea Expedition was undertaken in Sweden during August 2014, starting in Gothenburg and ending in Stockholm, on the sailing boat Sea Dragon. Sampling the open water in Skagerrak, Kattegat, the Baltic Sea and Gulf of Bothnia was performed during three weeks using a manta trawl and a specially designed high volume plankton pump. Both, manta trawl and plankton pump, were used for surface water sampling. The pump was constructed to sample micro plastic by pumping sea water through three different metal filters in series with the mesh size of 500, 300 and 50 µm. For the pump a sampling time of 60 - 120 minutes on each site was used. The manta trawl had a mesh size of 333 µm and a length of 3 m. It was towed at between 0.5 and 1.5 m/s on the side of the boat for 60 minutes at every sampling point. During the sampling campaign 12 pump samples and 27 trawl samples from different sites were obtained. These samples were analysed for the amount, size fractions and identity of micro plastic by using stereomicroscopy to distinguish between natural and anthropogenic particles. Furthermore a new approach in the identification of the plastic material was carried out by using hyperspectral imaging to obtain spectral information of the different plastic materials. Therefore a Videometer, a Malvern and a MicroNIR camera (Near Infra Red) were tested. Based on spectral information of reference plastics a model was created that should be able to detect micro plastic in the samples. Further studies of the sampled micro plastic aim at the detection of persistent organic pollutants that might be absorbed to the material by using chemical and bioassay analysis.

##### **Assessment of microplastic contamination on beaches in South Korea**

Y. Song, Oil and POPs research group; W. Shim, S. Hong, Korea Institute of Ocean Science and Technology / Oil and POPs research group; M. Jang, Korea Institute of Ocean Science and Technology / oil and POPs research group OPRG; G. Han, Oil and POPs research group; M. Rani, Korea Institute of Ocean Science and Technology

The composition and distribution of microplastics in twelve beaches along Korean coast and six beaches of Geoje Island affected by riverine discharge from nearby Nakdong River were determined in 2012 and 2013-2014 respectively. On the beaches, ten quadrats (0.5 m x 0.5 m) were randomly placed along the high-stranded line and 1L sand passed through a 1 mm sieve was collected. In the laboratory, 50 mL sand from each 1L of ten quadrats was sub-sampled to make a composite sample (500 ml) representing each beach. The microplastics were separated with sediment using saturated NaCl solution. Supernatant was filtered through a 1.2 µm filter paper and plastic like particles on the filter papers were identified with a FT-IR microscope. The abundance of microplastics from eighteen beaches was in the range of 12-9,280 particle/L-sediment. The mean abundance of microplastics (< 1mm) from six beaches of Geoje (2,721 particles/L-sediment) was significantly ( $p < 0.05$ ) higher than those in others beaches (213 particles/L-sediment). The beaches in the East coast of Geoje Island were severely contaminated by microplastics. Among the five categories of microplastics (fragment, fiber, spherule, sheet and expanded polystyrene (EPS)), fragment type accounted for the highest portion (50-100%) in the 12 beaches, while in Gangneung, the highest portion was fiber (50%) and in 5 beaches were EPS (49-100%). In polymer composition, polypropylene, polystyrene (expanded) and polyethylene accounted for 30%, 29% and 22%, respectively. The unit used to compare abundance of microplastics with other countries was converted from particles per liter to particles per meters cubed and particles per meters squared. The abundances of microplastics in beaches of Korea were orders of magnitude higher than those reported in the world. **Keywords: microplastics, distribution, beach, Korea**

#### TU062

##### **Towards a baseline database of microplastics contamination in Scottish Marine Environments**

N.E. Mearns, S.J. Paterson, M.G. Hartl, Heriot-Watt University / Centre for Marine Biodiversity and Biotechnology School of Life Sciences

Microplastics are defined as fibrous or particulate pieces of plastic smaller than 5mm and are commonly found in seawater, intertidal sediments, and other coastal environments. These plastics can enter the marine environment from the breakdown of macroplastics discarded at sea or onland as well as from consumer products containing microbead technologies. They have recently become an area of interest because of potential health risks they may pose to marine organisms. Microplastics have been shown to absorb toxic and persistent bioaccumulative compounds from seawater, including metals and persistent organic pollutants (POPs), which can be taken up and biomagnified up the food chain. In recent years the UK has taken a stronger stance on reducing plastic pollution around the coast with more focus put on recycling plastics. Microplastics need to be monitored in order to evaluate the effectiveness of the Scottish Government's initiatives to reduce plastic debris in the environment. The aim of the present study, therefore, was to initiate the development of an hitherto lacking quantitative marine baseline microplastic database, for Scotland, starting with the Firth of Forth. This was done by taking intertidal sediment samples around the Forth, from Musselburgh on the South shore around to Burntisland on the North shore. Fragments were examined through the process of precipitation/floatation in a supersaturated sodium chloride solution and filtering the supernatant. The material retained on the filter was examined and sorted using a high powered dissecting microscope. Plastic particles or fibres were counted and representative particles removed for polymer identification using Raman microscopy. Using GIS to create a distribution map, the initial data suggest that sites with muddier sediment had less microplastic debris compared to sites with sandy sediment, and show that the majority of plastics found were fibrous, mainly polypropylene, with a range of different colours and sizes. Furthermore, on several sites along the North shore there was a substantial number of larger plastic nurdles scattered along the shore. Acknowledgements This project was partly funded by a Heriot-Watt Crucible V Interdisciplinary Research Fund grant.

##### **Distribution and quantification of microplastics present in mussels along the Scottish coast**

A. Catarino, Heriot-Watt University / School of Life Sciences; W. Sanderson, Heriot-Watt University / Centre for Marine Biodiversity Biotechnology; T.B. Henry, Heriot-Watt University / School of Life Sciences

The presence of small (< 5 mm) plastic debris, microplastics (MPs), in aquatic environments is recognised as among the highest international issues for environmental science and policy. Microplastics can be found in aquatic environments in suspension and/or associated with sediments and marine organisms can ingest MPs, raising concerns that negative effects may occur. Documentation of the presence and abundance of MPs in marine environments is an important initial step towards assessment of MPs effects on organisms. Microplastics have been found in most coastal areas where their presence has been

investigated, but little is yet known about the abundance and types present on the Scottish coast. Preliminary (unpublished) results from Scotland show that microplastics can be found both among sediments and in the lumen of fish digestive tracts, especially near urban areas. Our goal was to establish a standardised procedure for extracting and quantifying the presence of MPs in marine mussels, and to apply this procedure to inter and subtidal species from the East and West coasts of Scotland. The intertidal species was *Mytilus edulis* and the subtidal species was *Modiolus modiolus*. Methods for extraction and quantification of MPs from marine organisms have not been established, and some traditional methods (e.g. use of strong acids or bases) for extracting substances from tissues are likely to damage MPs. We have compared previously reported methods and developed a new method based on enzymatic digestion that is relatively easy, reproducible, and provides good recovery rate of MPs from spiked tissue samples. Mussels collected from various field sites on the East and West coast of Scotland are being processed according to this procedure and we anticipate providing information on the level of MPs contamination in mussels according to their site of collection and habitat. A field campaign is underway that involves transplantation of *M. edulis* into purpose built cages and use of passive water samplers to quantify MPs presence and abundance at specific sites on the Scottish coast.

#### TU064

##### **Microplastic in a macro filter feeder: humpback whale *Megaptera novaeangliae***

E. Besseling, Wageningen University & Research Centre / Aquatic Ecology and Water Quality Management Group; J.A. Van Franeker, M.F. Leopold, E.L. Bravo Rebollo, S. Kuehn, L. Mielke, E. Heße, IMARES / Institute for Marine Resources Ecosystem Studies Wageningen UR; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group  
Marine filter feeders are suspected to be exposed to microplastic because of their selection of small particles as food source. Bivalve, worm but also whale species feed by means of filtering, thereby harvesting small particles from large water volumes. Macroplastic, as well as phthalates possibly serving as indicators of microplastic, were found in whales before. This study is the first to show the presence of microplastic in the intestines of a humpback whale (*Megaptera novaeangliae*), which stranded in the Netherlands in 2012. After cutting away the left sided blubber and ribcage, part of the stomach and intestines were removed. These were dissected, contents were rinsed sequentially over 1 mm and 0.5 mm sieves, dissolved in 10% potassium hydroxide and washed in double bags (mesh 120 µm and 300 µm) in a washing machine. From the remaining dried material, possible synthetic polymer particles were selected based on density and appearance and subjected to Fourier transform infrared (FTIR) analyses. The obtained FTIR spectra were compared with reference spectra by linear regression in 'R' statistical software. Particles for which the comparison with reference spectra had a quality index ( $R^2$ ) of  $> 0.7$  were identified as synthetic polymers. Several polymer types were found in the processed stomach and intestine content, in varying particle shapes: threads, sheets and fragments. The diversity in polymer types and particle shapes found, can be interpreted as a representation of the varying characteristics of marine plastic and the unselective way of ingestion by *Megaptera novaeangliae*.

#### TU065

##### **Feedbacks between bioturbation and microplastic at the sediment-water interface**

E. Besseling, Wageningen University & Research Centre / Aquatic Ecology and Water Quality Management Group; E. Foekema, Wageningen IMARES; Y. Ren, Wageningen University & Research Centre / Aquatic Ecology and Water Quality Management Group; M. Van den Heuvel-Greve, Wageningen IMARES / Marine Coastal Systems; A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group  
Dynamic processes at the sediment-water interface are crucial for either burial or resuspension of microplastics in aquatic systems. Biofouling and subsequent settling are thought to remove microplastics from the water phase, to enhance sediment concentrations and therewith to affect benthic organisms. It is unknown whether bioturbation affects the role of sediments as a sink for microplastics. During a 28 d exposure assay with 10-180 µm polyethylene, microplastic concentrations in water and sediment were monitored in systems with and without the bioturbating marine lugworm *Arenicola marina*. Additionally, survival, feeding activity, body weight, and microplastic in faeces, gut content and tissue of *A. marina* were studied. Microplastic appeared to negatively affect the feeding activity of *A. marina*, which is in line with earlier reports. Microscopy analyses showed occurrence of microplastic in the gut content, while no indication of transport into tissues was found. *A. marina* appeared to enhance the concentration of microplastic in the overlying water compartment. This study therefore shows that besides effects of microplastics on organisms, organisms can also affect microplastic distribution in surrounding compartments, implying a direct feedback between microplastic fate and effects. Using a simple sedimentation-resuspension model, the biodiffusion coefficients were derived from the experimental data. Bioturbators can be hypothesized to affect the relative importance of sediments being a sink and the temporal bioavailability of microplastics.

#### TU066

##### **Nanoplastic in the Aquatic Environment**

A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group; E. Besseling, Wageningen University & Research Centre / Aquatic Ecology and Water Quality Management Group; W. Shim, Korea Institute of Ocean Science and Technology / Oil and POPs research group

An increasing body of literature reports on the abundance and effects of plastic debris, with an increasing focus on microplastic particles smaller than 5 mm. It has often been suggested that plastic particles in the  $< 100$  nm size range as defined earlier for nanomaterials, may be emitted to or formed in the aquatic environment. Nanoplastics is probably the least known area of marine litter but potentially also the most hazardous. This poster provides a review on sources, effects and hazards of nanoplastics. Detection methods are in an early stage of development and to date no nanoplastics have actually been detected in natural aquatic systems. Various sources of nanoplastics have been suggested such as release from products or nanofragmentation of larger particles. Nanoplastic fate studies for rivers suggest an important role for sedimentation of hetero-aggregates, similar to that for non-polymer nanomaterials. Some prognostic effect studies have been performed but effect thresholds for nanoplastics probably are higher than nanoplastic concentrations expected in the environment. The high surface area of nanoplastics may imply that toxic chemicals are bound by nanoplastics, possibly increasing overall hazard. Release of non-polymer nanomaterial additives from small product fragments may add to the hazard of nanoplastics. Because of the presence of such co-contaminants, effect studies with nanoplastics pose some specific practical challenges. We conclude that hazards of nanoplastics are plausible yet unclear, which calls for a thorough evaluation of nanoplastic sources, fate and effects.

#### TU067

##### **Sorption of polar and non-polar organic compounds by microplastics**

T. Hüffer, T. Hofmann, University of Vienna / Department of Environmental Geosciences

Over recent years, the presence of plastic debris has become an issue of public concern as well as among scientist and regulators[1]. While so far the majority of studies have investigated the occurrence of microplastics (MP) in marine environments, there have few but growing number of reports on the occurrence of plastic debris in non-marine aquatic ecosystems. The input of MP presents a potential hazard to environmental ecosystems resulting from entanglement or ingestion of these particles by organisms[2]. There has also been a growing concern about an "indirect" effect, which results from plastic particle acting as a contaminant carrier[3]. To this end, sorption of organic compounds by MP is an important processes as it may affect the compound distribution in sediments and aqueous phases. For example, strong sorption of organic compounds by microplastics, even at comparable low sorbent concentrations, could consequently result in a decrease of the (free) available aqueous concentration of these compounds in sediments. Thus, a detailed knowledge of sorption properties of microplastics is of crucial importance and will significantly contribute to the discussion on potential relevance of the presence of microplastics in the environment. To date, research on sorption by MP mainly focusses on the investigation of individual sorption mechanisms by a rather limited number of sorbate compounds. As a consequence, there are significant gaps in knowledge with respect to a fundamental and systematic understanding of the relevant sorption mechanisms. Both compound-specific factors and polymer properties need to be considered for a comprehensive understanding of the relevant interactions. Recently observed differences in sorption strength between different sorbates could not be ascribed purely to a sorbent size effect, but may also be affected by contributions from individual interactions[4]. In this contribution, we therefore combine sorption isotherm analysis of selected polar and non-polar aromatic organic probe sorbates and extensive solid phase characterization data of most commonly found MP. The results are expected to contribute to a better understanding of the molecular interactions to occur in the environment. [1] Cole et al. (2011) Mar.Pollut.Bull., 62, 2588-2597. [2] Wright et al. #### TU068

##### **GC-MS screening of additive chemicals in plastic products from beaches and local markets**

M. Rani, Korea Institute of Ocean Science and Technology; S. Hong, Korea Institute of Ocean Science and Technology / Oil and POPs research group; M. Jang, Korea Institute of Ocean Science and Technology / oil and POPs research group OPRG; G. Han, Oil and POPs research group; Y. Song, Korea Institute of Ocean Science and Technology; W. Shim, Korea Institute of Ocean Science and Technology / Oil and POPs research group  
Plastics are utilized in various applications because of their versatile characters. Due to their formulation and/or processing, these synthetic polymers contain additives and impurities which may leach out under conditions of use and accumulate in environment. The threat of plastics pollution to the marine environment has been ignored for a long time, and its seriousness has been only recently recognised. Therefore, to check the role of plastic debris in spreading these chemicals as contaminants in marine environment, a number of marine debris were collected from coastal beach and sorted to food (bowl, straw, cider and water bottles, packaging films of cookies, tiffin box etc.), aquaculture (buoys, buoy rope, ropes, eel fish trapper, fish trapper float, fish trapper disassembler) and general uses

(rope, birthday bomb, polythene bag and writing pen). Simultaneously fresh plastics (same or same brand) were also bought from local market. This screening consists of two steps; first the identification of the plastic using FTIR and second the sonication-assisted extraction of the material using dichloromethane. Total 43 plastic samples (25 new and 18 debris) belong to the different polymers (PP>PE>PP+PE>PET>poly(acetylene:styrene) were analysed by GC-MS in full scan mode and chemicals were identified using NIST library. A database on the presence of 353 different chemicals were grouped into monomers, oligomers, intermediates, antioxidants, compounds for dyes and inks, flame retardants, plasticizers, lubricants, UV-stabilizers and agents for vulcanization. The benzotriazole UV stabilizers (BUVSs) such as UV-326, UV-327, UV-328 and UV-320, uvinual MC80 (2-propenoic acid 3-(4-methoxyphenyl)- 2-ethylhexyl ester), butylated hydroxyl toluene (BHT), organox 1076, organox 1010, di-2-ethylhexylphthalate (DEHP), dibutylphthalate (DBP), antioxidant no 33 (2,4-bis(1,1-dimethylethyl)-phenol), dioctyl phthalate, diisooctyl phthalate, hexanoic acid 2-ethyl-Hexadecyl ester, hydrocarbons including chlorinated were most frequently detected in new and debris plastic samples. The comparison of total ion chromatogram of fresh and debris plastics clearly indicated the leaching and absorption of these chemicals in environment. Therefore, it can be assumed from the results that the plastics found at coastal beaches can be media for transferring these additives in marine environment.

#### TU069

##### **The effect of particle size on POP sorption to microplastics**

E. Troia, University of Amsterdam / IBED; R. Helmus, University of Amsterdam; J. Westerveld, J. Parsons, University of Amsterdam / IBED

The distribution coefficients of polycyclic aromatic hydrocarbons (PAHs) and polybrominated diphenyl ethers (PBDEs) between salt water and different sizes of polystyrene (PS), polypropylene (PP) or polyethylene (PE) were determined. The polymer sizes ranged from mm to  $\mu\text{m}$  particles and nm-sized particles were included for PS. A passive dosing system with silicone O-rings was used to provide a constant concentration of the poorly water soluble compounds in an equilibrium sorption experiment of >30 days. Phenanthrene adsorption was estimated to be almost one order of magnitude stronger to nm-sized PS compared to that for  $\mu\text{m}$ -sized PS. Adsorption of pyrene was 0.8 orders of magnitude stronger to  $\mu\text{m}$ -sized PP compared to mm-sized PP. In contrast, no significant differences were seen for PAH sorption to the three sizes of LD-PE polymer. Overall, an increasing trend was demonstrated for the adsorption of several hydrophobic contaminants to smaller plastic particles with increasing specific surface area. At PAH concentrations comparable to those in oceans a 6 fold concentration increase was estimated for PP particles that were 10 times smaller in diameter. Although the results were not sufficient to determine if degrading plastics need to be considered as sink and transport vector for hydrophobic contaminants, they do indicate that further studies, preferably with higher log  $K_{\text{OW}}$  compounds, and including more nano-sized plastics are needed.

#### TU070

##### **Evaluation of desorption kinetics for persistent organic pollutants (POPs) from microplastics (MPs)**

H. Lee, Division of Environmental Science and Ecological Engineering; W. Shim, Korea Institute of Ocean Science and Technology / Oil and POPs research group; J. Kwon, Korea University / Division of Environmental Science and Ecological Engineering

Marine microplastics (MPs) are thought to hold high sorption capacity for persistent organic pollutants (POPs). It is suspected that the fate of POPs in the marine environment is influenced by the strong potential of MPs sorbing them. For example, sorbed POPs on MPs may exhibit "shuttle" effects on the bioaccumulation in marine organisms. However, the rate of sorption to and desorption from MPs has not been extensively evaluated to quantify the contribution of these effects to the accumulation of POPs. Desorption of POPs from MPs can be considered to occur via two processes: internal diffusion in the plastic phase and phase transfer from plastic to water driven by activity gradient. In this study, a desorption model for POPs from MPs was developed and evaluated using laboratory measurement of desorption rates. Internal diffusion coefficients ( $D_{\text{plastic}}$ ), an important parameter determining the overall desorption rate, were determined in separate experiments. Six compounds - a-, b-, g-, and d-hexachlorocyclohexanes, pentachlorobenzene, and hexachlorobenzene - were chosen as model POPs covering wide range of hydrophobicity with known partition coefficients between plastic phases and seawater. Two polymers - polyethylene (PE), and polypropylene (PP) - were used as model MPs because of their abundance in marine environments. Values of  $D_{\text{plastic}}$  were determined by measuring the rate of diffusion through separate thin plastic films. The overall desorption rate of POPs from MPs was determined in a batch test. To model infinite sink, sufficiently high volume of polydimethylsiloxane (PDMS) was added in seawater containing MPs suspension initially loaded with POPs. Time-course changes in the concentrations in MPs, seawater, and PDMS were monitored over 14 days. The values of  $D_{\text{plastic}}$  were higher in PE than in PP for all POPs tested and they ranged  $10^{-15}$  to  $10^{-14} \text{ m}^2 \text{ s}^{-1}$ . Rapid desorption occurred within 24 h followed by slow decrease in the concentration of POPs in MPs for 14 days. The apparent desorption was well-explained by the two-stage desorption model. The findings suggest that internal diffusion in the plastic phase is a key process determining bioavailability of

POPs sorbed to MPs.

##### **Size-segregated HOCs contents in field-collected microplastics**

I. Kim, Incheon National University / Department of Biology; S. Noh, Incheon National University / Department of Marine Science; S. Kim, Department of Marine Science, College of Natural Sciences, Incheon National University / Department of Marine Science

Microplastic contamination is an emerging issue in conservation of marine ecosystem. Expanded polystyrene (EPS), one of plastic polymer, is widely used in marine environment as aquaculture buoy and packing materials. A number of used EPS is lost and transported via current and wind to other region. Unlike other plastic debris, these transported EPS buoy is easily fragmented to smaller particles and is segregated to particles with various sizes from nanometers to micrometers by weathering on beach where they reached. EPS was known to be a major constituent (on basis of counted number) of microplastics as well as debris found on high-stranded line of coastal sand beach. According to a recent study (abstract No. 301, 24<sup>th</sup> EU SETAC), considerable amounts of hexabromocyclododecanes (HBCDs) of several mg/g was detected from EPS buoys. This flame-retardant chemical newly listed-up in the Stockholm Convention can be easily released to environments (air or seawater) when EPS is fragmented because HBCD is not chemically bond to EPS but an additive. This indicates the possibility of EPS as a strong source of HBCD in marine environments. In this study, we collected EPS particles at each five stations of several sand beaches and sorted EPS with size as for particles over 1 mm and thereafter measured HBCD contents in each size group of EPS particles. From this study, we expect to be able to determine HBCD release rate by weathering (i.e., fragmentation) under the field condition.

#### TU072

##### **Can beach-collected microplastic pellets be an alternative matrix to represent the contamination level of HOCs in local marine environment?**

D. Chae, Department of Marine Science College of Natural Sciences Incheon National University; S. Kim, Department of Marine Science, College of Natural Sciences, Incheon National University / Department of Marine Science

Seawater is a medium for marine organisms directly exposed to pollutants. However, it is a great challenge to monitor extensively in time and space hydrophobic organic chemicals (HOCs) in seawater owing to difficulties in detection of trivial levels and variation of concentration via currents. Hydrophobic organic chemicals (HOCs) such as persistent organic pollutants sorbs to the organic matter of solid matrix in the marine environment. Thus, HOCs in sedentary marine organisms such as mussel and oyster and sediment has been monitored (called "mussel watch program") as an alternative to monitor contamination in marine environment. Recently, "pellet watch program" in which HOCs adsorbed on microplastic pellets collected at local beaches are measured is suggested to determine and compare HOCs contamination in coastal environment because microplastic pellets is known as another organic matrix to adsorb HOCs in seawater. Unlike sedentary organisms or bed sediment, however microplastic pellets collected beach sediment is exposed to air permanently after moved to beach sediment and thus HOCs on the beach-pellets can experience other fates by evaporation and/or pellet weathering. Furthermore, residence time of pellets in seawater before reaching beach can be different locally. This indicates a possibility for pellet-associated HOCs (mostly, adsorbed HOCs) not to represent the local contamination status, unlike sedentary organisms and marine bed sediment which contact with seawater permanently or semi-diurnally. In this study, we collected the pairs of oyster-mud flat sediment-pellets from 13 beaches in Incheon/Kyeonggi coast of South Korea. After sorting pellets with the same size, weathering extent, and source polymer, HOCs concentration adsorbed on pellets will be compared with those in oyster and bed sediment collected the same beach. The result is expected to answer to the question of "is pellet-watch still applicable to HOC monitoring in local-scale marine environment?"

#### TU073

##### **Distribution of polybrominated diphenyl ethers (PBDEs) in microplastics in coastal waters and open ocean : application of International Pellet Watch**

H. Takada, Tokyo University of Agriculture and Technology / Laboratory of Organic Geochemistry LOG; R. Yoshida, Y. Okazaki, K. Tanaka, K. Mizukawa, R. Yamashita, Tokyo University of Agriculture and Technology; N. Trenholm, Ocean Research Project

PBDEs with less than 8 bromines are regulated by Stockholm Convention, because of their toxicity and persistence. Higher brominated congeners have not been regulated, although their debromination to lower and toxic congeners has been indicated. Higher brominated congeners have been detected in mm-size in marine environments. Their transfer from ingested plastics to organisms has been also suggested. However, our understanding of presence and distribution of PBDEs in microplastics are still limited. Thus, we applied International Pellet Watch to understand the distribution and sources of PBDEs in microplastics. We analyzed PBDEs in plastic resin pellets collected from several locations in the world including remote island (Galapagos Island), industrially developed countries (USA and Japan), industrially developing country (Belize). PBDEs and PCBs in the plastics were determined by GC-MS following solvent extraction. Concentrations of lower brominated congeners were higher in USA and Japan. However, moderate

concentration of lower brominated congeners was observed in pellets from Belize, though the PCB concentration was in background level. This is probably due to current inputs of PBDEs occurring in industrially developing country. Higher brominated congeners, mainly BDE209, was sporadically detected in pellets from USA and Japan. These suggest that BDE209 is compounded into plastic resin pellets intentionally or unintentionally (i.e., transfer from former products through recycling). Additives are desorbed from plastics during floating and fragmenting in the ocean. We collected microplastics from water samples in Tokyo Bay and sorted into two size fractions (315 µm – 1000 µm and 1000 µm to 5000 µm) and analyzed for PBDEs and PCBs. Lower brominated congeners as well as PCBs were detected in both fractions of plastics. Both are thought to be derived from sorption from surrounding seawater. Higher brominated congeners were detected even in 315 µm – 1000 µm as well as 1000 µm to 5000 µm fractions. This indicates that BDE209 is not completely leached out and is still contained in µm-size plastics in coastal waters. We are analyzing PBDEs in microplastics (315 µm – 1000 µm and 1000 µm to 5000 µm fractions) in open ocean and the results will be presented on the poster.

#### TU074

##### **Transfer and accumulation of organic pollutants in Atlantic salmon; Effect of incorporation of plastic particles in feed**

M. Kotterman, IMARES / Fish; B. Larsen, University of Mississippi / Pharmacology; J. Sloth, DTU Technical University of Denmark / Food; K. Granby, DTU Technical University of Denmark

One of the objectives of the EU project ECSafeSEAFOOD is to assess food safety issues related to priority contaminants present in seafood as a result of environmental contamination, including those originating from harmful algal blooms and those associated with marine litter. In natural waters as well as in aquaculture carryover of contaminants from feed, suspended matter and water to fish can take place. In order to prioritize how to mitigate the levels of contaminants in the fish for human consumption the carryover should be estimated and modelled. The transfer and accumulation of relevant priority contaminants from feed to fish, as well as depuration of the fish is studied in an experiment with salmon, as case study for fish of high European dietary consumption. Control feed with low contaminant levels and feed spiked with contaminants at levels relevant for European waters are fed to the fish. To assess the effect of marine litter, i.e. plastic, on the level and type of contaminant uptake, the feeding experiment is also performed with inclusion of non-contaminated polyethylene microplastics (2% w/w, LDPE 125-250 µm) in both types of feed. The fish are kept in 600 L cages with a maximum of 100 kg fish each (full size) with saltwater and a flow-through system at DTU aqua Denmark. The exposure (feeding) period is 12 weeks, followed by an eight week depuration period. Samples (filets) will be taken every three weeks during exposure and two weeks during depuration. The contaminants being studied are brominated flame retardants, fluorinated compounds, PCBs and methyl mercury. In this poster we will show the preliminary results concerning PFCs as well as PCBs; uptake from the feed in the presence or absence of plastic particles. *Acknowledgement* - The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under the ECSafeSEAFOOD project (grant agreement n° 311820).

#### TU075

##### **Modeling the relationship between POPs in ingested plastic debris and in tissue of Norwegian Northern Fulmars**

D. Herzke, NILU - Norwegian Institute for Air Research / MILK; B. Koelmans, Wageningen University; T. Anker Nielsen, M. langset, NINA  
Plastic has become a major part of marine litter and may threaten marine ecosystems seriously.. Marine plastic can also act as a vector for transfer of hydrophobic chemicals polluting the oceans, potentially increasing the hazards of plastic to marine life . Recently, plastic-inclusive bioaccumulation models have been shown to be helpful tools to mechanistically understand transfer to marine organisms. In Europe, Northern fulmars have been used for quite some time to monitor plastic ingestion by seabirds, due to their longevity and spending almost their whole life off shore. Few data exist for Northern fulmars from Norwegian waters, but the load of plastic particles in fulmars beached in SW Norway is monitored annually as a contribution to EcoQO monitoring implemented by OSPAR (e.g. van Franeker et al. 2011). In 2012 and 2013, 84 fulmars were unintentionally caught as by-catch on long-lines off the coast of Northern Norway. Liver and muscle samples were collected together with plastic particles found in the stomach of each individual. Plastic particles (particles as well as fibres) were found in 82% of the birds stomachs, ranging from 1 to 127 pieces (0.002 - 0.725 g) per individual. Liver, muscle and plastic pieces were analysed for persistent organic pollutants in selected individuals (n=30). Birds with a high, medium and no load of ingested plastic were selected for comparison. The correlations (r<sup>2</sup>) of POP concentrations between liver and plastic samples origin from the same individual, ranged between 0.46 (PCB153 and 0.88 (*p,p'*-DDE). No correlation was found for PBDEs. Muscle samples of birds with ingested plastic did show no elevated levels compared to muscles of birds which did not ingest plastics. We implemented a novel plastic-inclusive bioaccumulation model for the fulmars. The model used the gradient between ingested plastics and bird lipids to calculate the driving force for transfer, used a gut clearance of ~70% of the ingested plastic per day and was applied to mechanistically explain the observed bioaccumulation data. When

estimating the contribution of POP intake caused by the ingested plastic, a median contribution of 0.4, 0.3 and 7.0 ng/ ingested plastic of sumPCB, sumPBDE and sumDDTs can be found.

#### TU076

##### **Adsorption of polycyclic aromatic hydrocarbons and AhR-mediated agonistic activity of lipophilic extracts of different plastic types after deployment in the San Diego Bay, California**

M.M. Lam, RWTH University Aachen / MTM research center Department of Science and Technology; M. Larsson, Orebro University / MTM research center Department of Science and Technology; C.M. Rochman, UC Davis / Department of Ecology; G. He, University of California; M.S. Denison, University of California / Department of Environmental Toxicology; M. Engwall, Orebro University / MTM research center Department of Science and Technology

Plastics make up the most of the marine litter worldwide and due to their persistency they are distributed all over the world. The composition of plastic is organic polymers and different additives (e.g. plasticiser, flame retardant, pigments), which gives desired properties for specific applications of the plastic. However many of those additives are hazardous for human health and wildlife. In addition environmental contaminants from the aquatic environment can sorb to the plastic debris. The ingestion of plastic debris by marine animals, i.e. fishes, seabirds, turtles and invertebrates leads to exposure to the embedded and adsorbed chemicals of the plastic. This transport vector of chemicals into the food web can pose a threat to wildlife and human health. The present study investigated clean plastic pellets, which had been exposed in the sea in San Diego Bay in California at three different locations in mesh nets submerged 0.5 m below the water surface for 9 or 12 months. Samples were extracted three times with n-hexane and PAH concentrations were analyzed by GC-MS. In addition AhR-mediated agonistic activity of the plastic pellets extracts was measured in the recombinant HIL6.1C2 mouse hepatoma bioassay. Total PAH concentrations varied among locations, plastic types and different exposure time and ranged between 6.6 and 981.7 ng/g. Most of the samples showed increasing PAH concentrations over time. In pellets made by low density polyethylene (LDPE), PAH concentrations were significantly higher than in the other plastic types (polypropylene (PP), polyvinylchloride (PVC), polyethyleneterephthalat (PET)). The bioassay data were in agreement with the chemical analysis. The AhR mediated agonistic activity of PE (low and high density) samples was also significantly higher than in the other plastic types. Our data suggests that the adsorption and concentration of environmental contaminants to PE is higher compared to the other types. Thus products made of PE may pose a greater risk to marine wildlife than those, which made of PP, PVC and PET.

#### TU077

##### **Bioavailability of microplastics and associated toxic substances for aquatic organisms - a food web experiment with *Artemia nauplii* and zebrafish (*Danio rerio*)**

A. Batel, COS University of Heidelberg / Aquatic Ecology and Toxicology; M. Scherer, University of Heidelberg; T. Braunbeck, University of Heidelberg / Centre for Organismal Studies

In this experiment, the biotransfer of microplastics along a simulated two-organism food chain was analyzed as well as the effect of potentially bound toxic substances on microplastic particles by ingestion using the EROD activity test. Microplastics are of major focus in the recent detection of new potential hazards for the aquatic environment. Many researchers showed that microplastics are ingested by a great variety of different organisms. Still, the one question for the major concern that all researchers share has not been sufficiently analyzed: To which extend are microplastics transferred *via* the food chain and do toxic substance attached to microplastics become available for organisms after ingestion? The two-organism food chain in this experiment consisted of freshly hatched *Artemia nauplii* and zebrafish (*Danio rerio*) under laboratory conditions. We first analyzed the ingestion of fluorescently labelled microplastics in nauplii and then the transfer and accumulation of these particles in zebrafish offered nauplii with ingested microplastics. *Artemia nauplii* can be shown to ingest microplastics already after 3 to 9 hours, and ingested microplastic particles are transferred *via* the simulated food chain into zebrafish. The particles remain 4 to 5 hours within the gastrointestinal tract of zebrafish before defecation. Histological analyses show the accumulation and movement of the particles within the gastrointestinal tract of zebrafish. In order to analyze the effect of potential attached substances on zebrafish, microplastic particles were spiked with substances known to induce CYP 1 A activity, and the EROD activity was then, after ingestion of these particles, tested in livers and gills of zebrafish. With this experiment, the fate and hazard of environmental microplastics and associated toxic substances in the aquatic environment can be traced.

#### TU078

##### **Interactions of microplastics with freshwater mussels (*Anodonta anatina*)**

I. Paredes Losada, Doñana Biological Station CSIC / Department of Conservation Biology; E. Besseling, Wageningen University & Research Centre / Aquatic Ecology and Water Quality Management Group; B. Koelmans, Wageningen University

The presence of microplastics in freshwater ecosystems has been reported recently and new investigations focus on assessing the potential risk that these particles may

cause while flowing their way to the oceans. However, little is still known about their fate and impact on the freshwater community. Microplastics are particles of < 5mm in diameter that can easily be ingested by a wide range of aquatic organisms, especially by filter feeders. Among them, bivalves are one of the most efficient filter feeding groups spread worldwide, which feed on all kind of suspended particles such as diatoms, algal cells, bacteria, small zooplankton and detritus. It is expected that suspended microplastic particles are likely to be filtered by bivalves as well. Here, we present an experiment conducted under laboratory conditions, aiming to assess the filtration and excretion of microplastic over time by adult duck mussels (*Anodonta anatina*). We used green fluorescent polyethylene (PE) microspheres ranging from 10 to 90 µm in diameter. A total of four treatments with different PE concentrations (0.01, 0.1, 1 and 10 mg/L) and the control (without PE) were performed and replicated in 45L-aquaria filled with 20L of copper-free tap water. Three mussels were placed in each aquarium and maintained under same light, temperature and aeration conditions in a climate room. Mussels were fed daily on a mixture of instant algae during the 5 day exposure assay. Every 24 hours water and excreted material (faeces and pseudofaeces) were collected. Valve opening and movement were also monitored daily. All the samples were analysed for microplastics by UV flow cytometry. Particle size was also analysed by flow cytometry and contrasted with measurements of particle diameter under the microscope. Observations on valve opening and excreted material showed that mussels were actively filtering in all treatments including the control. No treatment effect was observed in valve opening. Concentrations of microplastics were in all cases higher in the excreted material than in the water.

#### TU079

##### **Long-term exposure of weathered microplastics from toothpaste to mussels (*Mytilus galloprovincialis*) - a case study**

I. Nerland, Ecotoxicology and Risk Assessment; M. Blazquez, Marine Renewable Resources; P. Thomas, CEHTRA SAS / Ecotoxicology and Risk Assessment

**Keywords: Microplastics, toothpaste, weathered, long-term** Microplastics are small plastic particles or fibers ubiquitously spread in the marine environment. This is threatening wildlife since several species are known to ingest microplastics. One source of microplastics released into the ocean is primary microplastics used in personal care products. These typically are released in treated wastewater, with an estimated use of 2.4 mg of microplastic/person/day of primary microplastics. Most microplastic exposure studies to date have used pre-labeled fluorescent spheres but to the best of our knowledge, this is the first report showing the effects of exposure to microplastics (polyethylene ; >50 µm) isolated from toothpaste. With this purpose, blue mussels (*Mytilus galloprovincialis*) were exposed to “raw” and weathered microplastics using a chronic semi-static system over 21 days with 4 sampling points (day 0, 5, 9 and 21). Several endpoints were measured, including filtration rate, histological organization, uptake in several tissues, DNA-damage, growth and condition index. Our results showed differences in filtration rates between the different exposures, indicating possible adverse effects of toothpaste-derived weathered microplastics on a marine species.

#### TU080

##### **Effects of microplastics on the toxicity of cephalixin to the common goby (*Pomatoschistus microps*) and modulation by temperature: predatory performance and biomarkers**

E. Fonte, ICBAS CIIMAR University of Porto; P. Ferreira, ECT Oekotoxikologie GmbH; L. Guilhermino, CIIMAR University of Porto  
The contamination of estuaries by microplastics (MP) and pharmaceuticals and the effects of temperature on the toxicity of these substances raise a high concern in relation to their potential adverse effects on environmental and human health. More knowledge is needed to improve the basis for the risk assessment of these stressors. Thus, the effects of MP on the toxicity of cephalixin (CEP), a widely and intensively used antibiotic, to the common goby (*Pomatoschistus microps*), a key-stone species in several European ecosystems, were investigated at 20°C and 25°C. Short-term (96h) laboratory bioassays with early *P. microps* juveniles exposed to CEP alone and in combination with MP were carried out at both temperatures. Post-exposure predatory performance (PP), the activity of the enzymes acetylcholinesterase (AChE) and glutathione S-transferases (GST), and lipid peroxidation levels (LPO) as effect criteria. At 20°C, exposure to cephalixin alone (low ppm range) significantly decreased the PP and increased GST activity; under simultaneous exposure to cephalixin and MP, the effects on PP and GST increased and AChE was significantly induced. The 5°C of temperature rise increased the toxic effects of MP and CEP. These findings highlight the importance of considering temperature variation of the risk assessment of chemicals.

#### **Wildlife ecotoxicology from molecular to population effects (P)**

#### TU081

##### **Temporal variation of Water vole exposure to bromadiolone following the recolonization of a treated plot**

M. Sage, Wildlife Environment Expertises; M. Coeurdassier, University of Franche-Comte / UMR ChronoEnvironnement; I. Fourel, Vetagro-sup, campus vétérinaire / Toxicology; R. Defaut, S. Bagnoud, FREDON Franche-Comté; P.

Giraudoux, Université de Franche-Comté / Laboratoire Chrono-environnement  
The anticoagulant rodenticide bromadiolone is widely used as plant protection product to control Water vole outbreaks in European grasslands. Following a treatment, vole population declines rapidly and reaches very low density 3 weeks after bait applications. Then, the plot could be recolonized by voles coming from surrounding plots. When buried in artificial galleries, the persistence of bromadiolone in baits has been showed to be short (DT50 ~ 3 to 6 days). However, baits may be stored in cavities by voles, which increases dramatically the persistence of bromadiolone in the environment (DT50 from 25 to 43 days, Sage et al. 2007, Environ. Pollut. 147). In this study, we aim to document the exposure to bromadiolone of Water voles recolonizing a plot several months after a treatment. To simulate the recolonization, some water voles were trapped alive in non-treated grasslands and marked. Then, they were reintroduced in an experimental plot 1.5, 3 and 6 months after bait application, trapped during the 7 to 10 days following their re-introduction and bromadiolone residues were measured in their tissues. The week before re-introduction, the voles already present in the treated plot (i.e., potentially surviving or naturally recolonizing individuals) were trapped in order to avoid competition with the ones we re-introduced. 1.5 months after the treatment, 75% of the re-introduced voles (6/8) exhibit bromadiolone residue in the liver, the concentrations (median: 2 mg / kg) being low compared to those measured by Sage et al. (2008 STOTEN 407) in voles trapped during the days following bait application. Fifty eight % of the individuals re-introduced 3 months after the treatment were exposed to bromadiolone (7/12), liver residues were also globally low with a median of 1.6 mg/kg but one vole exhibited a concentration of 25 mg/kg that was similar to those reported by Sage et al. (2008, STOTEN 407) in voles trapped just after a treatment. Six months after bait application in the experimental plot, no re-introduced voles were exposed to bromadiolone while, among the 7 voles trapped the week before the re-introduction, 2 have very low bromadiolone concentrations in the liver (< 1 mg/kg). Our results show that bromadiolone may persist in vole populations during several months after a treatment and thus, may lead to chronic exposure of wildlife to low doses of rodenticides.

#### TU082

##### **Temporal variations of wood mouse exposure to Cd and Pb in a smelter-impacted area and relationships with diet**

C.C. Fritsch, CNRS / UMR ChronoEnvironnement; F. Raoul, University of Franche-Comte / CNRS / UMR 6249 Chrono-environnement; M. Coeurdassier, University of Franche-Comte / UMR ChronoEnvironnement; N.W. van den Brink, Wageningen University / Dept of Toxicology; R. Scheifler, University of Franche-Comte / ChronoEnvironnement

Although levels of pollutants accumulated in organisms and related deleterious effects may vary in time, few studies have investigated inter-annual and inter-seasonal variations in exposure in terrestrial animals chronically exposed in metal polluted environments, and the temporal trends of metal transfer in food webs after termination of atmospheric emissions from point-sources such as smelters. The aim of this work was to study temporal trends of exposure of the wood mouse *Apodemus sylvaticus*, an omnivorous rodent, to cadmium (Cd) and lead (Pb) at three sites constituting a soil pollution gradient around a smelter that closed down in 2003. Investigating inter-annual and inter-seasonal differences in accumulation, the goals were to test whether ageing of soil pollution may decrease wood mice exposure, whether exposure was greater in autumn as observed for some other pollutants, and whether temporal variations may be related to changes in the diet. The sample sizes were 116, 88, 73, 75, and 35 individuals in the years 2006, 2007, 2008, 2010 and 2013, respectively, with 191 captured during autumn and 196 during springtime. Concentrations of Cd and Pb were measured in liver and kidneys for exposure assessment. Samples of mouse muscles, and potential diet item (grass, leaves, seeds, berries, above-ground invertebrates, earthworms) were collected for measurements of carbon and nitrogen stable isotopes in order to assess the diet. Preliminary results showed both inter-annual and inter-seasonal variations of metal accumulation, with different patterns for Cd and Pb. The relationships between hepatic Cd and soil Cd did not differ between seasons but between years, concentrations in tissues increasing with soil pollution until 2008 but decreasing in 2010 and 2013, suggesting a decrease of Cd transfer in food webs. Conversely, the relationships between hepatic Pb and soil Pb did not vary between years for a given season, but Pb levels in liver were greater in autumn than in springtime. Measurements of stable isotopes are ongoing. Further analyses will be conducted to investigate the temporal patterns of metal levels in kidneys, check whether temporal variations were site-specific, and relate the differences observed with diet.

#### TU083

##### **Population vs individual biomarkers in ecotoxicology: Exploring this gap in shrews from protected sites**

A. Sánchez-Chardi, Autonomous University of Barcelona / Microscopy Facility; M. Massa, Autonomous University of Barcelona / Animal Biology Vegetal Biology and Ecology; F. Muñoz-Muñoz, Universitat Autònoma de Barcelona / Departament de Biologia Animal

Small mammals have been often checked as bioindicators of environmental quality in ecotoxicological studies. Such studies have been usually focused on biomarkers from molecular to individual levels, whereas population effects have been scarcely evaluated. The aim of the present work is to quantify individual and population measures of asymmetry (total, fluctuating asymmetry or FA, and directional

asymmetry or DA) in shrews and compare them with metal levels in tissues. We quantified potentially toxic metals in main target tissues of 179 specimens of white toothed shrew *Crocidura russula* from 4 different localities in the Iberian Peninsula (Cercs, Garraf, Doñana, and Aljustrel), 2 of them being protected areas (Parc Natural del Garraf and Parque Nacional de Doñana). Within each locality, animals were trapped in two different sites, one polluted and one non-polluted. Thus, in addition to the ecological importance of studied localities, the polluted sites were selected for the relevance of the pollution source (a coal-fired power plant in Cercs, a landfill in Garraf, and two pyrite mines affecting Doñana and Aljustrel). The measures of asymmetry were obtained analyzing by means of geometric morphometrics the shape and the size of the two mandibles of each individual. Our results showed a general trend of increased levels of metals in animal tissues and of population asymmetry in the polluted sites compared with non-polluted sites. The highest levels of several highly toxic metals and total and fluctuating asymmetry were detected in shrews from the abandoned pyrite mine of Aljustrel. Only in one locality, Garraf, FA levels were higher in the non-polluted than in the polluted site, but interestingly in the polluted site of Garraf, DA levels were the highest, suggesting a transition from FA to DA in high stressed animals. Moreover, individual levels of asymmetry were correlated with heavy metal contents in target tissues (Pb, Cd, Fe, Sn, Co, Cr), indicating a direct effect between stress of pollutants and measures of developmental instability. Since small mammals are an important step on alimentation of high trophic levels and 2 of the studied localities are protected, these findings may be also interesting for management of wildlife on such areas and others on Mediterranean basin.

#### TU084

##### **Importance of the hare in ecotoxicology: Influence of gender, type of hunting and parasitism on oxidative stress biomarkers**

J. González Moreno, F. Soler, M. Míguez Santiyán, University of Extremadura / Faculty of Veterinary Medicine

Biological methods are frequently used in environmental studies to estimate the degree of environmental pollution versus so-called technical monitoring. Animals living in small acreage are especially valuable for bio-monitoring purposes because they may indicate a local degree of environmental degradation. Hares are accepted as a bioindicator of environmental pollution (e.g. with heavy metals) because of their settled mode of life, common occurrence in a studied area, and the possibility of obtaining a high number of specimens in hunting activities. The aim of this study was to establish the potential use of oxidative stress parameters as biomarkers of environmental contamination in Iberian hare (*Lepus granatensis*). For this purpose the physiological levels of the oxidative stress biomarkers as malondialdehyde (MDA) and reduced glutathione (GSH) in liver and kidney of Iberian hare need to be established, as well as to determine the influence of variables such as gender, type of hunting or parasitism on the levels of these biomarkers. Hares (34 males and 37 females) were sampled from two types of hunting: shooting (42) and hare coursing with greyhound (29). Livers and kidneys were collected and once examined for the presence of parasites were frozen (-80°C) until determination of MDA and GSH, which were assayed using the Recknagel et al. (1982) and Hissin and Hilf (1976) methods, respectively. Liver of parasitized hares showed higher levels of MDA and lower levels of GSH than non-parasitized ones. In addition, animals hunted with greyhound showed lower levels of GSH than animals shot. These results could indicate that the presence of parasites in the animals induce oxidative stress in liver, which is also observed when hunting with greyhound as indicated by the GSH depletion. In kidney, male hares showed higher levels of MDA than females. This could be due to the protective effect of female hormones against oxidative species. On the other hand, animals hunted with shotgun showed lower levels of MDA than animals hunted with greyhound what could be explain by the stress caused by the coursing. Then, although oxidative stress parameters could be used as biomarkers in environmental studies with hares as bioindicator, the type of hunting and the presence of parasites are factors that should be taken into consideration when interpreting their levels.

#### TU085

##### **Organochlorine contaminants (pesticides and PCBs) in red deer: levels and public health**

J. Chaves, M. Pérez López, F. Soler, University of Extremadura / Faculty of Veterinary Medicine

Game animal are used as bioindicators of environmental contamination in the places where they live due to the fact that they can accumulate organic pollutants in their tissues. Game is consumed by population and can be a way to increase the burden of contaminants in consumers, being a public health concern. The aim of this study was to determine the presence and levels of organochlorine pesticides and polychlorinated biphenyls (PCBs) in the adipose tissue of red deer (*Cervus elaphus*) from Extremadura (West of Spain), and their environmental and public health implications by analyzing a total of 46 individuals. Samples were obtained from 6 different hunting areas, and for each deer a sample of perirenal fat tissue was taken. Lipids were extracted with petroleum ether and cleaned-up with sulphuric acid. The final extract was analyzed by gas chromatography with mass detector (GC-MS) in NCI mode. The detected chlorinated pesticides and their frequency of occurrence (%) were: aldrin (11 %), heptachlor (17 %),  $\alpha$ -HCH (20 %), endosulfan sulfate (28 %), chlordanes (50 %), HCB and heptachlor epoxide (67 %),  $\gamma$ -HCH (70 %),  $\beta$ -HCH and DDD (87 %) and DDE (100 %). The detected PCBs were PCB 28 (2 %),

PCB 52 (9 %), PCB 118 (33 %), PCB 138 (72 %), PCB 180 (78 %) and PCB 153 (85 %). The highest mean level was that from DDE (249.65 ng/g), much higher than those from the other detected compounds. There were statistically significant differences between hunting areas only for beta-HCH between 2 areas, and for  $\Sigma$ DDTs between one area with respect to the others. For PCBs, a regular distribution between sampling sites were also observed, and only a statistically significant difference was observed for PCB 180 between 2 areas. Compounds and levels detected in this study are similar to those reported in other parts of Spain and other countries for red deer, indicating not very different environmental status in hunting areas with respect to these compounds. The number of samples that exceeded the maximum residue limits (MRLs) established in the EU by Regulations (EC) 396/2005 and 1881/2006 was:  $\Sigma$ DDT (2 samples),  $\beta$ -HCH (1 sample),  $\gamma$ -HCH (3 samples),  $\Sigma$ chlordanes (3 samples) and  $\Sigma$ PCBs (4 samples). No legal LMRs has been specifically established for these compounds in game animals. The much more lower production and consumption of game meat respect to domestic animals support the conclusion that red deer meat poses no risk to consumers.

#### TU086

##### **Mercury in golden eagle eggs - use of stable isotopes to distinguish dietary influences in long-term monitoring studies**

R.F. Shore, Centre for Ecology & Hydrology (NERC); L.A. Walker, H.K. Grant, Centre for Ecology Hydrology; E. Potter, Centre for Ecology and Hydrology; M.M. Pereira, CEH

Future global mercury (Hg) emissions may rise, in part through increased coal-fired power generation, but the recent United Nations Environment Programme Minamata Convention on Mercury aims to control anthropogenic releases of Hg to the environment. Long-term future trends in environmental Hg concentrations are therefore uncertain. One way of assessing such trends is to monitor accumulation by sentinel wildlife. We are investigating the potential of using added eggs from inland-nesting golden eagles (*Aquila chrysaetos*) to detect change in Hg deposition and bioavailability in the uplands of Britain. To date, nests have been defined as "inland" if >3 km from the coast but golden eagles have variably-sized territories and such classification is somewhat arbitrary. Some so-called "inland" nesting birds may feed partly or extensively on marine fauna, such as seabirds. We have found previously that egg Hg concentrations differ between nests that are 3 km from the coast, likely reflecting differences in terrestrial and marine Hg transfer pathways. If our current classification of nests as "inland" is inaccurate, dietary (terrestrial vs marine) influences on Hg accumulation may obscure detection of future changes in Hg accumulation arising from altered upland deposition. We examined stable carbon ( $\delta^{13}\text{C}$ ), nitrogen ( $\delta^{15}\text{N}$ ) and sulphur ( $\delta^{34}\text{S}$ ) isotopes in golden eagle eggs to determine how they varied with proximity of the nest to the coast. We found no clear patterns for  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  but  $\delta^{34}\text{S}$  values in eggs from nests (*Haliaeetus albicilla*) eggs from the same area. This suggests that female golden eagles from nests within 3 km of the coast had a significant marine component to their diet. We defined 95% confidence limits (CLs) for  $\delta^{34}\text{S}$  for those eggs. We then examined  $\delta^{34}\text{S}$  values for eggs from nests >3 km from the coast and found that 33% had  $\delta^{34}\text{S}$  values within the CLs for coastal nests, suggesting that females from a third of supposed inland nests were largely feeding on marine prey. Our results highlight the need for stable isotope measurements (especially  $\delta^{34}\text{S}$ ) to identify those eggs that truly reflect Hg derived from upland terrestrial diet. Such discrimination is essential if golden eagle eggs are to be used as a biomonitor of change in Hg deposition and bioavailability in upland Britain.

#### TU087

##### **Assessment of exposure and effects on stress response of perfluoroalkyl and polyfluoroalkyl substances in White-tailed eagle and Northern goshawk nestlings using non-invasive samples**

P. Gómez-Ramírez, Sociosanitary Sciences; J. Bustnes; T. Johnsen, Norwegian Institute for Nature Research; D. Herzke, NILU - Norwegian Institute for Air Research / MILK; G.S. Eggen, Norwegian University of Science and Technology / Department of Biology; V.L. Jaspers, Norwegian University of Science & Technology / Biology

Perfluoroalkyl and polyfluoroalkyl substances (PFASs) are a large group of compounds widely used in industry because of their water and oil repellence and thermal stability. Due to their persistence to degradation and low metabolism, most of them are nowadays ubiquitous. In addition, several toxic effects have been linked to these compounds. For example, perfluorooctane sulfonic acid (PFOS) can displace corticosterone (the main stress hormone in birds) from their binding globulins in blood, causing an increase of free corticosterone, readily able to activate glucocorticoid receptors in cells. In order to evaluate the influence of PFASs on stress response in birds of prey from Norway, corticosterone in plasma and feathers were analysed in 14 nestling White-tailed eagles (*Haliaeetus albicilla*) and 11 nestling Northern goshawks (*Accipiter gentilis*) using an ELISA method. PFASs were analysed using UHPLC-MS/MS in plasma and feathers of the same White tailed eagles while they could only be analysed in the plasma of 10 Northern goshawks due to too low sample availability of feathers. Mean  $\Sigma$ PFAS were higher in plasma (White-tailed eagles mean  $\Sigma$ PFAS=31.5 ng/mL; Northern goshawk mean  $\Sigma$ PFAS=19.05 ng/mL) than in feathers ( $\Sigma$ PFAS=12.97 ng/g). Although PFOSA was not found in any plasma sample, it was detected in all the feathers. This was also previously found in White-tailed eagles from Norway and Greenland and could

indicate either that the feathers/ preen oil are a route for excretion of PFOSA or that there is external contamination in feathers. PFASs levels in plasma of both species were up to 10 times lower than in Bald eagles (*Haliaeetus leucocephalus*) nestlings from the Upper Midwestern United States, but similar to nestlings of White-tailed eagles and Goshawks studied in Norway between 2008 and 2010. Also coinciding with the studies in birds of prey from Norway, levels were higher in White-tailed eagles than in Goshawks.  $\Sigma$ PFAS seem to cause an increase of free plasma corticosterone in our study, based on a positive correlation. However, according to *in vitro* studies in Bald eagles, our concentrations would be too low to cause a displacement of corticosterone from binding globulins. Moreover, the individuals from our study are not considered at risk for PFOS as their levels in plasma were hundreds to thousands times lower than the toxic reference values in Bald eagles (250-4000 ng/ml). Acknowledgements: NILS Science and Sustainability.

#### TU088

##### **Levels of perfluorinated compounds (PFCs) in northern gannet (*Morus bassanus*) eggs from two UK colonies**

M.G. Pereira, Centre for Ecology & Hydrology / Lancaster; S. Lacorte, IDAEA-CSIC / Environmental Chemistry; E. Potter, Centre for Ecology and Hydrology; L.A. Walker, Centre for Ecology & Hydrology; R.F. Shore, Centre for Ecology & Hydrology (NERC)

We measured PFCs in eggs of the marine sentinel species, the Northern gannet (*Morus bassanus*) from two Scottish colonies (Ailsa Craig in the Eastern Atlantic and Bass Rock in the North Sea). Eggs were collected as part of the UK Predatory Bird Monitoring Scheme (PBMS)—<http://pbms.ceh.ac.uk>. In this preliminary work, we used LCMS-MS to analyse 13 perfluorinated carboxylic acids (PFCAs) and 4 perfluorinated sulfonates (PFSs) in eggs collected in 2007. Of the compounds analysed, seven PFCAs and two PFSs were detected. In Ailsa Craig, the sum of the PFCAs ranged between 6.8-20.8 ng g<sup>-1</sup> ww and of the PFSs between 40.8 - 73.3 ng g<sup>-1</sup> ww, except in one egg with PFSs concentration of 206.5 ng g<sup>-1</sup> ww. In Bass Rock, the sum of the PFCAs and PFSs varied between 16.3-38.7 ng g<sup>-1</sup> ww and 28.0-85.3 ng g<sup>-1</sup> ww, respectively. We found no significant differences between colonies. As expected, PFOs (Perfluorooctanesulfonic acid) accounted for the majority of the PFSs (98 and 99%). The most abundant PFCAs were perfluorotridecanoate and perfluoroundecanoate in both colonies. Perfluorobutanoate and perfluorononanoate were the only two compounds with concentrations significantly higher in eggs from Ailsa Craig than from Bass Rock. From this limited data set it appears that gannet eggs from both colonies contain relatively low concentrations of PFCs compared to concentrations reported in the literature. Concentrations of PFOS were lower by an order of magnitude of residues associated with adverse effects, except for one egg from Bass Rock where these levels were exceeded. The majority of eggs from both colonies contained PFOS residues that exceeded a suggested predicted no effect concentration (PNEC) for this compound.

#### TU089

##### **Do parental feeding strategies affect early offspring exposure to mercury contamination in Lesser black-back gulls (*Larus fuscus*)?**

C.S. Santos, Ghent University (UGent) / Terrestrial Ecology Unit TEREC Department of Biology; L. Blondel, Ghent University / Terrestrial Ecology Unit Department of Biology; M.S. Monteiro, Aveiro University / Biology; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; S. Loureiro, Universidade de Aveiro / Biology; L. De Neve, L. Lens, Ghent University / Terrestrial Ecology Unit Biology Department

Acquisition and allocation of nutritional resources, which are vital for animals' survival and reproduction, are key elements of life-history variation. Nonetheless, if certain foraging strategies increase the exposure to environmental contaminants, such as mercury (Hg), this might induce shifts in the cost-benefit balance of consuming certain food items. Lesser black-backed gulls (*Larus fuscus*) are known to feed on a wide range of marine and terrestrial prey, including human waste, which are expected to differ in contaminant loads. In addition, individuals show significant variation in foraging strategies, thereby being a good animal model to explore the influence of parental foraging strategies on contaminant exposure of their chicks. **Previous studies have shown that exposure to high loads of Hg contamination may induce neurological dysfunctions or alter behavioural displays.** Therefore, the aim of this study was to assess if parental foraging strategies are related to mercury burdens in both parents and chicks (e.g. via maternal transfer or parental care). In order to address this topic, a long term study-population of *L. fuscus* that breeds at Zeebrugge harbour (Belgium, 51°2'N, 03°11'E) was monitored between 2012 and 2014. During this period, eggs, primary feather samples (adults) and down feathers (chicks) were collected to assess the isotopic signatures of carbon ( $\delta^{13}C$ ) and nitrogen ( $\delta^{15}N$ ) to distinguish marine from terrestrial foraging behaviour. The total Hg burden was assessed in the same matrices. As observed for other species, Hg transfer to chicks via maternal deposition in the egg was observed. Hg burden was higher in gulls displaying a predominantly marine foraging behaviour. Furthermore, consumption of marine prey during egg-laying increased in late breeding females. As a consequence, hatchlings from late breeding females were observed to have a higher input of Hg. These data suggest that parental feeding habits may, indeed, influence the exposure of chicks to mercury contamination in the environment.

#### TU090

##### **Effects of dietary lead exposure on plasma vitamin levels in great tit nestlings - an experimental manipulation**

s.r. ruiz, University of Turku / Department of Biology; S. Espin, University of Murcia / Department of Biology; S. Ruuskanen, Netherlands Institute of Ecology (NIOO-KNAW) / Department of Animal Ecology; J. Salminen, University of Turku / Department of Organic Chemistry; T. Eeva, University of Turku / Department of Biology

Lead is a widespread toxic environmental pollutant. Its toxic effects have been reported in wildlife living and foraging close to pollution sources, including mines and metal industry, urban and agricultural areas, as well as in the vicinity of game-hunting activities. Vitamins obtained through diet are essential micronutrients needed in small amounts for the normal functioning of the organism. So far, little is known about the impact of heavy metal pollution on vitamin homeostasis in free-living terrestrial vertebrates. The aim of this study was to find out the effects of lead on vitamin levels of great tit (*Parus major*) nestlings. Therefore, lead acetate, in a low and high dose, was fed orally to two groups of free-living nestlings for a period of 14 days. In addition, a group exposed to lead and mixture of other metals by a metal smelter was included in our comparison. Fat-soluble vitamins (A,D,E,K) were analyzed by UPLC coupled with MS from bird blood plasma. Preliminary results indicate that vitamin levels were not strongly associated with lead exposure but were higher in the vicinity of the smelter, where nestlings also grew slower. Since some vitamins have antioxidant functions against pollutants, we hypothesize that a stronger xenobiotic challenge and possibly pollution-related food shortage trigger a response leading to the up-regulation of vitamins.

#### TU091

##### **Bioadvection of mercury from the Great Salt Lake to surrounding terrestrial ecosystems and sublethal toxic effects on a terrestrial songbird**

H. Reynolds, Westminster College / Biology; J. Goodman, Westminster College / Biology; J. Collins, R. Scantlebury, C. Castro, H. Saxton, Westminster College / Biology; C.M. Stracey, Guilford College / Biology; F.J. Black, Westminster College / Chemistry

Mercury (Hg) is a neurotoxin and global pollutant that in aquatic ecosystems is converted into methylmercury (MeHg), the chemical form that is readily biomagnified up food chains to toxic concentrations. The Great Salt Lake (GSL) in Utah contains some of the highest MeHg concentrations ever measured in natural waters. While terrestrial organisms typically have very low concentrations of Hg because MeHg is produced almost exclusively in aquatic environments, the Hg concentrations we have measured in spiders along the shoreline of the GSL are 60 fold higher than in spiders along nearby Utah Lake. We hypothesized that brine flies with their larval stage in the GSL act as vectors that transfer Hg from the lake to surrounding terrestrial ecosystems where they are eaten by spiders and other organisms. We also hypothesized that songbirds that consume spiders would be exposed to high levels of Hg that could cause adverse effects. To test these ideas we characterized spatial and temporal variation in total mercury (HgT) and MeHg concentrations in surface water, brine flies, and spiders at the GSL in 2012-2013. We also quantified spatial distribution of HgT concentrations during the 2012-2014 breeding seasons in blood of adult and nestling Loggerhead Shrikes, *Lanius ludovicianus*, a terrestrial songbird of conservation concern, and investigated sublethal effects due to Hg exposure. Concentrations of HgT were roughly 100-700 ppb (dw) in brine flies and 400-3000 ppb (dw) in spiders. Seasonal maxima in concentrations of HgT and MeHg in brine flies and spiders occurred in spring and fall, periods of peak migratory bird numbers at the GSL. These seasonal trends mirrored HgT concentrations in surface waters of the GSL, suggesting the lake was the source of mercury. HgT concentrations in nestling shrike blood averaged 91 ppb (ww) and ranged from 7-354 ppb. Average HgT concentrations in adults/juveniles was 912 ppb and ranged from 127-4003 ppb. Approximately 20% of adults/juveniles had blood HgT concentrations above thresholds previously shown to reduce breeding success in other songbirds. HgT concentrations of shrikes decreased with increasing distance from the shoreline, again suggesting the GSL is the ultimate source of HgT in these organisms. Preliminary data from a subset of videos do not show a correlation between nestling Hg levels and nestling feeding rates. Ongoing research will attempt to correlate HgT concentrations and additional parental care behaviors.

#### TU092

##### **Assessment of embryotoxicity, post-hatching development, and long-term effects on behavior and reproduction following in ovo exposure to methylmercury in zebra finches (*Taeniopygia guttata*)**

M. Yu; M. Eng; T. Williams; J.E. Elliott, Environment Canada / Science Technology Branch

Mercury is a toxic heavy metal and common environmental contaminant found in terrestrial and aquatic environments as inorganic mercury and as organic methylmercury (MeHg). MeHg is considered to be the most toxic. Field and captive avian dosing studies have reported adverse reproductive effects from MeHg exposure. Many studies have been done on the effects of MeHg exposure via maternal transfer, and in ovo and perinatal exposure in waterbirds and poultry; however the effects of MeHg in passerine birds is less well understood. Also, avian studies have provided evidence that MeHg may cause adverse neurological and

behavioural effects. The objectives of the current study were: (1) to assess embryotoxic effects of in ovo exposure to MeHg; and (2) to assess post-hatching effects of in ovo exposure to MeHg on survival, development, mating behavior, and reproduction in a model songbird species, the zebra finch (*Taeniopygia guttata*). To assess the embryotoxic effects of in ovo exposure to MeHg, zebra finch embryos were exposed to MeHg via egg injection. Either a vehicle control (filtered ddH<sub>2</sub>O), a sham control, a high dose of MeHg (3.2 µg Hg/g egg), or a low dose of MeHg (1.6 µg Hg/g egg) was injected into the albumin the day the egg showed evidence of fertility. Following injection, eggs were returned to the nest and monitored to record embryonic toxicity, hatching success, chick growth, fledging success, and hematology (i.e., blood samples collected at 15 and 30 days of age). There was an effect of dose on overall hatching success, with decreasing hatching success in a dose-dependent manner. However, chick growth, hematocrit, and hemoglobin were not affected by MeHg exposure. In order to study potential long-term effects of embryonic exposure to MeHg, surviving chicks were raised to sexual maturity to assess potential adverse effects to male courtship behavior and female reproductive performance. Embryonic exposure to MeHg did not appear to have long term neurotoxic effects on male courtship behavior or song quality. This study is in progress, and *in ovo* exposed female zebra finches are undergoing breeding trials to assess effects on reproduction. There were no treatment differences in clutch size. Effects on hatching success, fledging success, and offspring growth are currently being assessed. The results gathered thus far would suggest that embryonic exposure to MeHg has acute effects on survival, but no overt long-term effects on growth, courtship behaviour, or reproductive performance.

#### TU093

##### **Biological responses of the "Rana Criolla" (*Leptodactylus latrans*) inhabiting a sewage-effluent receiving aquatic ecosystem of Argentina**

S. Rodríguez Fernández, Departamento de Biología Animal Biología Vegetal y Ecología / Facultad de Ciencias Universidad de A Coruña Campus da Zapateira; N. Bach, Instituto Centro de Investigaciones del Medio Ambiente / Facultad de Ciencias Exactas Universidad Nacional de La Plata CONICET; G. Natale, CIMA, Departamento de Química, Facultad de Ciencias Exactas; P. Carriquiriborde, Faculty of Exact Sciences, Universidad Nacional de La Plata / Chemistry In Argentina, sewage effluents are discharged on aquatic ecosystems raw or poorly treated. Previous studies showed the presence of both, traditional and emergent pollutants reaching the receiving waters. The objective of the present study is to assess the potential biological effects induced by sewage effluents on wild populations of the Rana Criolla frog (*Leptodactylus latrans*) inhabiting receiving aquatic ecosystem. Ten organisms (five females and five males) were collected either from the Girado stream (receiving the primary treated effluent from the Chascomús city sewage treatment plant) or from a reference site 15 Km south of La Plata City. External and internal abnormalities were inspected together with the assessment of the condition factor (K), the hepatosomatic (HIS) and gonadosomatic (GSI) indexes. In addition, catalase (CAT), ethoxy-resorufin-O-deethylase (ERO), benzyloxy-resorufin-O-dealkylase (BROD) activities together with total protein (PROT) and thiobarbituric acid reactive substances (TBARs) were assessed in the liver. Internal malformations were observed in 80% of the frogs from the Girado stream and none from the control site, characterized by swollen soft tissue along the backbone. In addition, significant ( $p=0.00001$ ) reduction in the GSI (35%) was observed in the females frogs at the Girado. No differences were observed for K or male GSI. A significant ( $p=0.028$ ) increase of BROD activity (62%) was observed in Girado frogs. EROD was significantly ( $p=0.042$ ) higher in males than females (74%) of the control site, but this differences disappear in the exposed population showing a sex/site interaction effect ( $p=0.043$ ). CAT and TBARs were not statistically different among populations, but showed the same trend than BROD contributing to the same factor in the PCA analysis. In summary, frogs living under the sewage effluent influence showed internal abnormalities and less development in female gonads together with a disruption of the EROD activity in the males, an increase of phase I detoxifying enzyme BROD accompanied by a subtle enhance of the antioxidant system and increase of the lipid peroxidation. All these evidences, show a clear impact of the sewage discharges on the health of Rana Criolla and probably other wild amphibian species inhabiting receiving aquatic ecosystems. CONICET-PIP0723, ANPCyT-PICT1598.

#### TU094

##### **Environmental impact assessment of chemical pollution in a Spanish natural reserve: a study of water quality**

C. Rivetti, IDAEA CSIC Barcelona / Environmental Chemistry; J. López Perea, Instituto de Investigación en Recursos Cinegéticos; J. Martínez, Conestoga-Rovers & Associates; M. Gorga, E. Eljarrat, IDAEA-CSIC / Department of Environmental Chemistry; R. Mateo Soria, Instituto de Investigación en Recursos Cinegéticos; B. Pina, IDAEA-CSIC / Environmental Chemistry; C. Barata, CSIC / Environmental Chemistry

The National Park of Las Tablas de Daimiel (central Spain) is the most representative Spanish floodplain ecosystem, important for its aquatic biodiversity. It offers permanent resting and breeding areas for many species of water birds, including endangered species. However, this wetland suffers the effect of waste water discharges coming from two rivers that supply water to this floodplain, namely the Gígüela and Guadiana Rivers, as the upstream urban communities are not provided with effective waste water treatment systems. Wastewater discharges,

besides adversely affecting water physicochemical parameters, carry chemical contaminants of many types that may have important effects on the biota of this aquatic ecosystem. Here we present data on a study performed during 2013 over 12 sampling locations in the wetland of Las Tablas de Daimiel and its nearby Navaseca lagoon that receives the effluent of the wastewater treatment plant of the town of Daimiel. We determined toxic components present in the waters and possible consequences for the resident wildlife. The study includes a combination of in-vivo and in-vitro bioassays coupled with chemical analyses performed by GC-MS/MS and LC-MS/MS. *Daphnia magna* post-exposure feeding inhibition assays were used to assess toxic effects in-vivo of whole water samples. Furthermore, dioxin-like activity and estrogenicity of organic extracts of water samples were determined using the recombinant yeast assays AhR-RYA and ER-RYA, respectively. These bioassays were used as efficient, fast and cost-effective screening systems to identify samples of interest and to provide basic information for further analyses and risk evaluation. The results were then compared with the chemical composition of the samples, with regards to their PAH, endocrine disruptors and estrogenic compounds content. Results indicated high dioxin-like and estrogenic activity in sampling locations close to waste water discharge points but also unexpected high dioxin like activities right at the core of the wetlands of Las Tablas de Daimiel. Biological activities were highly correlated with measured residue levels of PAHs and estrogenic compounds in both the dissolved and the suspended solid fraction. The results obtained may explain recent toxicity events on wildlife registered in the area.

#### TU095

##### **Response of wild fish to major infrastructure upgrades at a Canadian municipal wastewater treatment plant**

K. Hicks, P. Marjan, M. Fuzzen, University of Waterloo / Biology; L. Bragg, University of Waterloo / Department of Biology; K. McCann, University of Waterloo / Biology; G. Tetreault, University of Waterloo / National Water Research Institute; M.E. McMaster, Environment Canada / National Water Research Institute; M.R. Servos, University of Waterloo / Department of Biology Impacts on fish in waters receiving treated municipal wastewater treatment plant (MWWTP) effluents is a concern globally, with endocrine disruption being one of the most prominent effects observed. The objective of this study is to assess whether major treatment upgrades at a Canadian MWWTP will alleviate endocrine disruption and other impacts previously observed in wild fish. The MWWTP located in Kitchener, Ontario, discharges effluent into a heavily urbanized reach of the Grand River. Multiple years of data (since 2007) have been collected for rainbow darter (*Etheostoma caeruleum*) associated with the Kitchener MWWTP outfall. Endocrine disruption (intersex and decreased androgen production) in the male rainbow darter and the altered ability to store and utilize energy, as indicated by somatic indices (high condition, large livers, and small gonads) has been observed prior to the upgrades. These changes have been linked to effluent estrogenicity, which was reported to be as high as 17 ng/L 17 $\beta$ -estradiol equivalents. In addition, the nitrogen stable isotope ratio ( $\delta^{15}\text{N}$ ) is consistently depleted in fish downstream the Kitchener MWWTP revealing altered nutrient cycling in the food web. Between 2012 and 2013, major upgrades took place in the plant to allow effluent nitrification and extended solids retention. Rainbow darter were sampled in the fall of 2013 and 2014 to examine the same endpoints (endocrine disruption, somatic indices, and stable isotopes) as collected in previous years prior to the upgrades. Effluent quality improved with declines in select contaminants such as nutrients (e.g. ammonia), pharmaceuticals, and total estrogenicity (15N values measured in fish tissue which has returned to values similar to fish from upstream sites. Intersex condition and reduced androgen production in males was still prevalent in the fall 2013, and further analysis of the samples will reveal whether the intersex incidence and severity has decreased post upgrades. This study was a unique opportunity to assess the impacts of infrastructure upgrades of MWWTPs on effluent quality and biological responses in wild fish.

#### TU096

##### **Fluctuating energy intake through dietary restriction alters basal and induced levels of P-glycoprotein-mediated xenobiotic efflux activity in Rainbow trout (*Oncorhynchus mykiss*)**

C.J. Kennedy, Simon Fraser University / Department of Biological Sciences Teleosts can be exposed to natural conditions of fasting and starvation, often during over-wintering on an annual basis in temperate climates. In addition to natural periods of limited energy, exposure to chemical stressors can increase energy demands and may result in trade-offs that could affect the success of the organism, particularly under limited energy conditions. The energetic costs of basal and induced levels of P-glycoprotein (P-gp/ABCB1)-mediated, ATP-dependent efflux of xenobiotics as a primary line of cellular defense against exogenous compounds (multixenobiotic resistance, MXR) is currently unknown. In this study, P-gp activity as well as oxygen consumption (as an indicator of energy use) were examined under four treatment conditions: 1) fed fish, 2) fasted fish (12 weeks), 3) fish fed and P-gp induced (clotrimazole 10 mg/kg i.p.), and 4) fasted fish and P-gp induced (clotrimazole 10 mg/kg i.p.). Twelve weeks of fasting reduced the basal activity of P-gp compared to fed fish. Clotrimazole increased P-gp activity in fed fish and fasting did not alter the maximum induction of P-gp by clotrimazole. However, the increase to maximum induction was slower in fasted fish compared to

fed fish. Oxygen uptake at 12 weeks in fed or fasted fish exposed to a P-gp substrate (Rhodamine 123) only or induced with clotrimazole only were not affected, however, fed or fasted fish with induced P-gp levels and then exposed to the P-gp substrate exhibited increased respiration rates. In summary, prolonged fasting affects the ability of fish to efflux xenobiotics, and in addition, when P-gp is operating at maximum levels, energetic costs may be substantial.

#### TU097

##### **Toxicity Assessment of Ashes from Tropical Savanna Wildfires to Aquatic Biota**

D. Brito, University of Brasilia / Biology; C.J. Passos, University of Brasilia; E.C. Oliveira-Filho; Z. Malena, University of Brasilia

Fire plays an important ecological role in tropical savannas, meanwhile climate change scenarios predicts an increase in the frequency and severity of wildfires worldwide, mainly in those zones. The effects of forest fires on vegetation cover, catchment erosion and their detrimental effects on different environmental matrices have been well documented, however very few studies have examined the potential ecotoxicological effects of wildfire on aquatic organisms in tropical zones. We investigated the effects of ash from three different areas (two native vegetation areas and a pasture area - a landuse type very susceptible to wildfires in Brazil) through ecotoxicological bioassays using three aquatic species from distinct trophic levels: microcrustacean *Ceriodaphnia dubia*, fish *Danio rerio* and the mollusc *Biomphalaria glabrata*. Ashes (leaves, wood and bark) were collected in burnt areas, prepared the solution (100g.L<sup>-1</sup>) in culture water and mixed for 96hrs for different dilutions (3.12-100%). The results showed that there was a difference in acute toxicity among different ashes. All ashes showed toxicity to *C. dubia*. In relation to *D. rerio* and *B. glabrata* tests, no acute toxicity was observed when they were exposed to ashes from pasture and native vegetation. Only an area showed toxicity for *D. rerio* (LC<sub>50</sub> (24hs): 31.50%; LC<sub>50</sub> (48hs): 25.0%). The ashes mixed for long period (30 days) caused acute toxicity to *B. glabrata* (LC<sub>50</sub> (24hs): 50.0% (37.7- 66.4); LC<sub>50</sub> (48hs): 35.4%). Ash increased the pH (>10) in the test solution, however the serial dilutions minimized pH effects. The toxic effects were still evident indicating that components of ashes (e.g., metals) represent an important factor in the overall toxicity of vegetation ash. These results demonstrate that fires influence the toxicity of surface waters, making it toxic to the survival of aquatic organisms, specially zooplankton communities, and emphasize the need for more studies in order to understand the complexity of the ecological effects of fire on aquatic communities. \n

#### TU098

##### **Impacts of contaminants on metabolic capacities in American and European yellow eels**

A. Caron, INRS / Centre Eau Terre Environnement; M. Baudrimont, Université Bordeaux1; H. Budzinski, P. Labadie, University of Bordeaux / UMR EPOC Equipe LPTC; F. Pierron, CNRS; P. Couture, INRS / Centre Eau Terre Environnement

Since the 1980's, both European (*Anguilla anguilla*) and American (*Anguilla rostrata*) eel populations have drastically declined. Several factors likely contributed to this decline, including overfishing, climate change and obstacles to migration, but recent studies suggest that contamination also plays a role. The objective of this study was to examine the relationships between eel contamination and a range of enzyme indicators of various metabolic capacities. To this end, European yellow eels were sampled in two clean and two contaminated sites in France and the same design was repeated in the province of Québec (Canada) for American eels. We measured the concentrations of inorganic contaminants (Ag, As, Cd, Cr, Cu, Hg, Pb, Ni, Se and Zn) in liver and muscle and of organic contaminants (Sum of OCPs, sum of PCBs, and sum of PBDEs) in muscle. As indicators of aerobic capacities, we measured the activities of the mitochondrial enzymes citrate synthase (CS) and cytochrome C oxidase (CCO), while the activity of lactate dehydrogenase (LDH) was used as an indicator of anaerobic capacities and that of pyruvate kinase (PK) served to estimate glycolytic capacities. We also measured glucose-6-phosphate dehydrogenase (G6PDH), involved in lipid and antioxidant metabolism. In *A. rostrata* liver, CS activity was strongly and positively correlated with Pb contamination, while negative correlations were observed between G6PDH and Ag and between LDH and Ni. In muscle, correlations between PK (+), CS (-) and CCO (-) activities and Hg concentrations were observed. Also, a positive correlation was found between PK and PCBs, while strong negative correlations between both CS and CCO were observed with OCPs, PCBs and PBDEs. In *A. anguilla* liver, PK was positively correlated and CS negatively correlated with Pb concentrations. In muscle, PK and LDH activities were negatively correlated with As and Se respectively. Finally, CS, CCO and LDH did respectively show negative correlations with OCPs, PCBs and PBDEs. Overall, our study suggests that several of the contaminants investigated affect metabolic capacities of yellow eels of both species. Given the importance of aerobic and anaerobic capacities for locomotion, feeding and migration, the results of this investigation add to a growing body of evidence that environmental contamination plays a role in the decline of Atlantic eels.

#### TU099

##### **Aromatase and vitellogenin mRNA expression in an endangered fish species (Anguilla Anguilla) from the Loire estuary (France) : relationships with PCB**

#### contamination

I. Blanchet-Letrouve, I. poirier, MMS EA; A. ZALOUK-VERGNOUX, Univeristé de Nantes; A. Lafont, Muséum National d'Histoire Naturelle; S. Baloché, Muséum National d'Histoire Naturelle; S. Dufour, Muséum National d'Histoire Naturelle / UMR BOREA; C. Mouneyrac, Université Catholique de l'Ouest / MMS EA

Estuarine zones are extremely fragile due to increasing stress from anthropogenic activities. Among those, the Loire estuary (France) is potentially exposed to various contaminants including Endocrine Disruptors Compounds (EDCs) able to impact the reproduction physiology of fish. Even if the European eel (*Anguilla anguilla*) is not the most suitable sentinel species among Teleosts, this study aimed to investigate whether it may still be the target of estrogenic disruption, which could contribute to the decline of this species. Among the different molecules involved in reproductive function, vitellogenin (Vg) and aromatase (Arom) were of great interest because alterations in their expression could sign disruptions in sexual development. Quantitative real-time Reverse Transcription Polymerase Chain Reaction (q RT PCR) was used in this study to amplify responses of hepatic Vg and Arom transcripts in liver. European eels (*A. anguilla*) were sampled in May 2009 (N=57) and November 2010 (during the downstream migration, N=10) in two sites of the Loire estuary (upstream: Varades; downstream: Nantes). Reproductive (gender, sexual maturity stage) and biometric parameters of collected eels were determined. While only female silver eels should express hepatic Vg mRNA, abnormal levels were also detected in a large proportion (38%) of the other individuals: undifferentiated, yellow females, yellow and silver males. The principal component analysis performed between biometric parameters, Vg and Arom mRNA expression and PCB burdens revealed that Vg was not correlated to a sexual maturation stage, neither to the levels of PCBs. Arom mRNA seemed to occur in the early stage of gonadal maturation and was detected in the liver of 12 out of 67 organisms. Its expression was correlated to the dl and ndl-PCB of the muscles expressed in lw. Further investigations on other environmental estrogenic EDCs are needed in order to explain the unusual Vg expression.

#### TU100

##### **Fate of PCBs during developmental and sexual maturation of European eel (Anguilla anguilla)**

I. Blanchet-Letrouve, MMS EA; M. Couderc, Université de Nantes; A. ZALOUK-VERGNOUX, Univeristé de Nantes; P. Elie, CEMAGREF / Unité "Ecosystèmes Estuariens et Poissons Migrateurs Amphihalins"; C. Herrenknecht, University of Nantes / MMS EA; S. Dufour, Muséum National d'Histoire Naturelle / UMR BOREA; B. Le Bizec, ONIRIS / LABERCA; C. Mouneyrac, Université Catholique de l'Ouest / MMS EA; I. poirier, MMS EA

Among estuarine fish species, European eel (*Anguilla anguilla*) is emblematic and recognized as an endangered species, listed in Annex II of the Convention on International Trade in Endangered Species. Its population is considered to be outside safe biological limits on account of overfishing, climate change, habitat reduction, hydraulic barriers, diseases and parasitic infection and pollutant exposure. This fatty species is characterized by a high bioaccumulation potential for organic pollutants such as Endocrine Disrupting Compounds (EDCs), which may impair eel reproduction and further threaten their population. The objective of the present study was to investigate potential metabolic correlations during the silencing process comparing the PCB contamination levels in immature organisms such as glass eels and yellow eels and in potential genitori. PCB contamination levels of both gonads and muscles of yellow and silver eels from the Loire estuary have been compared in function of age class (6-10 y; 10-13 y; >13 y). The immature yellow gonads appeared two fold higher contaminated than the muscles for dl and ndl PCBs (expressed in wet weight (ww) and in dry weight (dw)) in yellow eels belonging to the age class 6-10 y. This result could be explained by the lipid weight of the gonads. For silver eels belonging to the 6-10 and 10-13 age classes, ndl PCB levels of gonads were significantly higher than those of muscles whatever the unit expression. Moreover, strong correlations between PCB levels of gonads and muscles in silver eels expressed in lw were found for each analyzed congener (except for PCB 81), whereas no correlation was found in yellow eels. These results highlighted significant correlations between the gonad and muscle lipids during the growing phase of silver eels. A mean contamination level of 18.5 ng TEQ WHO 1998.kg<sup>-1</sup> of gonad expressed in ww was obtained, suggesting a potential risk of abnormalities during the embryogenesis. The PCB patterns varied among the different developmental stage and matrices. The non metabolizable congeners 126 and 169 seemed particularly associated to the silencing process. Their constancy in glass eels could also sign an exchange of these contaminants during the hatching, from oocyte yolk to embryos, suggesting a materno foetal transfer.

#### TU101

##### **TOXICITY OF IMPROPERLY DISCARDED PHOTOVOLTAIC PANELS**

R. Panzuto, Biologia; B. Avallone, University Federico II of Naples; R. Cerciello, University of Naples Federico II / Biology; V. Mazzella, University of Naples Federico II / Biologia; M. Trifuoggi, University of Naples Federico II / Scienze chimiche; C.M. Motta, University Federico II of Naples / Department of Biology

The exploitation of solar energy is considered one of the possible solutions to the increasing energy demand and for this reason the use of photovoltaic cells (PVC) has progressively increased in the last thirty years. First commercially available PVC have been installed in the early '80s; they are now at the end of their life and need to be dismissed, a costly procedure due to the potential toxicity of their

components. The purpose of this work was to assess the environmental risk associated with an incorrect disposal of PVC and, in particular, to verify if damaged panels release in water components harmful to the aquatic environment. For this purpose, fragments of PVC panels were kept in infusion in water for 30 days. The resulting solutions were analyzed to determine chemicals released and to assess toxicity on *Daphnia magna*, *Artemia salina* and sea urchin (*Paracentrotus lividus*). Results demonstrate that the panels, if damaged, release different metals (especially antimony, aluminum and nickel) that exert a significant toxicity on the three species examined. In particular in the two crustaceans PVC solution increase mortality and induces cytological damages in the naupliar eyes. In *P. lividus*, PVC solutions alter normal progression of embryo development, causing asynchrony and producing amorphous plutei. In conclusion, data obtained indicate that it is essential to set up programs for safe disposal of photovoltaic panels.

#### TU102

##### **Toxicological effects of herbicide Raundup® and insecticide Fastac® on aquatic organisms**

**M. Balode, R. Medne, A. Mednis**, Latvian Institute of Aquatic Ecology

Due to the intensive farming all around the world, the usage of pesticides increase significantly in the last two decades. Consumption of pesticide combined with potentially high toxicity level is a huge threat to the wildlife. Acute toxicity of two commonly used pesticides - the pyrethroid insecticide Fastac with active substance alpha - cypermethrin and glyphosate based herbicide Raundup was detected. Laboratory cultures of different trophic level organisms (microalgae, zooplankton and fish) - green algae *Desmodesmus communis*, crustaceans *Daphnia magna* and fish species *Poecilia reticulata* were used as testobjects. No-observed effect concentrations (NOEC), the lowest observed effect level concentrations (LOEC) and EC<sub>50</sub> were detected using Standard Methods for Acute Toxicity Tests for freshwater algae, invertebrates and fish. The effect of recommended spraying concentrations (15ml/l for Raundup; 1,5ml/l for Fastac) were estimated as well. Growth inhibition, morfological changes and survival were used as testcriteria. Impact studies show high sensitivity of freshwater algae *Desmodesmus communis* - to the presence of herbicide Raundup and crustaceans *Daphnia magna* - to insecticide Fastac. Test organisms arranged from more sensitive to less one in following order: for herbicide Raundup - *Desmodesmus communis*, *Daphnia magna*, *Poecilia reticulata*, but for insecticide Fastac - *Daphnia magna*, *Poecilia reticulata*, *Desmodesmus communis*. Beside that Raundup and Fastac showed high toxicity level also for non target organisms (insecticide - to algae; herbicide - to crustaceans and fish), meaning that tested pesticides may pose an unacceptable risk to the aquatic environment. The study was financed by ESF Project "Creation of a new scientific group for modernization of aquaculture technology" project Nr. 2013/0067/1DP/1.1.1.2.0/13/APIA/VIAA/060 (2014-2015).

#### TU103

##### **Age-specific and time-specific life tables of natural and lab *Parhyale hawaiiensis* populations as potential endpoints for long-term effects of toxic agents**

**B. Burstin, L. Alegretti, LEAL** Laboratory of Ecotoxicology and Environmental Microbiology School of Technology; G.d. Umbuzeiro, FACULTY OF TECHNOLOGY - UNICAMP / LEAL; M.N. Flynn, LEAL Laboratory of Ecotoxicology and Environmental Microbiology School of Technology

Life table parameters and reproductive fitness parameters are being used as relevant tool to measure of ecological impact. The aim of this study is to describe the structure and dynamics of a natural and a lab population of *P. hawaiiensis* through the construction of age-specific life-table for a natural population and time-specific life-table following a cohort for de lab culture. The construction of age-specific life table of a natural population of *P. hawaiiensis* input data for the determination of age classes and fecundity were obtained following the procedure: 12 monthly samples from an algae belt in Itanhaem Beach – SP – Brazil were taken; individuals were screened for identification, sex determination, size measurement, and eggs count. Each sample provides a life table that is taken in account for production of mean parameters such as intrinsic growth rate ( $r$ ), reproductive potential ( $R_0$ ) and generation time ( $T$ ). ( $r = \ln(R_0)/T$ ). Data for the construction of time-specific life table of a cultured population of *P. hawaiiensis* was obtained through the follow up of a cohort (G1) extracted from 10 females in the same time interval brood spawn in laboratory conditions. Following the growth and development of each individual and analyzing the cohort decay, information were gathered in order to infer life cycle information and reproductive fitness parameters such as sex-ratio and reproductive potential. Manipulation described was performed at LEAL laboratory at the School of technology UNICAMP - FT / UNICAMP. Preliminary results up to date from six samples from the natural population show mean ( $r$ ) = 0.10467 ± 0.10782, variation in  $r$  value related to environmental and population stochasticity. Cohort follow up is still in process. Initial substantial decayment occurred in the first 2 weeks. Tendency has inverted, and very few deaths have been reported after sexual maturity has been achieved. Sex-ratio is 2 females for every male. From the vital parameters now in attainment, a life table response experiment (or LTRE) will be performed in order to document differences among treatments. The intrinsic rate of population growth and reproductive potential, will be tested through a life table response experiment and potential endpoints for long-term effects of toxic agents.

#### TU104

##### **Species-related changes in gene expression after 17 $\alpha$ -ethinylestradiol (EE2) exposure in water snails**

**C. Hultin**, Lund University / Lund University Centre for environmental and climate research; A. Persson, Lund University; M.C. Hansson, Lund University / CEC

The endocrine disruptive chemical (EDC) 17 $\alpha$ -ethinylestradiol (EE2) is today a widespread problem in the environment due to its high release and tendency to bioconcentrate in aquatic organisms. It is known that low levels of EE2 can affect both growth and reproduction of gastropods. Moreover, gastropods are considered sensitive to environmental changes, causing many aquatic snails to be endangered. Here, we will identify new information about how EE2 exposure affects aquatic snails at the gene expression level. This will enhance our general understanding of how human-derived endocrine disrupting compounds (EDCs) can interfere with endocrine-related genes of gastropods. This study is part of a long-term research collaboration that has previously shown how EE2 exposure can interfere with somatic growth of the aquatic natural snail *Bithynia tentaculata*. However, another natural water snail (*Radix balthica*) was unaffected by the treatment, indicating species-related differences of how a presence of EE2 affects growth. Here, we aim to investigate species-related consequences of EE2 exposure at the gene-level in *B. tentaculata* and *R. balthica*. Two gastropod species (*B. tentaculata* and *R. balthica*) were collected from a natural population in southern Sweden. By using before-and-after impact design, we exposed *B. tentaculata* and *R. balthica* snails to nominal concentrations of 10 and 100 ng/L EE2 at our laboratory during 24 hours and/or 72 hours. We exposed natural *B. tentaculata* and *R. balthica* snails to nominal concentrations of 10 and 100 ng/L EE2 at our laboratory during 24 hours and/or 72 hours. More specifically, we test if a species difference in growth also is reflected at the genetic level in terms of gene expression of the estrogen receptor (*er*) genes. Our analysis show a significant change in the *B. tentaculata* *er*'s gene expression and not in the *R. balthica* after 72 h of EE2 exposure (ANOVA,  $p < 0.05$ ,  $n=6-13$ , *prel. data*), which is coherent with our previous growth analysis of these species after EE2 exposure. Ongoing studies will try to further unravel the links between growth (population effect) and endocrine-related genes (molecular biomarkers) in gastropods.

#### TU105

##### **The effect of pond dyes on mosquito colonisation of water bodies**

**N. Ortiz**, University of Reading / School of Biological Sciences; A. Callaghan, University of Reading

Pond dyes are a cosmetic product for garden ponds and lakes; they inhibit algal growth and improve the overall appearance of the water body. The dyes block red light from entering the water, interrupting the process of photosynthesis and therefore inhibiting the growth of certain aquatic plants such as algae. Although these dyes are not directly toxic to fish and invertebrates, their impact on freshwater communities has yet to be studied. At Reading, we are studying the impact of pond dyes on pond ecosystems and on the community composition of artificial water bodies. To address these issues we are undertaking mesocosm studies as well as laboratory studies. Here we present data on the impact of a black pond dye on the oviposition of British mosquito species. Females lay eggs in many different types of water body including ponds, shallow lakes and artificial containers. Although British mosquitoes currently do not carry human diseases, they are a biting nuisance and are known to compete with other aquatic invertebrates such as water fleas. We undertook a number of oviposition choice experiments to compare water treated with and without dye at the concentrations specified by the manufacturer. Captive gravid *Culex pipiens* female mosquitoes (wild caught and laboratory strains) were presented with a choice of containers with or without dye in a field, semi-field (wild caught in a tent) and laboratory conditions. Our preliminary results show that there is a significant difference between treatments. The black dye is attractive to gravid mosquitoes, encouraging them to lay eggs preferentially in dark waters. Since these mosquitoes are known to be competitors of cladocerans and other macroinvertebrates, the dye is possibly altering the community composition in ponds. Although the pond dye is not exerting a direct chemical stress on the community, it is a potential engineer of community change.

#### TU106

##### **Comparing the impact of pesticide treatment on arthropod communities in different studies using trait based analyses**

**S. Aldershof**, Bioresearch & Evaluation; **F.M. Bakker**, Mitox Consultants

The impact of pesticides on terrestrial arthropod communities prevalent in agro-ecosystems are commonly evaluated with ordination techniques (i.e. Principal Response Curves Analysis, 1). Community responses towards pesticide treatments on different locations can not be compared directly due to the fact that species composition differ in different ecozones. This problem can be overcome by describing communities by an identical set of trait values rather than by taxonomic groups. This poster illustrates a method to compare arthropod community responses in two apple orchards in Northern and Southern Europe. Shifts in functional diversity (2) related to pesticide treatment were compared directly in the two studies by performing Principal Response Curves Analysis on Community Weighted

Means (3) rather than on species numbers. The suitability of trait based evaluations as a supplementary tool to enhance the understanding of compound specific differences in acute community effects and to reveal underlying mechanisms driving recovery processes is discussed. In addition, the added value of trait analyses to estimate impacts of pesticide treatments on ecosystem services is considered. 1) Van den Brink PJ and Ter Braak CJF. (1998). #### TU107

##### **Characterization of Qatari Porites (Growth and Photosynthetic Efficiency) Under Dynamic Variables, An Experimental Approach**

N.M. Al-Naema, ExxonMobil Research Qatar / Environmental Program; N. Deb, ExxonMobil Research Qatar / Environmental; S. Saeed, ExxonMobil Research Qatar; R. Ben-Hamadou, Qatar University / Department of Biological and Environmental Sciences; M. Al-Ghouthi, M. Abu-Dieyeh, Qatar University; D. Dupont, ExxonMobil Research Qatar

**ABSTRACT** Coral ecologies are very essential as they offer a habitat to marine species. Laboratory researches were initiated to understand corals physiology. Samples were collected and cultured in pre-acclimatized lab aquaria. Orthogonal experiments for 2 weeks were conducted under 3 stress stimuli: salinity, light intensity and temperature. Imaging-Pulse Amplitude Modulation Fluorometry (Imaging-PAM) and buoyant weight were utilized to measure photosynthetic performance and growth of the corals. We were able to detect biological responses of the corals to stress stimuli using PAM parameters Maximum Quantum Yield (Fv/Fm), Electronic Transfer Rate (ETR) and Non-Photochemical Quenching (NPQ) **OBJECTIVE** To establish corals culture under controlled conditions and detect biological and physiological responses to different levels of stress stimuli: salinity, light intensity and temperature using PAM and buoyant weight **METHODOLOGY** Corals samples were collected from mother colonies from different locations in Qatar. Acclimatization process started gradually at lab by adding corals into pre-acclimatized lab aquarium. Corals were stressed for 12 days under 3 stress stimuli (separately): salinity, light intensity and temperature. PAM measurements were taken every 3 days. Weight of individual corals was measured at the beginning and at the end **RESULTS & DISCUSSION** Results revealed that elevated levels of temperature and salinity have statistically significant effect on *Symbiodonum* photosynthetic activity; while light intensity did not. High level of salinity (50 psu) affected the corals photosynthetic efficiency by causing a drop to a very low range (0.28). As a result, corals weight dropped down too. In contrary, elevated light intensities showed normal regime of efficiency and growth rate increased with increasing lights. Finally, *Porites Symbidonum* are highly sensitive to increases in temperature up to 38°C, where they exhibited complete death “bleached” and PAM parameters dropped to zero value **CONCLUSION** Using high-resolution fluorescence PAM combined with its derived detailed image and gain percentage allowed us to identify the stress that is caused by elevated levels of parameters. High salinities (50 psu) and temperatures (38°C) affect the photosynthetic activities of *Porites Symbidonum*. **FUTURE WORK** PAM associated to genetic identification tools by correlating species tolerance to different stress stimuli sounds to be very promising to understand coral response mechanism

#### TU108

##### **Oscillating population dynamics, nutrient cycling and the subsequent effects on exposure sensitivity to daphnids and algae**

D. Eidsvoll, Norwegian Institute for Water Research NIVA; L. Nizzetto, NIVA; A. Lillicrap, NIVA / Ecotoxicology and Risk Assessment

The concept of assessing the ecotoxicity of chemicals under realistic environmental situations with increasing levels of complexities has become more frequently recommended to provide a more holistic approach to environmental hazard assessment. The direct and indirect effects of chemical contaminants on trophic interactions in a structured ecosystem model (such as for example an oscillating predator-prey dynamic) are not currently part of standard laboratory assays, while they may represent very sensitive “toxicity” endpoints. In order to assess the function of ecosystem dynamics with multiple stressors, we have developed a system incorporating chemostats with 2 different trophic levels; a primary producer (*Pseudokirchneriella subcapitata*) and a primary consumer (*Daphnia magna*). These chemostats are relatively self-sufficient, running for multiple generations over several months with oscillating biomass of both algae and daphnids exhibiting boom and bust outcomes in the populations. This coupled with varying the nutrient content of the media as an additional environmental stressor has been used within our laboratory to assess the effects of different personal care products, commonly detected in lakes and rivers within Northern Europe, at the population level of the organisms. Whilst it is recognised that increasing the level of complexities may cause challenges, it is envisaged that performing ecotoxicity assessments using such approaches will provide a more environmentally realistic assessment of the

effects of chemicals in the environment.

#### TU109

##### **Assessment of impacts caused by remediation technologies on phytoplanktonic and benthic communities of an urban eutrophic reservoir**

A.E. Sueiti, A.A. Mozeto, Federal University of Sao Carlos / Chemistry Mesocosm experiments were conducted at Ibirité reservoir (an urban eutrophic environment-SE Brazil) to assess the impacts of Phoslock® and nitrate on phytoplanktonic and benthic communities. In the mesocosms treated with Phoslock®, 21 phytoplanktonic taxa were identified: Cyanophyceae (5), Chlorophyceae (10), Zygnemaphyceae (2), Euglenophyceae (2) and Bacillariophyceae (2). Lower density of phytoplankton was observed just after treatment. Flocculation and sedimentation processes caused by treatment explain such drop. After 600 h phytoplankton density increased, but there was a change in the community structure: the number of organisms belonging to Cyanophyceae decreased (82% in water column; 99% in sediment-water interface) and an increase in Chlorophyceae and Euglenophyceae could be observed. Phoslock® application also interfered in the richness of benthic community: among the four taxa identified in controls (Oligochaeta, Chironomidae, Ancilidae and Planariidae), only Chironomidae persisted in treated mesocosms after 600 hours. In the mesocosms treated with calcium nitrate, 23 phytoplanktonic taxa were identified: Cyanophyceae (5), Chlorophyceae (8) Zygnemaphyceae (3), Dinophyceae (1), Euglenophyceae (3) and Bacillariophyceae (3). The effect of nitrate was noticed only after 600 h, when an abrupt decrease in the density of organisms was observed, especially in Cyanophyceae (92% in water column; 100% in sediment-water interface). It is believed that such decrease has occurred due to the reduction in the concentration of orthophosphate (average 60%) and not due to a toxic effects caused by nitrate. The treatment caused reductions in benthic communities: Oligochaeta (87%), Chironomidae (20%), Ancilidae (100%) and Planariidae (100%). Family Notonectidae were not identified in controls, but was present in the treated mesocosms. Aiming the restoration of Ibirité reservoir, it can be concluded that the decrease in cyanobacteria density is of great interest, since this group cause several problems to aquatic ecosystems. Considering that the resident phytoplanktonic and benthic organisms are mostly tolerant to pollution and typical of impacted environments, it is expected that either of the technologies would provoke a shift in communities structure, increasing complexity of trophic interactions and consequently the degree of ecosystem’s resilience in long-term, after natural recovery reset flora and fauna impaired by treatments.

#### TU110

##### **Interactions between chemical stress and dispersal in marine phytoplankton**

J. De Raedt, Laboratory for Environmental Toxicology and Aquatic Ecology; J. Baert, Ghent University / Bioscience Engineering; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; F. De Laender, Université de Namur ASBL / Laboratory of Environmental Ecosystem Ecology

The fast decline of biodiversity resulted in a growing concern about the effects of biodiversity loss on ecosystem functioning. The majority of the biodiversity experiments have found a positive relationship between diversity and ecosystem stability and performance. However, most of these experiments have been performed in closed communities in which species composition is the result of random species extinctions. In reality, final community composition is the result of a species’ specific responses to dispersal, environmental conditions and species interactions. In order to evaluate the effects of dispersal and toxic stress (i.e. environmental conditions), 5 different communities of 4 marine diatom species (Bacillariophyceae) were exposed to three levels of toxic stress (0, 25 and 250 ppb atrazine) and three levels of dispersal (no, low and high). Each treatment was replicated 3 times, resulting in 135 communities. Dispersal was performed by adding a fixed volume of 4 different species to the community once (low) or twice (high) a week from a species pool of 12 species. Dispersal had a negative effect on biovolume in communities. However, at high stress, there was a positive interaction effect between atrazine and dispersal on biovolume. This positive interaction effect was larger than the negative effect of dispersal. Hence, interactions between dispersal and the toxicant by far compensated for dispersal-induced biovolume loss. Dispersal had a negative effect on evenness in communities. However, the mechanism causing this negative effect was different for low than for high stress levels. At no and low stress levels, new arriving species barely contributed to biomass production. Indeed, community composition at the end of the experiment was dominated (average 94%) by species initially present in the community. Thus, newly arriving species were not able to colonize and grow, because of high biovolume of resident species and high competition. At high stress levels, this dominance of resident species decreased. Only species which were tolerant for the toxicant were able to grow. We conclude that the effect of dispersal changed along a toxic stress gradient.

#### TU111

##### **Technical realisation and validation of an outdoor stream mesocosm**

L. Dören, MESOCOSM GmbH Institut für Gewässerschutz; P. Janz, Technische Universität München; E.R. Rodriguez, Hochschule RheinMain; K. Ebke, MESOCOSM GmbH, Institut für Gewässerschutz

A new outdoor test system was constructed to study effects on stream organisms

under realistic conditions. All components of the test system which come into contact with water are made of stainless steel. The model streams are “recirculating” modular systems which can be adapted to the specific requirements of each study (e.g. water level, current velocity...). Each model stream has a water depth of 0.3-0.5 m, a volume of 1400-2400 L and a water course of about 10 m. The water is driven by paddle wheels with a current velocity up to 0.5 m/s. Since the hydraulic conditions are a key factor for the distribution of stream organisms, they should be taken into account when developing stream mesocosms. Preliminary studies were conducted in order to optimize the flow characteristics. An equal current velocity distribution along the cross section as well as along the water course was realised by the installation of flow conditioners and guide plates. These installations also ensure a high reproducibility between the model streams regarding the flow characteristics. Furthermore, specific sampling techniques to monitor leaf decomposition, phytoplankton, periphyton, macroinvertebrates, emerging insects and drifting organisms were adjusted and validated.

#### TU112

##### **Does habitat connectivity reduce the amount of stress-tolerance variability needed to preserve ecosystem functions?**

J. De Raedt, Laboratory for Environmental Toxicology and Aquatic Ecology; J. Baert, Ghent University / Bioscience Engineering; F. De Laender, Université de Namur ASBL / Laboratory of Environmental Ecosystem Ecology; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

There is a need for simple measures that, in conjunction with species sensitivity data, allow for a better risk assessment at the ecosystem level. Here, we have explored the use of migration rate as a proxy for habitat connectivity. In a microcosm experiment in which we exposed marine diatom communities to 3 atrazine levels, we found that increased immigration had no effect on ecosystem function in control and low stress conditions. However, in severely stressed communities increased immigration reduced the impact of atrazine on ecosystem performance ( $p < 0.0001$ ). Analysis of a stochastic Lotka-Volterra model indicated a trade-off between migration rate and community stress tolerance variability to buffer ecosystem functions: better-connected communities need a smaller degree of interspecific stress variability (i.e. a steeper species sensitivity distribution) to buffer ecosystem functions in the same way as less-connected communities. Both empirical and theoretical evidence suggest that landscape features can be important for future risk assessment.

#### TU113

##### **Schemes for further Consideration of Biodiversity issues in Ecological Risk Assessment**

E. Chaideftou, Benaki Phytopathological Institute / Department of Pesticides Control Phytopharmacy Laboratory of Toxicological Control of Pesticides Ecological Risk Assessment (ERA) entails the identification and Characterization of Ecological Effects towards the Characterization of Risk from Exposure posed to a specific Environmental Entity. For the Characterization of Ecological Effects to the Entity, the adverse effects elicited by the stressor are identified and quantified and the causal relationships are potentially evaluated. For the Determination of Exposure of the Entity, the spatiotemporal distribution of a stressor and the co-occurrence or contact of stressor with the ecological components is predicted or measured. Specific Protection Goals are determined in ERA after defining the Entity under protection. Each Entity is expressed by a specific Environmental Value which is not always defined and necessitates further investigation. These Values should be the driving forces linking Protection Goals with Ecosystem Services and assist experts on structuring explicit conceptual models. The determination of endpoints could also contribute to this direction. The Endpoint should be the explicit expression of the protected Value and an expression of the Ecosystem Service that is maintained by the protected Value. Two schemes are proposed to this direction each demonstrating the steps of ERA, where new studies for biodiversity as a protection goal at ecosystem level can be included to facilitate the chemical stressors' risk characterisation with an 'Ecosystem Services' approach. In the first scheme, studies on Ecosystem Services can be included in the ERA framework, for estimating parameters as a separate step. In the second scheme, Ecosystem Services are incorporated in ERA from the beginning considering findings and studies already available and potentially performed in parallel with the traditional ERA procedure to: 1) identify which Ecosystem Services are indeed protected by protecting the most sensitive organism(s) and 2) allow for drawing conclusions on which of the group organisms should be additionally tested in ERA since they may strengthen the Ecosystem Services that are already provided by the most sensitive organisms.

#### TU114

##### **The macroinvertebrate community in an outdoor stream mesocosm**

P. Janz, Technische Universität München; L. Dören, K. Ebke, MESOCOSM GmbH, Institut für Gewässerschutz

Outdoor stream mesocosms were developed to study the effects of chemicals on stream organisms under realistic conditions. A pilot study with four prototypes was conducted from the beginning of May to the end of June in Central Germany in 2014. A representative macroinvertebrate community containing the important taxonomic groups, trophic groups and ecological traits (particularly life-cycle

characteristics related to vulnerability as generation time and dispersal ability) typical for communities in small streams could be established. Over 70 taxa belonging to nine different classes were identified in the macroinvertebrate samples. A high diversity could be maintained throughout the entire study period of 8 weeks. Based on calculations of minimum detectable differences (MDDs) it was shown that the variability between the model streams was sufficiently low in order to enable a statistical evaluation for more than the required (by EFSA) 8 populations including EPT taxa (Ephemeroptera, Plecoptera, Trichoptera) and gammarids.

Li, Fudan University / The Institute of Biodiversity Science; D. Liu, D. Ye, C. He, X. Liu, Shanghai University / School of Environmental and Chemical Engineering; K.K. Vaananen, University of Eastern Finland / Biology; X. Chen, Shanghai University / School of Environmental and Chemical Engineering

Understanding the dynamics of the structure and function of the sediment microbial community across freshwater environments will help to predict how these ecosystems will change in response to anthropogenic activities. *Materials and methods* We compared the community structure and abundance of C/N transformation-related functional micro-organisms along two rivers in South-Eastern China that flow through three typical functional zones corresponding to agricultural, residential and industrial zones. *Results and discussion* Illumina sequencing of 16S rRNA amplicons revealed that the sediments are dominated by Proteobacteria (41.4-54.4 %) at all of the tested sites and demonstrated notable differences among the communities from different functional zones. The abundances of the *nifH* gene ( $5.57 \times 10^5$ - $8.27 \times 10^5$  copies  $\text{ng}^{-1}$  DNA), *nirK* gene ( $4.79 \times 10^4$ - $6.22 \times 10^4$  copies  $\text{ng}^{-1}$  DNA) and *pmoA* gene ( $7.02 \times 10^4$ - $9.29 \times 10^4$  copies  $\text{ng}^{-1}$  DNA) in the industrial area were significantly higher than in the residential and agricultural zones. The gene copy numbers from both ammonia-oxidising Archaea (AOA) and bacteria (AOB) from the agricultural zone were significantly higher than in the residential and industrial zones. The ratio of AOA:AOB *amoA* gene copy numbers in the agricultural zone was below 1.0, whereas those in both the industrial and residential zones were above 1.0 (1.10-5.34). Non-metric multidimensional scaling (NMDS) analysis showed that the microbial communities in the agricultural zone were mainly correlated with volatile phenol, and  $\text{NH}_4^+$ ,  $\text{COD}_{\text{Cr}}$ , and  $\text{COD}_{\text{Mn}}$  appeared to contribute to the segregation observed in the residential zone. *Conclusions* These findings indicate that the fluctuations of the microbial community in river sediment are impacted by different human activities, and particular functional groups, such as nitrogen fixers (*nifH*), nitrifiers (AOB), denitrifiers (*nirK*), and methanotrophs (*pmoA*), are sensitive to environmental changes.

#### TU116

##### **Use of mesocosm study data in current and future risk assessments - a review**

J. Postma, R. Keijzers, Ecofide; A.D. Redman, Exxon Mobil Biomedical Sciences; C.V. Eadsforth, Shell International; S. Linington, BP Castrol Technology Centre; S. Comber, Plymouth University / Environmental Science; M. Leon Paumen, ExxonMobil Biomedical Sciences / ExxonMobil Biomedical Sciences TES Division; K. den Haan, CONCAWE / Petroleum Products Safety

In estimating PNEC-values or the derivation of environmental quality standards (EQS), data from mesocosms can be used to argue that lower safety factors might be applied. The decision on the size of such an application factor (AF) is made on a case-by-case basis. A literature review was conducted to provide insight in the present use of available mesocosm data in risk assessments and in several technical aspects in relation to study design. The main conclusions were A large amount of information on mesocosm studies is available and there is not just one approach. All aspects of test design should be discussed and optimised in the light of the specific research objective. Available literature reviews on a limited amount of data indicate that the SSD approach, in which single-species studies are used to calculate a  $\text{HC}_5$ -value, is normally protective of populations in mesocosms and in the field. Replicability and repeatability of physical, chemical but especially biological parameters should be assessed as part of the test design. An experimental design encompassing more than 4 concentrations and at least two replicates is suggested in order to obtain sufficient resolution (Møhlenberg et al., 2001). Options to reduce variability can be: \n- to locate mesocosms near to the source system and allow communities to establish naturally \n- to control the settling of sediment and grain size distributions \n- to allow continuous recolonisation during the experiments The size of mesocosms itself is not one of the driving forces for the biological complexity of stream mesocosms. Nevertheless, several parameters are impacted by size such as mixing zone, flow-rate and sampling zones. These need to be carefully considered when setting up mesocosm experiments. Flow-through mesocosms, with a continuous inflow from upstream, can be highly replicable and can be considered realistic. The realism of the biological community tested in a mesocosm should be assessed as one of the elements in a weight of evidence approach in support of a low AF. Validating the ecological realism of mesocosms using “dimensional analysis” should be considered. Statistical considerations form

an essential part of both study design and interpretation. The use of multivariate analysis and especially the Principal Response Curve method has become state-of-the-art for interpreting mesocosm data.

#### TU117

##### **A new outdoor test system with stream mesocosms**

P. Janz, Technische Universität München; L. Dören, K. Ebke, MESOCOSM GmbH, Institut für Gewässerschutz

Lentic (static) aquatic mesocosms are most frequently used to refine aquatic risk assessments of pesticides when a potential risk is indicated by lower tier studies (e.g. laboratory single species tests). However, small lotic water bodies (small streams and ditches) in agricultural areas are often the most exposed water bodies. Lotic water bodies differ strongly from lentic water bodies in terms of their abiotic environmental factors and their biocenoses. Thus, the extrapolation of results from lentic mesocosm studies to small lotic water bodies is subject to many uncertainties. These uncertainties can be reduced if lotic mesocosms are used instead. A new outdoor test system with artificial streams was designed, with particular focus on macroinvertebrates including the EPT taxa (Ephemeroptera, Plecoptera, Trichoptera) and gammarids. In a pilot study a representative community containing the important taxonomical groups, trophic groups and ecological traits (particularly life-cycle characteristics related to vulnerability as generation time and dispersal ability) typical for communities in small streams could be established. Further it was shown that variations between the model streams were very low for physico-chemical parameter, leaf decomposition, phytoplankton and periphyton throughout the entire study period of 8 weeks. Minimum detectable differences (MDDs) were calculated to indicate the statistical power of the mesocosms. The MDD defines the difference between the means of the treatment and the control that must exist in order to conclude that there is a significant difference. According to the MDD calculations the variability between the model streams was sufficiently low in order to enable a statistical evaluation for more than the (required by EFSA) 8 populations of macroinvertebrates (including EPT taxa and gammarids). Thus, the test system meets all criteria for mesocosms according to the EFSA guidance document on tiered risk assessment for edge-of-field surface waters and it is considered as a very powerful tool to study the effects of pesticides on stream organisms under realistic conditions.

## **Latest advances in passive sampling and dosing (P)**

#### TU118

##### **POCIS for pesticide monitoring in groundwaters: from "low flow" pilot calibration to in situ monitoring**

a. togola, C. Berho, BRGM / Laboratory Division; S. Robert, Suez Environnement / CIRSEE; A. Bruchet, CIRSEE Suez Environnement

Since few decades, polar organic chemical integrative sampler (POCIS) has been successfully applied to the sampling of a wide range of polar organic contaminants including pesticides. Passive sampling offering time integrated sampling that compensates for fluctuations in concentrations and lower detection limits compared to standard water sampling. Applications have been implemented in surface water or wastewaters after obtaining sampling rate ( $R_s$ ) by laboratory calibrations. POCIS sampling rates are affected by environmental factors such as water flow rates, that is particularly significant for groundwaters, characterized by low water flow conditions. To develop a better understanding of the relationship between water flow and POCIS accumulation, an experimental system has been implemented to obtain sampling rates for POCIS on representative groundwater hydraulic conditions of alluvial aquifers. In parallel, monitoring campaigns have been undertaken during one year to obtain in situ sampling rate values. This work compares this two approaches with classic in lab results, to determine impact of flow on POCIS accumulation in groundwater context. By this way, lab calibration that is easiest to implement, could be used and corrected to better fit with environmental condition, allowing the use of passive sampler for a semi-quantitative approach.

#### TU119

##### **Passive samplers as cost-effective WFD screening devices**

J.M. Ronan, Marine Institute / Chemical Sciences; L. Jones, Dublin City University / Chemical Sciences; B. McHugh, E. McGovern, Marine Institute; f. Regan, Dublin City University / Chemical Sciences

The primary purpose of the WFD is to establish a framework for the protection of all surface waters throughout the EU territory. Conducting appropriate water and biota sampling to meet WFD monitoring requirements is both costly and challenging, given the analytical difficulties posed by low environmental quality standard (EQS) values, the availability of suitable and sufficient numbers of biota (for EQS<sub>biota</sub>), and the volume and frequency of sampling required. Passive sampling (PS) techniques are rapidly developing as very cost-effective state of the art pragmatic tools to identify and measure ultra-trace micro-pollutants in water as improved compound detectability and sensitivity may often be obtained relative to more "traditional" spot water sampling and analysis techniques. It is proposed that PS derived dissolved pollutant data in tandem with appropriate modelling techniques may be suitable for the derivation of individual precautionary principle based parameter "passive sampling EQS equivalent" (EQS<sub>eq</sub>) screening/threshold

values. When used within a tiered monitoring framework PS screening results would then be assessed against the derived thresholds whereupon exceedance may initiate further more focused sampling. It is thus suggested that this combination of PS thresholds within a tiered approach provides a cost effective option for surveillance monitoring to highlight possible compounds and locations of environmental concern.

#### TU120

##### **Applying silicone-based passive samplers in water monitoring**

B. Becker, Department of Qualitative Hydrology; A. Duffek, Federal Environment Agency; P. Lepom, Laboratory for Water Analysis; A. Paschke, Helmholtz Centre for Environmental Research (UFZ); C. Möhlenkamp, Federal Institute of Hydrology; E. Claus, Federal Institute of Hydrology BfG; S. Schaefer, Federal Institute of Hydrology / Department of Qualitative Hydrology

Quantifying hydrophobic organic chemicals (HOCs) in water is challenging due to the low concentrations which need be measured and the insufficient detection limits which are often achieved when taking 1 L spot samples. Passive samplers can accumulate HOCs while being exposed in the environment enabling not only low detection limits but also the measurement of time-weighted average concentrations ( $C_{TWA}$ ). In this study, silicone-based passive samplers were applied to monitor water quality in rivers. Silicone rubber sheets were exposed *in situ* at five sampling sites in different rivers in Germany (Elbe, Rhine, Danube, Saale and Saar). Three sampling campaigns were conducted from May until October 2014 with an exposure time of five weeks each. Target analytes were PAHs, PCBs as well as DDT and its metabolites. Analyte-specific sampling rates ( $R_s$ ) were determined by *in situ* calibration with ten performance reference compounds (PRCs). The remaining amounts of PRCs after the exposure period were measured.  $R_s$  were calculated by non-linear regression of the PRC fraction, which remained in the samplers and analyte-specific silicone-water partition coefficients according to Rusina et al. (2010). Abiotic factors such as water temperature and flow rate in the rivers were measured to study their effect on  $R_s$  of target analytes. Next,  $C_{TWA}$  of the target analytes were calculated at each sampling site based on the *in situ* calibration with PRCs. Results from the first sampling campaign in 2014 showed different contamination patterns for the five sampling sites. The highest PCB  $C_{TWA}$  of 110 pg/L was found for CB 138 in the Elbe river. PAH concentrations were in the pg/L range up to a few ng/L. PAH concentrations ranged from 2 pg/L indeno[1,2,3-c,d]pyrene in the Danube to 3.2 ng/L for fluoranthene in the river Saar. The PAH patterns varied between the different rivers with a higher fraction of the more hydrophilic PAHs seen in the rivers Saar, Danube and Rhine. As expected highest levels of DDT and its metabolites were measured in the Elbe river with up to 600 pg/L for p,p'-DDD. Detection limits of target analytes were below 1 pg/L depending on  $R_s$ . This contribution will compare the  $C_{TWA}$  obtained for the different sampling sites and sampling campaigns. Also the potential and limitations of implementing passive samplers in routine monitoring campaigns, e.g. for monitoring under the European Water Framework Directive, will be discussed.

#### TU121

##### **Targeted screening of emerging pollutants in Czech rivers by passive sampling**

V. Kodes, Czech Hydrometeorological Institute / Section of water quality; R. Grabic, University of South Bohemia in CB / Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses

A screening of more than 300 emerging pollutants such as pharmaceuticals (analgesics, psycholeptics, antidepressants, antibiotics, beta blockers), PCPs (UV blockers, musk's, repellents), illicit drugs, pesticides, perfluorinated compounds) and their metabolites at 22 monitoring sites throughout the Czech Republic was conducted in 2013 in the Czech Republic. Two types of passive samplers (pesticide and pharmaceutical POCIS) were deployed for 14 days in May and in October, 88 samples were collected in total. LC-MS/MS and LC-MS/HRMS methods were applied for analyses of POCIS extracts. In total 265 and 310 target compounds were analyzed in pharmaceutical and pesticide samplers respectively. Results showed that 150 of 310 (48%) and 127 of 265 (48%) analyzed substances had been found in pesticide and pharmaceutical samplers respectively. 27 substances (pharmaceuticals, PCPs, pesticides, caffeine, nicotine metabolite) occurred at all sampled sites, additional 39 substances (pharmaceuticals, PCPs, pesticides) occurred at more than 33 (75%) of sites. One of perfluorinated compounds occurred at 68% of sites, whilst one of illicit drugs was found at 61% of sites. The highest number of contaminants found in one POCIS at a single monitoring site was 111. The concentrations varied from nanograms to thousands of nanograms per sampler. Emerging contaminants occurring in highest concentrations (> 1000 ng/sampler) were BP-4 and PBSA (UV blockers), caffeine, DEET (insect repellent), imidacloprid (insecticide), telmisartan (hypertension drug) and tramadol (analgesic).

##### **Passive sampling monitoring of trace metals and organics in seawater in the area of the Costa Concordia disaster (Isola del Giglio, Italy).**

M. Schintu, University of Cagliari / Dipartimento di Sanità Pubblica Medicina Clinica e Molecolare; A. Marrucci, Università di Cagliari / Dipartimento di Sanità Pubblica; B. Marras, University of Cagliari / Dipartimento di Sanità Pubblica

Medicina Clinica e Molecolare; E. Cocco, M. Atzori, Università di Cagliari / Dipartimento di Sanità Pubblica Medicina Clinica e Molecolare  
This work presents the results of two years monitoring of organics and trace metals in seawater with passive sampling techniques in the area around the wreck of the Costa Concordia cruise ship, which sank off the Mediterranean island of Giglio (Italy) on January 2012. The aim was to monitor bioavailable contaminants released by the wreck and/or produced by the removal yard (Parbuckling project). Sampling was carried out at three sites from May 2012 to September 2014, one month after the removal of the wreck. Two sites were fixed in the vicinity of wreck, at the bow and at the aft of the ship; the third one was located in an unexposed beach of the island. Nine sampling campaigns were carried out. In each station a canister containing semipermeable membrane devices (SPMDs) and polar organic chemical integrative samplers (POCIS) was deployed at 10 m. depth, fixed at a buoy by scuba divers. Furthermore, at each canister, 9 diffusive gradients in thin films (DGTs) devices were attached. DGTs with three different resins have been used: Chelex-100 for Cd, Cr, Cu, Ni, and Pb; Fe-oxide for V; Spheron-thiol for Hg. Deployment time for all samplers ranged from 5 to 7 weeks. Repeatability was checked by the exposure of triplicate samplers. SPMDs and POCIS were extracted and analyzed for target compounds by GC/MS. Trace metals accumulated by DGTs were analyzed after elution by GFAAS. Mercury was determined with a direct mercury analyzer. SPMDs allowed the determination of dissolved PAHs, NPD, PCBs, OCPs, and PBDEs. POCIS were used to measure endocrine disruptors, such as alkylphenols, alkylphenol ethoxylates (APEs), and steroids. The results show higher concentrations of PAHs in the station near the bow of the ship, all along the monitoring period. A significant correlation with V measured by DGTs was pointed out, indicating a contamination by oil, more likely as a result of the yard activities. This work is part of a larger monitoring plan financially supported by the Italian Civil Protection.

#### TU123

##### **Equilibrium sampling of hydrophobic organic chemicals in sediments: challenges and new approaches**

S. Schaefer, Federal Institute of Hydrology / Department of Qualitative Hydrology; P. Mayer, Technical University of Denmark / Department of Environmental Engineering; B. Becker, Department of Qualitative Hydrology; C. Möhlenkamp, Federal Institute of Hydrology; E. Claus, Federal Institute of Hydrology BfG; F. Smedes, DELTARES / BGS

The exposure risk of contaminated sediments is traditionally assessed by exhaustive extraction methods that measure total concentrations ( $C_{total}$ ) including bound and freely dissolved contaminants. However, freely dissolved concentrations ( $C_{free}$ ) of hydrophobic organic chemicals (HOCs) are considered to be the effective concentrations for diffusive uptake and partitioning, and they can be measured by equilibrium sampling. We have thus applied glass jars with multiple coating thicknesses for equilibrium sampling of HOCs in sediment samples from various sites in different German rivers. The coated glass jars were very convenient for routine monitoring campaigns since (1) equilibration times are minimized by the very thin coatings, (2) the equilibration is done in the laboratory and (3) equilibrium sampling is confirmed by equal analyte concentrations in various silicone coating thicknesses without tedious time-serious measurements. However, for some sediment samples analyte concentrations decreased towards thicker silicone coating possibly caused by depletion of the sediment or equilibrium partitioning not being attained. In this study, we investigated the application of sediment depletion and kinetic uptake models. Sediment depletion was tested by the model for multi ratio equilibrium sampling (Smedes et al. ES&T 2013). If non-depletion was assumed by a sufficient capacity ratio between sampler and sediment ( $< 0.05$ ) and by low hydrophobic PCBs attaining equilibrium, the lower analyte concentrations in thicker silicone coating for more hydrophobic PCBs can be explained by non-equilibrium. Equilibrium concentrations in silicone were then determined by non-linear least square regression of analyte concentrations in polymer as a function of silicone mass using a first order kinetic model. Finally, the model was used to determine  $C_{free}$  of PCBs at different sites. Next to non-equilibrium partitioning for some compounds, we had difficulties in detecting target analytes such as p,p'-DDT in coated glass extracts despite high  $C_{total}$  in the respective sediment samples. We will demonstrate that microbial degradation can play a significant role during equilibrium sampling of biodegradable compounds even during short incubation times and despite confirmation of equilibrium partitioning.

#### TU124

##### **Evaluating the Effectiveness of Passive Sampling as a Surrogate for Organism Bioaccumulation**

A.S. Joyce, National Research Council U.S. EPA / Atlantic Ecology Division; R.M. Burgess, U.S. EPA / Atlantic Ecology Division

Measurement of hydrophobic organic contaminants (HOCs) and the subsequent evaluation of their ecological and human health risks are common endpoints in aquatic environmental monitoring. Due to their hydrophobicity, many anthropogenic HOCs will partition from the water into organic matter as well as into an aquatic organism's lipids. As such, the HOC concentrations in organismal tissues are often measured to evaluate bioavailability and the risks these HOCs can pose. Similar to lipid partitioning, HOCs have been found to partition into non-polar polymers – also known as passive samplers. Over the past several decades, passive sampling has become a widely accepted technique for quantifying

the freely dissolved concentrations ( $C_{free}$ ) of HOCs in the water column and sediment pore water. Polymers including polydimethylsiloxane (PDMS), low-density polyethylene (LDPE), and polyoxymethylene (POM) have become popular for quantifying  $C_{free}$ . In recent studies these passive samplers have been co-deployed with biomonitoring organisms. This work presents the results of a critical review comparing biomonitoring organism's lipid concentrations of several environmentally relevant HOCs (e.g., PCBs, PAHs, and halogenated pesticides) with concentrations accumulated by co-deployed passive samplers. Studies where the polymers PDMS, LDPE, or POM were directly compared to lipids from organisms including aquatic worms, bivalves, and midges were the primary focus of the review. Results from over 40 publications illustrated how passive sampler uptake of HOCs correlates to the bioaccumulation of HOCs by traditional biomonitoring organisms in the marine and freshwater environments. Linear regressions between lipid and polymer concentrations showed positive and statistically significant relationships where lipids had 1-20 times higher HOC concentrations (ng/g) than the polymers and the  $r^2$  values ranged from 0.3 – 0.99. These data suggest that in some applications, passive samplers could be used as surrogates for biomonitoring organisms.

#### TU125

##### **Remediation of dioxin-contaminated marine sediments using thin-layer capping with activated carbon and other sorbents: evaluation of bioavailability assessment techniques**

J. Gunnarsson, A. Gustafsson, Stockholm University / Department of Ecology Environment and Plant Sciences DEEP; S. Josefsson, Swedish University of Agricultural Sciences / Dept of Aquatic Sciences and Assessment; I.J. Allan, Norsk Institutt for Vannforskning; G. Cornelissen, NGI; M. Schaanning, Norwegian Institute for Water Research

Remediation of contaminated sediments *in situ* using thin-layer capping with carbonaceous materials such as activated carbon (AC) has proven successful in reducing the bioavailability and sediment-to-water release of hydrophobic organic compounds, e.g. PCBs, PAHs and dioxins, by several orders of magnitude. In two joint projects called CARBOCAP and OPTICAP, Swedish and Norwegian researchers have evaluated various capping materials for thin-layer capping *in situ*, using both mesocosms and large-scale field experiments. In the present study we collected sediment from a dioxin-contaminated area in the Grenlandfjord, Norway. The sediment was placed in boxcores and a thin-layer cap (1-5 cm) of either clay or crushed limestone was added to the surface. The caps were amended with two types of carbonaceous sorbents activated carbon (AC) or Kraft Lignin (KL). Two test organisms, a surface gastropod (*Nassarius nitidus*) and a deep burrowing polychaete (*Nereis* spp.) were added to the boxcores for bioaccumulation assays. Passive samplers (SPMDs) were placed in the water column and the boxcores were held at constant ambient temperature in a flow-through mode for 99 days. At the end of the experiment passive samplers, animals and sediment surface samples (0-3 cm) were collected for chemical analyses of dibenzo-*p*-dioxins and dibenzofurans, hexachlorobenzene, and octachlorostyrene. Bioavailability analyses of these compounds were conducted using synthetic digestive fluid extraction (DFE) or using Low-density Polyethylene pore water extraction (LDPE). Amendment with active sorbents (AC or KL) led to a significant reduction in bioaccumulation by the two test species. AC was more efficient than KL as sorbent. A 90% reduction in bioaccumulation was obtained with 3 cm caps with 3.3% AC. DFE and LDPE measurements both corresponded well with the bioaccumulation results. The addition of a 3 cm cap amended with AC measured by DFE resulted in a 93% reduced dioxin/furan-bioavailability, compared to a 91% reduction in the gastropod and a 75% in the polychaete. Our results are promising in terms of developing faster screening tools for assessing toxicity risks to biota from contaminated sediments, and to evaluate the efficiency of various capping materials, as these bioavailability methods are more rapid (days instead of months) and more cost-efficient compared to traditional bioaccumulation assays using live organisms.

#### TU126

##### **The Use of Passive Samplers to support the Short-term Performance Assessment of In Situ Remedial Treatment at Two Contaminated Sediment Sites**

V.J. Kirtay, SPAWARSYSCEN SAN DIEGO / Energy and Environmental Sustainability; J.M. Conder, Geosyntec Consultants; M.M. Grover, ENVIRON International Corporation; G.H. Rosen, SPAWAR Systems Center / Energy and Environmental Sustainability; B. Chadwick, SPAWAR Systems Center San Diego / Energy and Environmental Sciences

Passive samplers are being used as a part of a weight-of-evidence approach to evaluate the effectiveness of *in situ* remediation for reducing contaminant availability at two different contaminated sediment sites. At the first contaminated sediment site, two to three inches of AquaGate+PAC™ (a composite aggregate coated with activated carbon) was placed on a 0.5-acre target area to reduce polychlorinated biphenyl (PCB) bioavailability in sediment containing PCBs underneath and adjacent to an active pier. As part of the monitoring program, concentrations of freely dissolved PCB congeners in surface sediment pore water have been measured via *in situ* solid phase microextraction (SPME) at ten stations which received amendment both prior to and at 10- and 21-months following amendment placement. For each survey, passive samplers were constructed using twelve 12.5-cm pieces of fiber with 10-μm

thickness polydimethylsiloxane (PDMS) coating and a 210- $\mu\text{m}$  silica core diameter. The fiber pieces were placed in a 110- $\mu\text{m}$  stainless steel mesh envelope. Within two weeks of deployment the passive samplers were exposed to a solution containing PCB Performance Reference Compounds and stored at 4°C. On the day of deployment, each sampler was attached to a SEARing bioaccumulation chamber and deployed in situ for 14 days. Upon retrieval, each sampler was wrapped in foil and placed on ice for shipment to the laboratory for processing and analysis. At the second contaminated site, a similar approach is being used to evaluate the effectiveness of a thin layer cap for reducing the availability of DDT and its daughter products (DDx) to the benthic community. At this site, a six-inch layer of sand was placed over a 10-acre site. Concentrations of DDx were measured in sediment pore water in core samples collected from five on cap stations and two reference stations both prior to and at 12 months post cap installation. For this site, a similar approach was used to construct the passive samplers. However, because of the interest in evaluating the extent to which top-down versus bottom-up processes control the potential for recontamination of the cap surface, the core samples were sectioned and a passive sampler was added to each section and tumbled *ex situ* for two weeks prior to processing and analysis. Results from the pre-placement monitoring and post-treatment monitoring will be presented in terms of the effectiveness of the passive sampler to evaluate reductions in contaminant availability.

#### TU127

##### Using equilibrium passive dosing to maintain stable exposure concentrations of triclosan in a 6-week toxicity test

A. Sobek, Applied Environmental Science ITM; A. Ribbenstedt, Stockholm University; L. Mustajärvi, Stockholm University / Applied Environmental Science ITM; M. Breitholtz, Inst för tillämpad miljövetenskap / Department of Applied Environmental Science ITM; P. Mayer, Technical University of Denmark / Department of Environmental Engineering

Aquatic organisms are constantly exposed to hydrophobic organic contaminants. Although these chemicals may be present at low concentrations, they can still cause negative long-term effects on organisms. In chemicals risk assessment, the majority of the ecotoxicological data is based on acute toxicity tests. Yet, the European Commission's criteria for chemicals' risk assessments aim at protecting higher levels in the environment. To achieve protection of populations and ecosystems, reliable long-term ecotoxicological tests are needed. In this study, we used equilibrium passive dosing to maintain stable exposure concentrations of triclosan (log  $K_{ow}$  4.8) in a 6-week multigeneration test with the benthic copepod *Nitocra spinipes*. The tests were performed in 10 mL vials casted with 1000 mg of silicone (DC 1-2577). Based on a previous pilot study, three triclosan concentrations were selected and tested (15  $\mu\text{g L}^{-1}$ ; 30  $\mu\text{g L}^{-1}$ ; 60  $\mu\text{g L}^{-1}$ ) as well as a control (no triclosan). At test beginning, each vial contained 12 individuals consisting of 3 individuals from four different life stages. The test includes feeding with phytoplankton three times a week, which can lead to declining freely dissolved triclosan concentrations. In the present study this was buffered by passive dosing. Water was exchanged every 7<sup>th</sup> day by transferring the animals from the spend solution into a pre-equilibrated passive dosing glass. During the first two weeks, the copepods grow exponentially and can reach numbers of several hundred individuals in each vial. The increasing biomass of the test organisms can again lead to declining exposure concentrations, but such loss was buffered by passive dosing. Quality assurance tests showed that a) the loading and passive dosing procedures resulted in exposure concentrations with little variation (RSD 1-7 %), b) using two batches of passive dosing vials helped to maintain stable exposure concentrations, and c) the concentration of triclosan could be maintained throughout the whole 6-week test period. This study demonstrates that passive dosing offers a way forward to generate reliable and relevant toxicity data also from long-term studies with hydrophobic contaminants. The results on long-term toxicity of triclosan on *Nitocra* will be evaluated and discussed in relation to existing toxicity data from literature.

#### TU128

##### Effect-based monitoring of Danube river using mobile passive sampling approach

J. Novak, Masaryk University / RECETOX; B. Vrana, Masaryk University, Faculty of Science, RECETOX / RECETOX Research Centre for Toxic Compounds in the Environment; F. Smedes, DELTARES / BGS; T. Rusina, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; K. Okonski, Masaryk University Faculty of Science / RECETOX Research Centre for Toxic Compounds in the Environment; B.I. Escher, Helmholtz Centre for Environmental Research GmbH - UFZ / Cell Toxicology; M. Macova, The University of Queensland / National Research Centre for Environmental Toxicology Entox; P.A. Neale, Griffith University / Smart Water Research Centre; S. Ait-Aissa, INERIS / Ecotoxicology Unit; N. Creusot, INERIS; K. Hilscherova, Masaryk University, Faculty of Science, RECETOX / RECETOX Research Centre for Toxic Compounds in the Environment

Surface waters are often polluted by complex mixtures of pollutants whose toxic properties are relatively difficult to describe. Effect-based monitoring with a battery of bioassays represents an efficient approach for toxicological profiling and identification of samples of major interest through providing data of the toxic potencies and mode of action of the extracted mixtures that cannot be evaluated by

chemical analysis alone. In our work we used an "active" passive sampling system (APS) for temporally and spatially integrative sampling using silicone rubber and EMPORE disc based passive samplers, which efficiently preconcentrate a wide spectrum of polar and non-polar organic pollutants from the water column along a defined river stretch. This concept was employed during Joint Danube Survey 3 in summer 2013. Eight Danube river stretches were sampled to cover spatial distribution of the pollutants characterized through a set of bioassays investigating presence of contaminants with several non-specific and important specific toxic modes of action. Presence of contaminants with potentials for causing endocrine disruption (anti/estrogenic anti/androgenic), dioxin-like activities, potential to elicit adaptive stress responses associated with oxidative stress, p53-mediated apoptotic response and NF- $\kappa$ B-associated inflammatory response were characterized in samples from different river stretches. This wide range of assessed endpoints serves as a toxicological profiling tool to describe risks associated with fresh water pollutant mixtures. The obtained results also serve for spatial characterization of pollution gradients along the river and selecting hotspots for further studies. This research was supported by SOLUTIONS Project from the European Union Seventh Framework Programme (FP7-ENV-2013-two-stage Collaborative project) under grant agreement 603437.

#### TU129

##### Time Integrative Passive sampling combined with Toxicity Profiling (TIPTOP): an effect based strategy for cost-effective chemical water quality assessment

T. Hamers, VU University Amsterdam, Institute for Environmental Studies (IVM) / Institute for Environmental Studies; F. Smedes, DELTARES / BGS; J. de Weert, DELTARES; L. Posthuma, D. De Zwart, RIVM / Centre for Sustainability Environment and Health; P. Leonards, VU University, Institute for Environmental Studies / Institute for Environmental Studies IVM

Within the European Water Framework Directive (WFD) chemical water quality is assessed by comparing concentrations of predefined individual priority pollutant to their Environmental Quality Standard (EQS). This approach ignores not only non-analyzed (known or unknown) compounds that may contribute to the toxic burden of the water, but also mixture effects. In addition, it is based on a time-point grab sample that may miss incidental peak concentrations. We hypothesize that a combined approach of time-integrative passive sampling followed by toxicity profiling is not only a toxicologically and ecologically more relevant and more protective alternative for chemical water quality assessment, but also a more cost-effective alternative. For this purpose a demonstration study is designed at well-defined WFD sampling sites in the Dutch delta. Time-integrative sampling is performed using partitioning-based and adsorption-based passive samplers. Toxicity profiling is performed using a test battery consisting of *in vitro* and *in vivo* bioassays. Given the different mechanisms of action covered by the *in vitro* bioassays and the different trophic levels covered by the *in vivo* bioassays, the applied battery can be regarded as "safety net", signaling the mixture effect of toxic compounds at low concentrations. Ultimately, different approaches will be used to determine the surface water chemical status, i.e. (1) by the classical WFD assessment based on priority compound analyses, (2) by calculating the observed chemical profile into a toxicity profile and compare that to the actually observed toxicity profile, and (3) by a toxicological or ecological interpretation of the observed toxicity profile itself. The toxicological interpretation is based on a comparison to "worst case" toxicity profiles from waste-water treatment plant effluent or to trigger values for bioassays. The ecological interpretation is based on a comparison between predicted ecological effects and the actual ecological status and on the assessment of a margin of exposure in the field situation to expected ecological effects. The combined approach of passive sampling and toxicity profiling will be evaluated according to SWOT principles, using experiences from TIPTOP, previous studies from the partner institutes, and similar studies published in open (grey and peer-reviewed) literature. The outcome should ultimately lead to a proposal for a cost-effective approach for chemical water quality assessment.

#### TU130

##### Transferring the chemical activities of chemical mixtures from sediment to toxicity tests using silicone-based passive sampling and dosing

L. Mustajärvi, Stockholm University / Applied Environmental Science ITM; A. Jahnke, Stockholm University / Department of Cell Toxicology; A. Wiklund-Eriksson, ITM Stockholm University / Applied Environmental Science ITM; A. Sobek, Applied Environmental Science ITM

This study aims at validating an approach for transferring mixtures of the bioavailable fraction of hydrophobic organic contaminants (HOCs) from sediment to toxicity tests, using a combination of passive sampling and dosing. The approach consists of five steps: 1) partition-based sampling of HOCs into a sampling polymer; 2) solvent extraction of HOCs from the sampling polymer; 3) transfer of the HOC extract into a dosing polymer; 4) equilibration of the HOCs in the dosing polymer with the test medium; 5) *in vivo* toxicity test, with algae. The freely dissolved fraction of HOCs in sediment was sampled by silicone-coated glass jars (e.g. Reichenberg et al. 2008, Jahnke et al. 2012), a method which has been used successfully for sediment and soil samples. Each jar contained approximately 180 g wet sediment. The silicone thickness in the jars was modified to 30  $\mu\text{m}$  (0.3 g) to increase the sampling capacity. After three weeks of sampling, established as sufficient time to reach equilibrium by using different coating thicknesses, the

HOCs were extracted with acetone:n-hexane (1:1, v/v), and transferred to the dosing polymer (500 mg) cast in 10 mL vials (e.g. Smith et al. 2010). The loading of the dosing polymer with the HOC extract retrieved from sediment is a critical step, as it must have high precision, be quantitative and avoid swelling of the silicone. At the same time the extract, containing the complex mixture of hydrophobic substances extracted from the sediment, does not dissolve in e.g. methanol which is otherwise suitable for loading (e.g. Smith et al. 2010). For quality assurance, the loading step was evaluated using mixtures containing PCBs and PAHs at known concentrations. Furthermore, the whole sampling and dosing procedure was validated by tests with spiked sediment, using triclosan as test compound. The toxicity of increasing concentrations of the mixture of chemicals transferred from sediment will be assessed with respect to phytoplankton cell viability and growth rate. ### TU131

#### Comparison of passive and standard dosing of polycyclic aromatic hydrocarbons to the marine algae *Phaeodactylum tricornutum*

G. Witt, HAW Hamburg / Department of Environmental Engineering; N.C. Niehus, Hamburg University of Applied Sciences (HAW) / Department of Environmental Engineering; K. Konopka, Hamburg University of Applied Sciences HAW / Environmental Engineering; P. Mayer, Technical University of Denmark / Department of Environmental Engineering; C. Floeter, HAW Hamburg / Department of Environmental Engineering

Testing hydrophobic organic compounds (HOCs), like polycyclic aromatic hydrocarbons (PAHs), in aquatic toxicity tests is difficult due to compound losses through volatilization, sorption to the test vessel and culture medium constituents. This results in poorly defined exposure, the bioavailable concentration is reduced and concentration-effect-relation might be underestimated. Passive dosing can overcome these problems by the continual partitioning of HOCs from a dominating reservoir loaded in a biologically inert polymer such as silicone. This procedure provides defined and constant freely dissolved concentrations and eliminates spiking with cosolvents. Passive dosing using silicone O-rings as donor and PAHs as test substances (fluoranthene, naphthalene, phenanthrene, acenaphthene, fluorene, benzo[a]pyrene, anthracene and pyrene) were applied in the marine algal growth inhibition test with *Phaeodactylum tricornutum* (based on ISO EN 10253) in 24-well microtiter plates. The O-rings were loaded by partitioning from methanol solutions or suspensions of the respective PAHs (1), and these loaded O-rings were added to the wells in test media before the beginning of the test. Agitation of the plates was used to speed up the release from the O-rings. The toxicity of the individual PAHs was investigated at controlled concentrations up to their aqueous solubility in artificial seawater. The concentration-dependent growth inhibition of *Phaeodactylum tricornutum* was then compared for passive dosing and standard dosing according to the standard marine algae test procedure on microtiter plates. A comparison of the EC<sub>50</sub> values of passive dosing vs. EC<sub>50</sub> values of standard dosing showed an underestimation of the effects when using nominal standard dosing probably due to sorption, evaporation and limiting dissolution kinetics. Furthermore, passive dosing concentration-response curves were more reproducible and shifted towards lower concentrations. Results show that the response is clearly not only dependent on the potency of the compounds, but also on its supply, sorption and consumption during the assay. Passive dosing is a practical and economical way of improving the exposure of HOCs in aquatic toxicity or bioconcentration tests like the algae growth inhibition test. \n (1) K. E.C. Smith, N. Domb, R. Blust, P. Mayer (2010) Controlling and maintaining exposure of hydrophobic organic compounds in aquatic toxicity tests by passive dosing. *Aquatic Toxicology* 98, 15–24.

### TU132

#### The integration of passive samplers and bioassays to evaluate the water quality of an estuary affect by an effluent plume: case study in the Oiartzun estuary (southeastern Bay of Biscay)

M. Belzunce Segarra, Azti-Tecnalia / Marine Research; N. Montero, Azti-Tecnalia; J. Gonzalez, IFREMER; J. Garmendia, AZTI / Marine Research Division; I. Menchaca, Marine Environment Department; J. Franco, Azti-Tecnalia

The Water Framework Directive (WFD; 2000/60/EC) aims to achieve a 'good ecological and chemical status' for all European water bodies by 2015. However, it focuses on the biological elements of the system; therefore, it would be convenient to measure the contaminant concentration that could be more easily related to potential biological effects. The aim of this study is to evaluate the applicability of techniques based on the freely dissolved metal concentrations to characterize the impact of an effluent plume. In order to determine the effect of environmental variables in the speciation of metals and its associated toxicity, sampling campaigns were performed in dry and wet conditions. The Oiartzun estuary (southeastern Bay of Biscay) was selected, as it has been historically contaminated by the surrounding industries and shipyard activities. Twelve stations were chosen along the estuary and water contamination was assessed by means of DGTs. Also, at the outermost stations, located inside the harbour domain, *in situ* sea-urchin bioassays (48 h) were performed and water samples were collected during a tidal cycle. In the laboratory, the toxicity of composite water samples collected during the tidal cycle was

evaluated by the sea-urchin bioassay and Toxicity Identification and Evaluation procedures (TIEs) were applied to identify the chemicals responsible of the observed toxicity. TIEs consist on the physical/chemical manipulation of the samples to reduce the bioavailability of specific contaminants and to establish cause-effect relationships. Different metal distribution patterns were observed in dry and wet conditions by means of DGTs. In general, a decrease in metal concentrations from the inner stations to the mouth of the estuary was observed. Moreover, a pollution gradient was observed from the inner part of the harbour domain to the mouth of the estuary, as demonstrated by the improvement of sea-urchin larvae development in laboratory and *in situ* bioassays. Additionally, metals were identified as the contaminants responsible of the observed toxicity by means of TIEs. On basis of our results, the application of techniques based on contaminants labile concentration seems promising for the assessment of the impact of effluents. *Key words:* estuary, DGT, *in situ* bioassays **PLATFORM**

### TU133

#### Analysis and ecotoxicological investigations on poorly soluble cosmetic compounds - Project ECOSM

F. Stibany, RWTH Aachen / Institute for Environmental Research Biology; K. Rettinger, IKW Industrieverband Koerperpflege.; J. Steber, German Cosmetic Toiletory, Perfumery and Detergent Association; A. Coors, ECT Oekotoxikologie GmbH; C. Schulte, Umweltbundesamt / Chemicals; H. Hollert, A. Schaeffer, RWTH Aachen University / Institute for Environmental Research

Cosmetics include a broad range of highly hydrophobic compounds that are poorly soluble in water, i.e. far below 1 mg/L. Due to the high cosmetics production and the typical 'rinse off' application, substantial amounts of these poorly soluble chemicals end up in waste-water treatment plants and may subsequently enter aquatic systems with the effluent. Additionally the highly hydrophobic properties of the substances result in extensive adsorption to surfaces like test vessels and organisms. Thus, difficulties in maintaining constant test concentrations occur in standard ecotoxicity tests and may lead to improper environmental risk assessments. One possibility addressing this problem is the 'poorly solubles approach' defining an 'ecotoxicological threshold concentration of no concern' (ETNC<sub>aqua</sub>) for inert substances with a narcotic mode of action. Substances with solubility below this threshold concentration (1.9 µg/L) are expected to have neither acute nor long-term adverse effects on aquatic organisms. The aim of the project is to develop pragmatic tools to test the ETNC<sub>aqua</sub> hypothesis in order to allow better environmental risk assessment of poorly soluble substances. The surfactant precursor Dodecylbenzene (DDB) has been selected as a suitable model compound reflecting substance properties of the poorly soluble approach. DDB has a calculated log K<sub>ow</sub> of 8.65. Gas chromatography/mass spectrometry (GC/MS) has been successfully developed allowing the detection of concentrations below the solubility threshold. The maximum solubility in distilled water, Elendt M4 Daphnia medium, and algae medium was determined. Passive Dosing, a promising tool which allows a controlled release of the substance from an inert reservoir (i.e. silicone) to the test medium up to its solubility limit, compensating losses by sorption and degradation, has been successfully adapted to DDB, resulting in sufficiently stable concentrations near and below the ETNC<sub>aqua</sub>. It was also shown, that Passive Dosing can be applied for liquids like DDB (previously shown mainly for solid substances). First acute and chronic ecotoxicological tests with organisms of different trophic levels as proposed by OECD guidelines (algae, daphnids, and fish-eggs) have been performed to verify the 'poorly solubles approach' according to the ETNC<sub>aqua</sub> hypothesis.

### TU134

#### Contribution of organic contaminants to marine phytoplankton dynamics: an experimental approach

G. Everaert, Ghent University / Laboratory of Environmental Toxicology and Aquatic Ecology; F. De Laender, Université de Namur ASBL / Laboratory of Environmental Ecosystem Ecology; M. Claessens, DuPont de Nemours; J. Baert, Ghent University / Bioscience Engineering; E. Monteyne, Royal Belgian Institute of Natural Sciences MUMM / Management Unit of the North Sea Mathematical Model; P. Roose, Royal Belgian Institute of Natural Science - MUMM; P. Goethals, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology; C. Janssen, University of Ghent / Laboratory of Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

Despite their low freely dissolved concentrations, organic contaminants can cause ecotoxicological effects in marine biota owing to their persistency and bio-accumulative potential. Therefore, organic contaminants should be seen as a potential driver impacting the marine environment. In the present research, the specific growth rate of the marine diatom *Phaeodactylum tricornutum* was studied in an algal growth inhibition test using a full factorial design with the following factors: three nutrient regimes (14 µmol P.L<sup>-1</sup> & 588 µmol N.L<sup>-1</sup>; 2.8 µmol P.L<sup>-1</sup> & 120 µmol N.L<sup>-1</sup> and 0.7 µmol P.L<sup>-1</sup> & 30 µmol N.L<sup>-1</sup>), two water temperatures (16°C and 23°C), three illumination conditions regimes (100, 250 and 400 µmol/m<sup>2</sup>.s) and three chemical exposures (a blank control, a growth control and the actual exposure). Passive samplers were used to achieve exposure to ambient concentrations of organic contaminants after a deployment period of 15 weeks along the Belgian coast. We found that organic contaminants did not alter the specific growth rate of the marine diatom *Phaeodactylum tricornutum* in the first 72h of an algal growth inhibition test. The moment of sampling and the nutrient

regime explained about 65% of the observed variability in the data. Taking into account water temperature as an extra covariate increased the explained variability to almost 80%. The contribution of organic contaminants to the model fit was estimated to be 1%, but was not significant at a 5% level of significance. Most of the variability in the specific growth rate of the marine diatom was explained by the moment of sampling, the nutrient regime and the water temperature. More research is needed to confirm the preliminary results that are reported here.

### TU135

#### Calibration and field evaluation of passive samplers as a new tool for monitoring pesticides in water

A. Daneshvar, A. Lau, Swedish University of Agricultural Sciences; M. Gönczi, SLU / Centre for Chemical Pesticides; J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides; L. Ahrens, Swedish University of Agricultural Sciences (SLU) / Dept of Aquatic Sciences and Assessment

The continuous emission of pesticides into the aquatic environment is posing a risk to wildlife and human health. Hence, there is a need for reliable monitoring tools for priority pollutants including pesticides in surface waters. Passive sampling techniques have been developed to improve water quality assessment to determine time-integrated pesticide concentrations at ultra-trace levels and with minimal infrastructure. Five different types of samplers including i) polar organic chemical integrative sampler (POCIS)-A, ii) POCIS-B, iii) silicone rubber (SR), iv) Chemcatcher® SDB-RPS, and v) Chemcatcher® C18 were characterized in terms of sampling rates ( $R_s$ ) and sampler-water partition coefficients ( $K_{pw}$ ) for 124 pesticides. In addition, the performance of three types of passive samplers (i.e. POCIS-A, SR, and Chemcatcher® C18) were investigated in two Swedish river systems over a period of six weeks, and passive sampler-derived concentrations were compared against time-integrated active sampling. The results showed that the passive samplers were capable to accumulate pesticides with a wide range of KOW. SR shows a better uptake for the more hydrophobic compounds, whereas POCIS-A, POCIS-B, and Chemcatcher® SDB-RPS are more suitable for hydrophilic compounds. The median  $R_s$  (L day<sup>-1</sup>) were 0.86 for SR, 0.22 for POCIS-B, 0.18 for POCIS-A, 0.05 for Chemcatcher® SDB-RPS, and 0.02 for Chemcatcher® C18. The median of log  $K_{pw}$  (L kg<sup>-1</sup>) were 4.78 for POCIS-B, 4.56 for POCIS-A, 3.17 for Chemcatcher® SDB-RPS, 3.14 for SR, and 2.71 for Chemcatcher® C18. Comparison of time-weighted average (TWA) concentrations for active and passive samplers in the field showed a good agreement. In total 52 pesticides were detected in the two rivers using active sampling, while 69, 58, and 32 pesticides were detected using the passive samplers SR, POCIS-A, and Chemcatcher® C18, respectively. There were 4 pesticides (i.e., clopyralid, fluroxypyr,  $\gamma$ -HCH, phenmedipham) that could only be detected by the active sampler. On the other hand, passive samplers detected in total 38 pesticides, which were not detected by the active sampler. The outcome of this study indicates that the passive samplers are suitable as a monitoring tool; however, the reliability of the passive sampler-derived TWA concentrations needs to be improved to apply passive samplers for regulatory purposes, for example in respect to the EU Environmental Quality Standards (EQS).

### TU136

#### Automated Thin Film Microextraction (TFME) of ivermectin from streaming water

M. Wohde, Institute of Soil Science; J. Bartz, K. Martin, Justus Liebig University Giessen / Institute of Soil Science; R. Düring, Justus Liebig University Giessen / Institute of Soil Science and Soil Conservation Research Centre for BioSystems Land Use and Nutrition IFZ

In this study, the potential of Thin Film Microextraction (TFME) as the future Solid-Phase Microextraction (SPME) for HPLC environmental analysis is investigated. With its comparatively large extraction surface, beneficial extraction kinetics and efficiency for aqueous samples can be realized. The special geometry of the coated supports ("blades") - adapted to the common HPLC equipment - enables a reproducible automated sampling and sample preparation. The innovative TFME was embedded in an automated sampling system. With this, it is possible to extract liquid samples out of 12 individually valve-controlled flow through channels. In this way, defined volumes can be extracted automatically with defined extraction times. This enables for example to measure sorption kinetics within method development in a very elegant way. To further increase the extraction efficiencies and thus to reduce the needed extraction times, the blades are shaken by an overhead shaker at 1,000 rpm in the aqueous medium. After extraction, the analytes can be eluted immediately into HPLC vials or be analyzed directly by coupling with the Desorption Electrospray Ionization High Resolution Mass Spectrometry (DESI-HRMS) avoiding both elution and chromatography. The system has been applied in an ecotoxicological field study with a streamline mesocosm. Within this, it was possible to automatically study the dissipation of the lipophilic and highly sorptive antiparasitic agent Ivermectin. The special features of this system allowed for a highly time-resolved sampling which is crucial with regard to acute effects of the analyte in the aquatic system. With the elegant external dosage of an internal standard before extraction, it was possible to normalize variance of the individual blades. Different coatings (PDMS, C-18 and PS-DVB) were compared. The poster illustrates the system itself and furthermore presents results of method development, validation and application. With recovery rates >

80 % and relative standard deviations (RSD) of well below 10 %, the method can be considered principally suitable as a tool for highly time-resolved sampling of surface waters with simultaneous extraction of environmental contaminants such as the antiparasitic agent Ivermectin.

### TU137

#### Passive dosing of pyrethroid insecticides to *Daphnia magna*: Expressing excess toxicity by chemical activity

S.N. Schmidt, Technical University of Denmark / Department of Environmental Engineering; J. Gan, University of California, Riverside / Department of Environmental Science; A.C. Kretschmann, University of Copenhagen; N. Cedergreen, University of Copenhagen / Department of Plant and Environmental Sciences; P. Mayer, Technical University of Denmark / Department of Environmental Engineering

Pyrethroid insecticides are nerve poisons and used as active ingredients in pesticide mixtures available for household and agriculture. The compounds are hydrophobic, and their strong sorption to organic material may result in decreasing exposure levels during toxicity tests and consequent underestimation of pyrethroid toxicity. This poster addresses three questions regarding the acute toxicity of pyrethroids towards the aquatic invertebrate *Daphnia magna*: (1) Is pyrethroid toxicity generally underestimated in the literature due to insufficiently controlled exposure levels? (2) At which chemical activity do pyrethroids exert their toxicity, and how similar are the effective chemical activities ( $Ea_{50}$ ) for different pyrethroids? (3) How much more toxic are pyrethroids relative to baseline toxicity? Toxicity experiments were conducted using passive dosing: Polydimethyl siloxane (PDMS) silicone was loaded with  $\gamma$ -cypermethrin, esfenvalerate and bifenthrin, respectively, and then applied to control the exposure to *D. magna* for 48 h by equilibrium partitioning. In this way, the exposure was kept constant since various losses were efficiently buffered by re-partitioning from the polymer. Based on results from the conducted passive dosing experiments and literature data, the three questions will be addressed in the following manner: (1) The effective concentration resulting in 50% immobilisation ( $EC_{50}$ ) will be determined for each of the three pyrethroids and compared to literature values, (2) Effective chemical activities resulting in 50% immobilisation ( $Ea_{50}$ ) will be estimated from pyrethroid  $EC_{50}$  values via the correlation of sub-cooled liquid solubility ( $S_L$ , [mmol/L], representing  $a=1$ ) and octanol to water partitioning ratios ( $K_{ow}$ ), (3) The excess toxicity observed for pyrethroids will be evaluated by comparing  $Ea_{50}$  values for individual pyrethroids to the chemical activity needed to initiate baseline toxicity ( $a=0.01-0.1$ ).

### TU138

#### Exploring the role of herbicide mixture exposure on streams in the degradation of macrophyte communities.

r. carafa, LIST / ERIN; S. Marley, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; T. Galle, CRP Henri Tudor / CRTE; R. Altenburger, UFC Centre for Environmental Research / Department of Bioanalytical Ecotoxicology; M. Bayerle, CRP Henri Tudor

Approximately 44% of the total land area in the European Union is used for agricultural purposes and there are over 1000 pesticides available for use. Pesticide contamination has been shown to exert pressure on surface waters by having negative effects on non-target species, from point and diffuse pollution sources. Given the huge number of possible combinations of pesticides, it is necessary to determine areas that are high risk for pesticide contamination and the compounds that are most likely to pollute a given area. Such pollution may result in a direct impact on autotrophic species, as well as an indirect impact on freshwater communities through primary production degradation. Surface water bodies in Luxembourg often fail to achieve good ecological status due to a paucity of macrophytes and poor quality macrophyte communities. The situation calls for the clarification of cause-to-effect relationship between herbicides mixture exposure and macrophyte population deficits. Using Luxembourgish Rivers as case study, the role of herbicide loading on the degradation of macrophyte communities is explored coupling field measurements of the temporal and spatial distribution of herbicide loading, and mixture toxicity effect models, calibrated with ad-hoc laboratory bioassays based on field extracts. Catchment area, soil permeability, agricultural land use, substrate composition, and water quality (based on the Biological Macrophytes Index for Rivers), were all taken into account to determine representative and high risk sites. In order to identify high risk substances, crop type and production, historical and projected sales data, compound characteristics, compound toxicity, and historical monitoring data, were all used. Field monitoring campaigns took place in spring and spanned eight months over two years (2013-2014). Passive samplers POCIS were used to monitor loading of sixteen selected high-risk herbicides in a total of 24 sites. In addition physicochemical parameters and river flows were also monitored. POCIS samples extracts were in part analysed to determine the time-weighted average of herbicide load during the exposure period and in part used in laboratory bioassays to expose a reference autotroph to real mixtures. These data were then used to investigate and predict cause-effects relationships between the herbicidal mixtures exposure and macrophyte community biodiversity, also taking into account nutrients/organic and morphological pressures.

### TU139

#### Atmospheric deposition of inorganic contaminants in Alaska as measured by

#### **ion-exchange passive samplers and moss biomonitors (*Hylocomium splendens*)**

B.G. Brumbaugh, US Geological Survey / Columbia Environmental Research Center; J. Arms, USGS Columbia Environmental Research Center; P. Neitlich, National Park Service

At remote locations, the use of conventional systems for monitoring deposition of atmospheric pollutants over extended time intervals is generally not practical; consequently, sampling methods that require minimal maintenance and no power for operation are needed in these areas. Mosses have been successfully used as biomonitors in many studies, particularly in northern Europe; however, few studies have examined relations between accumulation of atmospheric contaminants by mosses and actual deposition. We compared accumulation of selected inorganic atmospheric contaminants in one- and three-year moss growth segments to contemporaneous deposition, the latter as measured by a combination of over-winter snowpack samples and specially adapted, passive ion-exchange collectors (IECs). Sampling was conducted at eight sites within interior Alaska, some of which were located near known sources of atmospheric contaminants so that depositional gradients might be measured. Snow and IEC extracts were analyzed for major cations (ammonium, calcium, magnesium, potassium, sodium); major anions (chloride, nitrate, nitrite, sulfate); and a suite of trace metals including cadmium, copper, nickel, lead, and zinc. Annual growth segments of moss tissue samples were analyzed for total nitrogen, total sulfur, extractable cations and anions, and trace metals. Relations between moss concentrations and annual deposition as measured by IEC passive samplers and snowpack samples will be examined to develop exploratory empirical models that characterize bioaccumulation of atmospheric pollutants by the moss.

#### **TU140 SPANISH AIR MONITORING OF ORGANOCHLORINE PESTICIDES, PCBs, PCDD/Fs, AND PBDEs**

P. Sanz, A.d. Torre, I. Navarro, M. Martínez, CIEMAT

The Stockholm Convention (SC), is a global treaty to protect human health and the environment from Persistent Organic Pollutants (POPs). This Convention, coming into effect in 2004, requires Parties to take measures to eliminate or reduce the release of POPs into the environment. Since 2007, the Ministry of the Agriculture, Food and Environment manages the Spanish Implementation Plan (SIP). The main objective of the SIP is to establish a national monitoring network to characterize the current status and temporal trends of POPs and to evaluate the effectiveness of practices adopted to reduce POP emissions. In 2008 this network began monitoring POPs in air but, afterwards, it has been extended to other matrices such as soil and water. The aim of this study, framed in the SIP of the SC, was to investigate the POP levels in Spanish air using passive air samplers (PASs) with polyurethane foam disks (PUF disks) as the sorbent media. These PASs are advantageous because of their low cost, simple construction, and electricity-free operation. Remote locations from an existing sampling network in Spain (European Monitoring and Evaluation Program (EMEP) / Global Atmospheric Watch (GAW) / Control Atmospheric Monitoring Program (CAMP)), and urban sites close to the remote locations, were chosen as monitoring points. Target analytes were PCDDs, PCDFs, dl-PCBs, i-PCBs, DDTs, HCB, HCHs and PBDEs. Global results revealed HCB, DDTs and HCHs as the major pollutants with similar concentrations, followed in decreasing order by PCBs, PBDEs and PCDD/Fs. However, this pattern varies when samples collected in urban areas are evaluated separately of those associated with remote locations. Statistically significant differences ( $p < 0.05$ , Mann-Whitney U test) related to remote and urban areas have been found for all the families studied, except for HCB. These differences are due to the higher levels that present urban areas compared to remote locations. The data obtained in this study are used to elucidate the background concentrations and their potential sources, resulting very interesting for the proper evaluation of the measures taken to reduce the POP levels into the environment. The present work has been funded by the Spanish Ministry of Agriculture, Food and Environment through the project "POP monitoring in some matrices and areas of interest".

#### **TU141 A passive air sampler for elemental mercury monitoring in air**

F. Wania, University of Toronto at Scarborough / Department of Physical and Environmental Sciences; D.S. McLagan, University of Toronto Scarborough / Chemistry; C. Mitchell, University of Toronto Scarborough / Dept of Physical and Environmental Sciences; Y. Lei, University of Toronto Scarborough / Departments of Chemistry and of Physical and Environmental Sciences; P. Huang, University of Toronto Scarborough / Dept of Physical and Environmental Sciences; A. Cole, H. Hung, Environment Canada / Air Quality Processes Research Section; A. Steffen, Environment Canada

Mercury as a contaminant is under international scientific and regulatory scrutiny due predominantly to its adverse effects on human health. These effects are caused largely by consumption of bioaccumulative methyl-mercury in seafood. However, it is in its gaseous elemental form (GEM; atmospheric lifetime ~1 year) that mercury achieves global distribution. The Minamata Convention, which aims to reduce mercury emissions globally, has created the need for an economical way to monitor time-averaged atmospheric GEM concentrations, including at remote and hard-to-access sites, for long periods of time. We are presently developing and testing a passive air sampler aimed at addressing this need. The major difficulty of

passive air sampling in such environments is the high level of precision required due to the small fluctuations in GEM concentrations caused by its atmospheric persistence. Another potential application is the cost-effective mapping of GEM concentrations in source areas at high spatial resolution. The sampler consists of a stainless steel mesh cylinder filled with activated carbon placed in a commercially produced radial diffusive barrier and housed in an PET external windshield, which doubles as a storage and transport container. Indoor and outdoor experiments were performed, in which multiple samplers were deployed for increasing periods of time ranging from a few days to a year alongside an automated sampler that continuously recorded GEM concentrations. The empirical sampling rate is on the order of 0.1 m<sup>3</sup>/day, in good agreement with a sampling rate theoretically estimated assuming molecular diffusion as the rate limiting step in the uptake kinetics. Future work will include the further characterisation of the sampler's uptake kinetics and uptake capacity and their dependence on factors such as temperature, wind speed, relative humidity, and ambient GEM concentrations.

#### **TU142 Concentrations in air and potential emission sources of POPs in Chittagong, Bangladesh**

T.H. Nøst, S. Randall, Cowi AS; M. Schlabach, Norwegian Institute for Air Research; A. Paul, A. Rahman, University of Chittagong; K. Breivik, Norwegian Inst. for Air Research

At present there is limited information on concentrations of POPs (persistent organic pollutants) in air in many developing regions compared to those of industrialized countries. However, several studies have demonstrated surprisingly high levels of various legacy POPs in some developing countries, e.g. because of continued use of organochlorine pesticides or emissions of industrial-use POPs from informal recycling and disposal of e-waste (electrical and electronic waste). However, the potential emissions of POPs from informal ship breaking activities in developing regions remains to be assessed. Global estimates for 2012 reveal that 1,250 ocean ships were scrapped in this year alone, and the beaches on the Chittagong coast in Bangladesh is one of the areas of most intense ship breaking in the world. The ship breaking activities in this area have caused concern for both environmental and human health because of various contaminants released from - or emitted as a result of - these activities. The aim of the study was to monitor the concentrations of polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), polybrominated diphenyl ethers (PBDEs) and organochlorine pesticides in air in the urban environment of Chittagong city (population approximately 4 million) and in vicinity of the ship-breaking areas. A sampling campaign was carried out using passive air samplers (PASs) based on polyurethane foam (PUF) at 23 sites in February 2013. PUF was selected as sampling material because their performance is well characterized as they have previously been used extensively for spatial mapping on both a regional and global scale. Performance reference compounds (PRCs) were furthermore used for back-calculating air concentrations. The results from the campaign in Chittagong will be compared and contrasted with concentrations of POPs in air reported from both developed and developing regions, and to discuss potential sources and source regions controlling the atmospheric burden of various POPs in the study area.

#### **TU143 Occurrence of Persistent Organic Pollutants in Argentina, South America: use of passive atmospheric sampler (PAS) vs. pine needles**

K.S. Miglioranza, University of Mar Del Plata / Lab of Ecotoxicology and Environmental Pollution; P.M. Ondarza, Universidad Nacional de Mar del Plata / Lab de Ecotoxicología y Contaminación Ambiental Depto Ciencias Marinas; P. Gomes Costa, Universidade Federal do Rio Grande FURG / Laboratório de Microcontaminantes Orgânicos e Ecotoxicologia Aquática; M. Gonzalez, UNMdP / Lab Ecotoxicologia and Environmental Pollution UNMdPCONICET; F. Mitton, Universidad Nacional De Mar Del Plata; S. Gronдона, University of Mar Del Plata CONICET; M. Silva Barni, Ciencias Marinas; F. Wania, University of Toronto at Scarborough / Department of Physical and Environmental Sciences; R. Barra, Universidad de Concepcion / Facultad de Ciencias Ambientales Eula; G. Fillmann, Universidade Federal do Rio Grande / Institute of Oceanography

Persistent organic pollutants (POPs), included in the Stockholm Convention, are chemicals of global concern due to their persistence, long-range transport and toxicity. Atmospheric transport is responsible for pollutant dispersal over long distances. As part of the Latin American Atmospheric Passive Sampling Network (LAPAN), a monitoring program involving the use of pine needles and passive air samplers (PAS) was conducted. PAS using XAD-2 resin as a sorbent were deployed for three consecutive one-year periods (2010-2013) at seven sites in agricultural, urban, industrial and natural areas throughout different regions of Argentina. The latitude of the sites ranged from Bahía Blanca (38°42'S-62°16'W) in Buenos Aires Provinceto Río Gallegos (51°38'S-69°14'W), the southernmost site of Argentina. The main objectives of the project were: 1- To gather new data on atmospheric pollution (at improved spatial and temporal resolution); 2- To assess the influence of local and global sources by deploying PAS in rural, industrial, urban and remote areas; 3- To compare the occurrence and distribution of POPs in PAS and pine needles. Organochlorine pesticides (OCPs), polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs) were determined by GC-PCD and GC-MS and concentrations expressed in units of pg/m<sup>3</sup>. At sites at lower latitudes, which are close to agricultural zones endosulfans (150 pg/m<sup>3</sup>) were

the predominant POPs in air, with a relative abundance of a-/b-isomers similar to that of the technical mixture (7:3). DDTs levels were also higher at lower latitudes with a predominance of the parent DDT (100 pg/m<sup>3</sup>). On the other hand, PCBs concentrations, ranging from 3.7 to 46 pg/m<sup>3</sup>, increased with latitude with higher average values at Río Gallegos with a predominance of lower chlorinated congeners (#18, 44, 52, 118). The industrial area of Bahia Blanca appears to be a source of PBDEs (8.3 pg/m<sup>3</sup>), increasing in strength from 2010 to 2013. Our previous results for pine needles showed a similar pollutant distribution pattern as the PAS. However, metabolites (DDE, endosulfan sulfate, heptachlor epoxide) were more dominant in pine needles. Although both samplers were useful to assess the atmospheric pollution by POPs, an integrated study using PAS and biological samplers is suggested in order to understand the behavior of these compounds in the atmosphere.

#### TU144

##### **Air-water exchange, spatial and temporal trends of PBDEs along an urban River using passive samplers**

M. Khairy, URI; R. Lohmann, University of Rhode Island / Graduate School of Oceanography; K. Barrett, Manhattan College / Civil Environmental Engineering. Passive low density polyethylene (LDPE) samplers were deployed at six different locations along the lower Passaic River (NJ, USA) covering the region from the Dundee Dam to Newark Bay. Six sampling campaigns (~2 months each) were performed during September, 2011 through November, 2012. LDPE samplers were extracted and analyzed for PBDEs by GC-MS/MS. Estimated freely dissolved PBDE concentrations (average of the six deployments at each location) ranged from 13 ng/L to 35 ng/L. Except for lower concentrations located above Dundee dam, all the other samples showed comparable concentrations with slight variations. Dissolved PBDE concentrations recorded during the different deployment periods at each location were found to significantly increase with increasing the water temperature (r range: 0.71-0.92 at p < 0.01) indicating a shift in the dissolved phase-particulate partitioning of PBDEs towards the soluble phase at higher temperatures. Alternatively, warmer temperatures could have increased biological activity in the sediments, leading to enhance release of contaminants from porewater. As for the congener patterns, PBDEs in all the deployment periods above the dam, at mile 12 and mile 8.6 were dominated by BDE-47 with a contribution ≥ 40 % of the total PBDE concentrations followed by BDE-2 (13-24 %) and BDE-99 (11-15 %). Closer to the Superfund site (miles 5.5, 4.2) reaching to Newark Bay (NB), PBDEs were also dominated by BDE-47 (38-41 %), BDE-49 (14-17 %), BDE-2 (9-13 %) and BDE-99 (10-13 %). BDE-49 significant contribution observed at these samples can be also observed in the sediment samples, where samples collected from the same locations had a considerable contribution from BDE-49 as compared to the other samples. Gaseous PBDE concentrations ranged from 0.8 to 1.5 pg/m<sup>3</sup>, with only slight variations observed in detected gaseous PBDE concentrations between the sampling locations. The highest concentration was observed at mile 18 above Dundee Dam, whereas the lowest concentration was observed at mile 5.5. PBDE concentrations during the six deployments at each site increased with the increase in the atmospheric concentration (r: 0.6-0.96). All the deployed passive samplers were dominated by the lower brominated congeners namely BDE-2 (17-84 %) > BDE-15 (1-30 %) > BDE-8 (3-29 %), with a considerable contribution from BDE-28 (3-28 %) and BDE-47 (2-19 %) only at mile 4.2 and Newark Bay during June-August deployment (highest atmospheric temperature). .

##### **Monitoring of POPs in ambient air in the Czech-Austrian border region using passive samplers**

R. Prokes, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; P. Cupr, Masaryk University, Faculty of Science, RECETOX / RECETOX Research centre for toxic compounds in the environment; P. Weiss, W. Moche, Umweltbundesamt GmbH; D. Barakova, M. Chropenova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; O. Šaňka, Research Centre for Toxic Compounds in the Environment RECETOX; P. Hohenblum, Umweltbundesamt GmbH; P. Pribylova, Masaryk University; K. Bányiová; I. Vackavikova, L. Vankova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; O. Audy, Research Centre for Toxic Compounds in the Environment RECETOX; J. Klanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment

This project was aimed at a specific assessment of the open air contamination in selected regions of both countries by using a coordinated monitoring of substances subject to a long-range transport that are also persistent and toxic to humans and to the environment. Passive air samplers using polyurethane foam disk (PUF) were applied at a total of 20 selected sampling sites of Czech Republic and Austria for a period of one year (2011-2012). PUF samplers are useful to provide information on the long-term average air pollution levels with low sensitivity to episodic fluctuations. The collection of needle samples from Norway spruce trees (*Picea abies*) in addition to PUF samplers was employed. The wax layer of coniferous trees can collect and accumulate atmospheric persistent organic pollutants (POPs) over long time periods and therefore can be used as plant passive air sampler. The results obtained identify regional as well as distant sources of POPs pollution in ambient air for the whole studied territory. The newly established passive sampling

network was also linked the existing long term-monitoring networks (such as MONET and MONARPOP).

#### TU146

##### **Passive sampling of ionized pharmaceuticals using C18-based SPME coatings**

H. Peltenburg, Institute for Risk Assessment Sciences; s.T. droge, Utrecht University / IRAS; I. Bosman, Netherlands Forensic Institute; J.L. Hermens, Utrecht University / Institute for Risk Assessment Sciences. Commonly used extraction phases in solid-phase microextraction include neutral coatings such as polyacrylate (PA) or polydimethylsiloxane (PDMS). However, these coatings only show high sorption coefficients for neutral analytes, with ionizable compounds only sorbing after matrix-modifying steps to ensure a large neutral fraction. Previously, we showed that the C18/SCX fiber (containing C18 and strong cation exchange (SCX) groups) showed limited pH-dependent sorption for ionizable compounds, indicating that these coatings could be beneficial for charged species especially. We compared sorption of pharmaceuticals to two C18-based SPME coatings. Sorption of four model compounds was studied for both the analogous C18 fiber and the C18/SCX fiber. The chosen model compounds are all bases: amitriptyline (log K<sub>ow</sub> 4.81, pKa 9.7), amphetamine (log K<sub>ow</sub> 1.80, pKa 9.9), diazepam (log K<sub>ow</sub> 3.08, pKa 2.9) and tramadol (log K<sub>ow</sub> 2.45, pKa 9.2). Our results indicate that sorption to both C18 and C18/SCX coatings is only slightly pH-dependent. Furthermore, with sorption coefficients for cationic compounds still high at very low pH, this indicates that it is not the remaining neutral fraction that has high affinity for C18-based coatings but that also the charged species has similar affinity for these fibers. The C18/SCX coating showed somewhat higher sorption affinities for cationic compounds compared to C18 coating alone. However, sorption of charged species to the C18/SCX fiber decreases with increasing ionic strength, whereas the C18 coating might be less affected by the competitive effects of salts. To prove that sorption of cationic compounds to the C18 coating was not driven by available silanol groups, anionic diclofenac (log K<sub>ow</sub> 4.26, pKa 4.0) was used to test this. Sorption of diclofenac to the C18 fiber was also only slightly pH-dependent. This proves that completely ionized compounds (albeit cationic or anionic) are able to sorb to C18-based coatings. Furthermore, diclofenac sorption to the C18/SCX coating is comparable to sorption to the C18 fiber at pH 7.4, showing the large contribution of C18 in the C18/SCX fiber to the sorption of diclofenac. It is clear from our data that C18-based SPME coatings show improved sensitivity over conventional SPME coatings, can be applied without matrix-modifying steps, and are able to sorb both neutral and charged drug species. These insights highly contribute to the use of SPME in the measurement of sorption processes.

#### TU147

##### **Developments, Applications and Perspectives of the Passive Water Sampler for organics - o-DGT**

C. Chen, A.J. Sweetman, H. Zhang, Lancaster University / Lancaster Environment Centre; M. Bowkett, TelLab; K.C. Jones, Lancaster University / Lancaster Environment Centre

Passive water sampling has several advantages over active methods: it provides time weighted average (TWA) data, saves time and money and can yield highly spatially resolved data. A novel passive water sampler (called o-DGT) for organic chemicals (antibiotics as model compounds) based on diffusive gradients in thin-films (DGT) has been developed<sup>1</sup> and tested<sup>2</sup>. This sampler has been used to for a wide range of applications including chemical fate in wastewater treatment plants (WWTPs) to access their removal efficiencies, and in-stream fate within rivers. This passive sampling technique has been further explored and applied to soils for in situ measurement of the concentrations and fluxes of antibiotics in soils<sup>3</sup> and for understanding the desorption kinetics in soil<sup>4</sup>. DGT is also being used for similar studies in sediments. The development of this technique for other groups of chemicals is ongoing, with other pharmaceuticals, personal care product ingredients (PPCPs) (including some parabens, estrogens, bisphenol A, and triclosan) and pesticides being assessed. Recent results show that PPCPs can be measured with this sampler under laboratory test conditions, but also in the field (i.e. WWTPs) by modifying the binding agent, diffusive gels and filter members (unpublished data). Further development and validation of the passive sampler which can be used to determine a wide range of priority substances under the Water Framework Directive (WFD)<sup>5</sup> is an important development goal for our research. Overall, o-DGT is a promising tool for understanding the fate and behaviour and *in situ* approach for assessing the availability of polar organic chemicals in environment. With further development and calibration, o-DGT might be also be applicable to persistent organic pollutants (POPs) to assess their fate, behaviour and availability. **Keywords:** o-DGT, passive sampling, organic pollutants, PPCPs

**Acknowledgement** – We thank EPSRC and TelLab for their financial support.

##### **NAKED PASSIVE SAMPLING OF POLAR ORGANIC CONTAMINANTS**

## USING THIN SILICONE SHEETS IN A WASTEWATER TREATMENT PLANT AND RECEIVING RIVER

K.E. Smith, Korean Institute of Science and Technology Europe / Convergence Environment Team; Y. Jeong, KIST Europe

The advantages of passive sampling include the provision of equilibrium or time-weighted averages of the dissolved concentrations, the possibility of *in situ* sampling and no power requirements. In addition, the selective up-concentration of the target contaminants via partitioning into the passive sampling phase results in relatively clean samples with high levels which simplifies analysis. Silicone is commonly used for hydrophobic organic contaminants due to their high partitioning into this polymer. However, it has a lower relative affinity for more polar contaminants (including many pharmaceuticals, biocides etc.) which can lead to problems with analytical detection. To some extent this limitation can be solved by using larger silicone volumes in conjunction with highly sensitive analytical methods. To ensure high exchange kinetics, in this study “naked” passive samplers were directly exposed to waste and river waters. These consisted of thin 100 cm<sup>2</sup> PDMS sheets with thicknesses of 96 and 203 µm enclosed in a fine copper mesh to limit biofouling and provide rigidity. Prior to deployment, the PDMS sheets were spiked with labelled surrogates of the target contaminants as performance reference compounds. The passive samplers were deployed for week long periods over 1 month in the inlet and outlet of a wastewater treatment plant, as well as in the Saar River which receives the treated effluent. After recovery the silicone sampling sheets were solvent extracted, blown-down and analyzed by LC-MS/MS for a set of compounds based around the Water Framework Priority list. In addition to hydrophobic contaminants such as PAHs, a wide range of polar contaminant types were routinely detected including pharmaceuticals (e.g., atenolol, metoprolol and carbamazepine) and biocides (e.g., isoproturon, diuron, cybutryne). The similar polymer concentrations measured for both sheet thicknesses, along with the almost complete disappearance of the labelled surrogates, indicate that equilibrium was almost reached. This allows the measured polymer concentrations to be easily converted into the corresponding dissolved concentrations using partitioning ratios. Therefore, this study shows that silicone can be used for the passive sampling of polar organic contaminants in waste and surface waters.

#### Partitioning kinetics of polar organic contaminants to OASIS HLB as a function of pH and ionic strength for optimization of passive sampling and solid phase extraction approach

Y. Jeong, KIST Europe; K.E. Smith, Korean Institute of Science and Technology Europe / Convergence Environment Team; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research

The monitoring of aquatic ecosystems for organic contaminants assumes an ever increasing importance, and here sampling is the initial step. Passive sampling is regarded as a promising technique for the monitoring of water quality providing time-weighted averages of the dissolved concentrations which are considered to be the bioavailable concentrations driving uptake and toxicity, the possibility of *in situ* sampling, and no power requirements. Furthermore, the selective up-concentration of target contaminants in the passive sampling phase results in relatively clean samples with high levels to simplify analysis. Increased concerns about polar organic chemicals in aquatic environments led to the development of the polar organic chemical integrative sampler (POCIS). This consists of an adsorbent polymer enclosed between two membranes. POCIS are typically deployed in kinetic sampling mode, where uptake is linear and proportional to the dissolved concentrations. The latter can be calculated using the sampling rate, and depends on factors such as the properties of the target chemicals as well as POCIS materials and the hydrodynamic conditions. Therefore, one of the key factors determining the accumulation behavior of polar organic contaminants in the POCIS relates to their sorption behavior to the adsorbent polymer. Oasis hydrophilic lipophilic balance (HLB) is the one of the most widely used sorbents in the POCIS, yet a detailed understanding of the partitioning behavior of different polar organic contaminants to this porous polymer is missing. Therefore, a miniaturised batch set-up was established in HPLC vials allowing the sorption of a wide range of polar organic contaminants at environmentally relevant levels to OASIS HLB to be measured. Initially equilibrations experiments were performed, and based on these the equilibrium sorption of mixtures polar organic chemicals as a function of concentration, temperature, pH and ionic strength determined. Increasing concentrations led to a flattening of the sorption isotherms, likely due to limited availability of sorption sites. As expected, increasing temperature led to a decrease in sorption, with the magnitude of this depending on the compound. The effects of pH and ionic strength were complex, leading to an increase, decrease or having no effect on the sorption. The partitioning results of polar organic chemicals to OASIS HLB are discussed in terms of the properties of the chemical, sorbent and aqueous solvent.

### TU150

#### Passive sampling of cationic surfactants in sorption studies with various environmental matrices

N. Timmer, J.L. Hermens, Utrecht University / Institute for Risk Assessment Sciences; S.T. droge, Utrecht University / IRAS

Cationic surfactants are a challenging but poorly studied group of environmental contaminants that are worldwide observed to accumulate in sediments and soils that

receive sewage waste material, either via waste water effluents or via sludge disposal. Cationic surfactants can sorb to hydrophobic phases as well as to matrices containing negatively charged surfaces – such as humic acids, fulvic acids and clay particles. A major analytical challenge is that long chain cationic surfactants strongly sorb to most lab surfaces – i.e. glass vials, pipet tips and microtiter plates – rendering the measurement of actual freely dissolved concentrations problematic. For this study, a group of alkylated primary, secondary, tertiary and quaternary ammonium compounds was selected, including benzalkonium and pyridinium structures. WCX-SPE and 7 µm coated polyacrylate coated SPME-fibers were used to calculate fiber partitioning coefficients. These SPME-fibers were subsequently used to determine free concentrations of cationic surfactants in different media and under different conditions. In addition, SPME-fibers were used to determine sorption affinity for a small set of surfactants to different types of sediment (i.e. clay, sandy, organic rich), LUFA soils, and for various soil/sediment constituents (Aldrich humic acid, kaolinite, illite), revealing the importance of various individual soil components in controlling bioavailability in contaminated ecosystems.

#### Sampling polyhexamethylene guanidine (PHMG) aerosols using Eosin Y coated glass beads

S. Choi, S. Park, H. Kang, Korea University; K. Lee, Korea Institute of Toxicology; J. Kwon, Korea University / Division of Environmental Science and Ecological Engineering

Fatalities caused by the use of polyhexamethylene guanidine (PHMG), a general-purpose chemical germicide used as a humidifier disinfectant in Korea, have raised concerns about biocide aerosols in indoor environments. A sampler capable of accumulating PHMG from aquatic aerosols was developed as an alternative to low-volume air samplers. This sampler was prepared by placing glass beads coated with Eosin Y (2-(2,4,5,7-tetrabromo-6-oxido-3-oxo-3H-xanthen-9-yl)benzoate) in a custom-made plastic holder. Passive sampling rates, measured in a bench-top exposure chamber at two different aqueous PHMG aerosol generation rates, were found to be independent of the experimental conditions. This suggests that the capacity of the sampler to accumulate the PHMG aerosol was sufficient for the sampling duration tested. However, the passive sampling rate was 0.0065 L h<sup>-1</sup>, which is lower than the typical human breathing rate and inadequate for quantitative instrumental analyses at low concentrations in indoor air. A 25-fold enhancement of the sampling rate was achieved by forced convection using a commercial battery-operated fan above 2000 rpm. This suggests that it would be possible to utilize this sampler for quantifying time-integrated concentrations of PHMG aerosols in the air.

### TU152

#### Silicone passive samplers for organic pollutants in water: Utilizing accelerated solvent extraction (ASE) for purification and extraction

B. Brockmeyer, German Federal Maritime and Hydrographic Agency (BSH); N. Theobald, BSH / Marine Chemistry

In recent years, silicone passive samplers have gained increasing attention as single phased, practical and robust samplers for monitoring of organic contaminants in the aquatic environment. However, analytical challenges arise during extraction of analytes as silicone associated oligomers are co-extracted and interfere with the chemical analysis. Thus, solvent and time-consuming preclean-up methods are necessary both prior to deployment in the water phase as well as after the extraction of target compounds before analytical procedures. In this study, we present a fast, practical precleaning procedure for silicone passive samplers utilizing accelerated solvent extraction (ASE) for the removal of silicone oligomers prior to the water deployment. ASE was also shown to be a very fast and efficient extraction method for non-polar contaminants sampled by the silicone membrane. For both applications, temperature, extraction time and the solvent used for ASE have been optimized. Purification of the ASE extract was done with silica gel and size exclusion chromatography (SEC). Because of the negative effects of the silicone oligomers on the analytical performance (e.g. gas chromatography) it is essential to check their absence or at least low level in the analytical samples. For this, the silicone oligomer content was determined by total reflection X-ray fluorescence spectroscopy (TXRF) prior to analysis of passive sampler extracts. The newly developed method was tested on field samples deployed in the German Bight (Helgoland) and in the Baltic Sea (Fehmarn). Finally, this study optimizes the preparation, as well as extraction and purification of PDMS samplers in order to make silicone passive samplers more favorable for the monitoring of contaminants in the water phase.

### TU153

#### Effect of environmental temperature on the loss of PAHs in passive samplers

N. Domínguez, URVIISPV; M. Schuhmacher, Rovira i Virgili University / Chemical Engineering; J. Sierra, Universitat Rovira i Virgili / Soil Science Unit; J.L. Domingo, Universitat Rovira i Virgili / Laboratory of Toxicology and Environmental Health; M. Nadal, University Rovira i Virgili / Laboratory of Toxicology and Environmental Health

Polyurethane foams (PUFs) are materials commonly used in passive air samplers (PASs), from local to global scale. However, the influence of environmental

variables such as wind speed and temperature, which may significantly affect the uptake capacity of these devices, has not been fully investigated. Previous studies have analysed the role of temperature on the retention capacity of semi-volatile organic compounds (SVOCs) by PUF-PAS, with polycyclic aromatic hydrocarbons (PAHs), organochlorine pesticides and polychlorinated biphenyls having attracted most of the attention. The results of these studies show the increase of the temperature enhances PAHs volatilization and, in some cases, their subsequent transformation. Therefore, metabolites, even more toxic than the parent compounds, may be generated. It is estimated that climate change could induce major changes in environmental factors such as temperature, which may promote the volatilization/degradation of these compounds. In order to study the influence of the temperature over the loss, transformation and toxicity of PAHs in a PUF-PAS, a study in a climate chamber was carried out. An experimental study at 2 different temperatures (25°C and 38°C, representative of average and maximum values in Tarragona County, Spain, respectively) was conducted in a climate chamber. Eight PUF-PASSs, spiked with a mixture containing 16 priority PAHs, were kept at each working temperature for one week, being samples removed daily. The chemical analysis was carried out by using microwave organic extraction, according to the US EPA method 3546, and by using a GC-MS, following the US EPA method 8270. A specific toxicity study was carried out to determine any potential changes in the toxicity, likely associated to the loss of PAHs and/or generation of degradation byproducts. Since it is a quick and sensitive method, a bioassay based on *Vibrio fischeri* in organic phase was tested. It is hypothesized that statistically significant differences in the volatilization, degradation and toxicity of 16 PAHs are observed according to the temperature (25°C and 38°C) and exposure time (1 hour, 1, 2, 3, 4, 5, 6 and 7 days), showing a gradual decrease in 16 PAHs concentration with increasing exposure time. The results of this study will help elucidate potential temperature-based PAH loss mechanisms, thus maximizing the optimum uptake of PAHs by PUF-PAS.

#### TU154

##### Assessing the role of passive sampler geometry

J.K. Juntunen, Finnish Environment Institute / Freshwater Centre; H. Ahkola, Finnish Environment Institute; K. Krogerus, Finnish Environment Institute / Freshwater Centre; S. Herve, Finnish Environment Institute / Research and Innovation Laboratory; T. Huttula, Finnish Environment Institute / Freshwater Centre

Several passive sampling techniques have been developed for monitoring pollutants in aquatic environment for decades. One of those is Chemcatcher passive sampler which was developed to be a tool for implementation of environmental legislation. Although it has been recognized that the prevailing conditions near the sampler body effect on its performance, the cross scientific approach has not been considered thoroughly. The environmental variables (such as pH, turbulence and temperature) have been observed to effect on the exchange kinetics of the sampling procedure. Still, the studies of the contribution of the sampler housing geometry on the accumulation have been very limited, focusing mainly on the cavity depth of the Chemcatcher sampler. However, this could be discovered based on existing physical or engineering literature and without extensive field measurements. In physics and engineering sciences the issues related to heat and mass transfer are extensively studied. With a literature review it could be possible to find the best shape of the passive sampler housing that would minimize the effects of unwanted phenomena's and magnify the desired ones. For example geometry which includes pins on the surface of the sampler body generates flow environment that would smoothen the rapid changes occurring in surrounding aquatic media. That creates more regular flows near the receiving phase of the sampler and thus makes the interpretation of passive sampling results more reliable. Based on the literature it is evident that the shape of an item in which the receiving phase of the passive sampler is fixed can have significant effect on the exchange kinetics of sampling. Theoretically we can define the effect as an amount of material accumulated in the receiving phase which increases with the water flow. Thus when selecting sampler housing with suitable geometry the sampling period can be increased or decreased depending on the flux the item is creating with surrounding media. In this poster the fluxes created by selected shape of passive sampler housings and their effect on the sampling kinetics are discussed.

#### TU155

##### MIXING POLYMERS WITH DIFFERENT PARTITIONING PROPERTIES TO OPTIMISE THEIR APPLICATION IN PASSIVE SAMPLING AND DOSING

K.E. Smith, Korean Institute of Science and Technology Europe / Convergence Environment Team; Y. Jeong, KIST Europe

Polymers such as polydimethylsiloxane (PDMS) silicone are widely used in passive sampling and dosing applications. In aqueous systems, advantages include its high relative affinity for hydrophobic organic contaminants, interaction by absorptive partitioning as well as chemical and biological inertness. However, its chemistry means that the relative affinity for polar organic compounds is not optimal, leading to a lower up-concentration. Therefore, porous adsorptive polymers such as OASIS HLB® with a higher relative affinity for such polar organic contaminants have been developed. However, these polymers interact by adsorptive partitioning, which is more complex to understand due to competitive sorption effects, possible desorption hysteresis and the effects of environmental conditions on the sorption

behavior. Furthermore, they are mainly in the form of fine beads, making their handling complicated. Therefore, to combine the desirable properties of both polymer types, this study followed a simple approach of casting OASIS HLB® beads with PDMS silicone at different ratios. Subsequently, the partitioning behavior of a wide range of polar organic contaminants (biocides, pharmaceuticals, hormones etc.) was determined at 4°C, 20°C and 37°C. Compared to PDMS alone, the mixed polymer showed a marked increase in affinity for the polar organic compounds due to the increased affinity of the embedded OASIS HLB®. Furthermore, in most cases desorption was reversible, and immobilizing the 5 µm OASIS HLB® beads in the PDMS greatly simplified the handling. Therefore, the simple approach of mixing polymers with different chemistries offers a practical approach to tune the sorption affinity for a wider range of organic contaminants for passive sampling and dosing applications.

#### TU156

##### Development of a passive sampler for the monitoring of nanosilver in environmental waters and wastewaters

L. Shen, Li Shen / Department of Chemistry; C.D. Metcalfe, Trent University / Water Quality Centre; V.V. Yargeau, McGill University / Chemical Engineering  
As a result of expanding use, nanomaterials such as nanosilver (AgNP), are being continuously released into the environment through production, usage, and disposal. Research is currently needed for the development of cost-effective methods to quantify AgNP in various environmental compartments in order to fully evaluate the exposure and risks on the environment and public health associated with the presence AgNP. The present study focused on the development, calibration and application of passive sampling to the detection of AgNP and the measurement of low concentrations in complex matrices. Our recent work has allowed us to calibrate a sampler containing carbon nanotubes (CNT) in powder form as the sorbent for AgNPs in aqueous matrices. The calibrated CNT samplers have been applied to determining the concentrations of AgNP in a wastewater treatment plant (WWTP) and in a river upstream and downstream of the WWTP discharge. Results showed a concentration of AgNP of 0.3 ppb in the treated effluent with a limited impact on the concentration in the receiving stream; 1.0 ppb upstream and 1.3 ppb downstream of the wastewater discharge point. Data will also be presented for samplers deployed in Lake Ontario near WWTP discharges and in a lake experimentally dosed with AgNPs. This study demonstrated the potential of the CNT samplers as a tool for monitoring the concentration of nanomaterials in wastewater and in surface waters impacted by wastewater discharges.

#### TU157

##### Comparison of the Uptake of Perfluorinated Alkyl Substances by Carrot Plants and Passive Samplers

E. Bizkarguenaga, I. Zabaleta, Analytical Chemistry; A. Vallejo, University of the Basque country UPVEHU; A. Prieto, University of the Basque country UPVEHU / Analytical Chemistry; L. Fernández, O. Zuloaga, University of the Basque country UPVEHU

The aim of this work was to study the uptake of perfluoro alkyl substances (PFASs) such as perfluorooctane sulfonic acid (PFOS), perfluorooctanoic acid (PFOA) and perfluorooctane sulfonamide (FOSA) by two carrot varieties (Chantenay and Nantesa). Carrots were grown in two types of compost-amended soils (characteristics of soil are the following, pH: 7.2 and 5.68 and TOC (%): 2.26 and 53.32 for soil 24 and substrate, respectively) fortified at 500 ng g<sup>-1</sup> concentration level (two pots for fortified samples and one pot for unfortified samples for each analyte). Together with the carrots three different passive samplers (polyoxymethylene, POM, polyethersulfone, PES, and silicone rod, SR) were also exposed to the fortified and unfortified compost-amended soils. The concentration of the target analytes was determined in the different carrot compartments (peel, core and leaves), the passive samplers and the soils. The highest bioconcentration factors (BCF) were obtained in the carrot leaves compared to the peel and core for the three target analytes. Besides, degradation of FOSA to PFOS was observed in all the experiments carried out (two different types of soils and two different varieties of carrot). For PFOS a higher BCF was observed for the soil with the lowest content in organic matter, while the differences were not so significant for PFOA. The three different passive samplers (POM, PES and SR) were also tested to predict the bioavailability of these target compounds and to compare the uptake observed in the passive samplers with the BCFs obtained in the carrots. PFASs were detected in all the passive samplers except SR. Therefore, comparison between BCFs obtained for PES and POM and BCFs of all the sum of the three compartments of the plant (sum of BCF<sub>root</sub>, BCF<sub>core</sub> and BCF<sub>leaves</sub>) were carried out. No correlation was observed between BCF<sub>POM</sub> and BCF<sub>plant</sub>, while a linear trend was achieved for PFOS (r<sup>2</sup>= 0.78) and PFOS coming from the degradation of FOSA (r<sup>2</sup>= 0.81) in the case of PES passive sampler. Besides the slopes of the correlations between the uptake of PES and the BCF for PFOS coming from the amended soils fortified with PFOS (10.66) and fortified with FOSA (10.89) were the statistically comparable. To our knowledge, this is the first time that the uptake of PFASs by carrots is satisfactorily correlated with the uptake in a passive sampler.

#### TU158

##### Microbial Passive Samplers: How reliable?

J. Monier, C. Malandain, C. Baguein, O. Sibourg, ENOVEO  
Successful bioremediation of subsurface environments, such as contaminated soil

or groundwater, can depend on a good understanding of microbial degradation processes. Taking into account the complexity of interactions that occur between the solid matrix, indigenous microorganisms and pollutants, initial on-site characterization and *in situ* monitoring of microbial communities over time are essential. One of the major challenges with subsurface systems has been the development of sampling techniques for microbiological investigations. Reliable sampling is highly critical since detection of microbes and/or their expression, and the quantification of genes involved in degradation processes are often used to design and monitor remediation processes. Conventional (active) sampling usually relies on the collection of individual spot samples and may often lead to an underestimation of the abundance and diversity of the community as well as an important variability. The objective of our work was to develop and optimize tools for reliable on-site passive sampling of microbial communities in non-destructive manner. Different matrices ranging from activated carbon to coarse sand were tested for enrichment of bacterial growth in monitoring wells. Samplers were maintained over 30 days and the microbial communities enriched on the different matrices compared to the communities of the surrounding soil and interstitial water using molecular tools (e.g., Next Generation Sequencing, RISA, Phylogenetic microarrays). Results obtained showed that the amount of biomass and structure of the communities are different on the different matrices tested. Some solid supports seem less adapted than others in order to sample in a reliable manner the microbial communities present in the surrounding water and soil. Therefore, the choice of the matrix selected to passively sample subsurface microbial communities is highly critical and some material are to be avoided. Data obtained with the different matrices in different environments will be presented and the advantages and limitations of such approach for different applications will be discussed.

##### **Lichen bioaccumulation data at support of PM10 diffusional models: the case study of a coal power plant in a highly heterogeneous territory**

L. Fortuna, Department of Life Sciences; G. Adami, University of Trieste / Department of Chemical and Pharmaceutical Science; M. Tretiaich, University of Trieste / Department of Life Sciences

Diffusional models are requested by standard authorization processes for new industrial plants or modification of old ones, but their limit is that they are validated only rarely through the cross-check with further environmental data (e.g. direct field measurements of pollutant concentration). In this work we show that lichen bioaccumulation data can be used for the validation of diffusional models of PM<sub>10</sub> concentrations at ground level. The study was carried out in a low-elevation territory (Monfalcone, NE Italy), characterized by high land use heterogeneity and high anthropic pressure. The tested models describe the PM<sub>10</sub> fall-out of a medium-size coal power plant (models *a*, *b*, respectively), and that of all the industrial plants present in the survey area (model *c*). They were specifically developed for obtaining the original licence (in 1996 and later in 2009; models *a, c*) or as a consequence of a recent environmental litigation, opposed by a citizen committee (2014, model *b*). The lichen survey, was based on a simple systematic sampling, in order to strongly reduce the subjectivity of the samplers: the study area (176 km<sup>2</sup>) was divided into 44 Primary Sampling Units (PSU) of 4 km<sup>2</sup> each. The lichen sampling was limited to 10 PSUs, of which five, indicated as “potentially polluted” (PP), corresponded to the maximum fall-out described by models *a* (3 PSUs) or *c* (2 PSUs), and other five, indicated as “potentially unpolluted” (PU, i.e. the controls), were selected externally to the plumes of the two models, according to the same land use of their PP counterparts. In each PSU one to three samples of *Flavoparmelia caperata* and *Xanthoria parietina*, co-occurring on one and the same tree were collected, for a total of 42 samples, that were prepared and digested according to standard protocols. Element concentrations were measured by ICP-AES, GFAAS, and DMA. The comparison between the bioaccumulation data of PPs and PUs revealed that two PPs of model *a* did not differ statistically from their putative controls, while the third one showed a lower content for 13 elements with respect to its control. This contradiction was substantiated through the comparison with the outputs of model *b*. In fact, that specific “control” PSU, purportedly unpolluted according to model *a*, was found to correspond to a significant portion of the fall-out plume described by the more recent model, elaborated according to more sophisticated algorithms.

#### TU160

##### **TOTAL GASEOUS MERCURY CONCENTRATION AND LICHENS BIOACCUMULATION IN THE NORTHERN ADRIATIC COASTAL AREA (GULF OF TRIESTE, ITALY)**

A. Acquavita; R. Grahonja, M. Pasquon, F. Tamberlich, G. Mattassi, ARPA FVG The Gulf of Trieste (NE Italy) and the adjacent Marano and Grado Lagoon have been affected by significant mercury (Hg) contamination mainly for the existence of mining activities in Idrija (Slovenia) and, to a lesser extent, the chlor-alkali plant in Torviscosa. Due to its volatile nature, Hg emission from terrestrial and aquatic surfaces is an important part of its biogeochemical cycle. Contaminated sites and surrounding enriched soils can be regarded as substantial atmospheric mercury emission sources. Lichen species have proven to be a good indicator of long-term Hg dispersion patterns around an industrial facility and in other Hg dispersion

studies. In this work, a preliminary assessment of Hg bioaccumulation and its relationship with gaseous mercury levels was conducted. Mercury determination in lichens was performed by means of a mercury direct analyzer (DMA-80, Milestone), whereas measurements of Hg<sup>0</sup> were made using an RA-915+ Lumex Zeeman portable mercury spectrometer. Concentrations of Hg in *in situ* lichens ranged from 50 to 150 ng g<sup>-1</sup>, which are typical values of uncontaminated sites. However, some hotspots were recorded in near the chlor-alkali plant and Grado seaside (~ 400 ng g<sup>-1</sup>). Mercury in air showed an average concentration of about 3.0 ng m<sup>-3</sup>, similar to that reported in uncontaminated area, rarely exceeding 10 ng m<sup>-3</sup>. It is well known that Hg bioaccumulation in lichens from the atmosphere depends on the ambient levels, age of the lichens and the physiological conditions. In this work no significant correlation was found, thus suggesting that a more exhaustive survey of biological and soil matrices is necessary in order to increase behaviour of Hg in these contaminated sites.

#### TU161

##### **Mercury and POPs in marine debris from a remote coral reef island in the Indian Ocean**

H. Bouwman, North-West University / Environmental Sciences and Development; M. Krátká, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; R. Choong Kwet Iyve, University of Mauritius / Chemistry; H. Kylin, Linköping University / Department of Thematic Studies Environmental Change; J. Klanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment

The real and potential impacts of marine debris is attracting much attention due to the amounts involved and the large areas affected. This presents the potential of facilitated long-range transport of accumulated persistent organic pollutants (POPs), the inherent organic chemicals, and heavy metals such as mercury. We found large amounts of plastic debris (± 3.1 million pieces) on the beaches of the remote atoll of St Brandon's Rock (SBR) in the Indian Ocean. The brand names on the debris indicate origin from countries bordering the East Indies and northern Indian Ocean. We predicted that islands can scrub debris from ocean currents and that UV, wave action and biological action will release the pollutants to contaminate coral reefs. We collected small pieces of plastics, coral rubble, coralline beach sand, and sand from tern breeding colonies, which were analysed for mercury and POPs. Concentrations and compositions of the OCPs, new BFRs, and PFCs were quite variable within and between the different matrixes. Plastic debris pieces generally had the highest concentrations of all compound classes. However, for all classes, there were natural matrix samples that had higher concentrations. HCHs dominated the OCPs. Most were α-HCH. Of the DDTs, p,p'-DDT seemed to dominate in the plastics, with almost no p,p'-DDE to speak of. No DDTs were found in the coralline matrixes. Plastics had very variable compositions and concentrations of BFRs, with decabromodiphenylethane (DBDPE) and 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE) dominating, but the coralline matrixes almost exclusively had syn-dechlorane plus and anti-dechlorane plus. Perfluorobuteric acid (PFBA) and perfluoropentanoic acid (PFPA) dominated the PFAS in all matrixes, and generally had the highest concentrations in plastics. PFOS and PFOA occurred in relatively small amounts compared to the other PFAS in all samples. The concentrations of mercury was highest in those plastics that had them, but levels were quite variable within each matrix. The heterogeneity of compositions and concentrations of pollutants in the coralline samples indicate plastics as sources rather than derived from a homogenous background. It is clear that plastics can accumulate pollutants such as mercury from seawater and transport them to remote “pristine” regions. Small island states may wish to take note when considering the Minamata Convention.

#### TU162

##### **A mechanism for the reduction of HgCl<sub>2</sub> on environmental surfaces**

G. Brown, John Jay College of Criminal Justice / Sciences; A. Ho, University of California Davis / Plant Biology; R. Khushf, John Jay College of Criminal Justice-CUNY / Sciences; A. Carpi, John Jay College

The mechanism of the reduction of divalent mercury (Hg) in the environment and its subsequent emission from soil into the atmosphere is not well understood. Reduction and emission is known to be influenced by many environmental factors such as temperature, light, or microbial activity; however, the nature of these effects are not known. Identifying the mechanism by which Hg species are reduced in soil can shed light on the dynamic biogeochemical cycling of Hg and possible remediation of contaminated sources. In this study, the mechanism of the reduction of inorganic mercury (Hg<sup>2+</sup>) to elemental mercury (Hg<sup>0</sup>) on environmental surfaces was investigated through laboratory analysis and computational modeling. Laboratory analysis was carried out under a laminar flow hood using a Tekran 2537 Mercury Vapor Analyzer (Tekran Inc., Toronto Canada) which detects trace levels of Hg<sup>0</sup> on a scale of ng/m<sup>3</sup>. Elemental mercury emissions were measured from HgCl<sub>2</sub> treated samples of inert materials even in the absence of third party intermediaries. Hg<sup>0</sup> emissions were seen to be primarily driven by Ultraviolet-B (UVB) radiation. Emissions were seen to be independent of temperature in the dark, but correlated with ambient temperature in the presence of light. Gaussian computational modeling shows that the molecule exhibits a transition state when the chlorines are excited such that they bend to 62 degrees. This transition state occurs at an energy of 99.1 kcal/mol, which corresponds to light in the UVB range (288 nm) of the electromagnetic spectrum. Thus, this work will present a

preliminary mechanism for the reduction of  $\text{HgCl}_2$  in the environment and subsequent emission of  $\text{Hg}^0$  from  $\text{HgCl}_2$ -treated soil surfaces.

##### Effects of wildfires on mercury mobilisation in eucalypt and pine forests

**I. Campos**, Universidade de Aveiro / Department of Environment; **C. Vale**, IPMA Instituto Portugues do Mar e da Atmosfera; **N. Abrantes**, University of Aveiro / CESAMDAO; **J. Keizer**, Department of Environment Centre for Environmental and Marine Studies CESAM University of Aveiro Aveiro Portugal; **P. Pereira**, Department of Biology and CESAM

Wildfires and subsequent rainfall have a major impact on forest ecosystems and on the redistribution of trace elements, which are mobilized from soil and ashes. In particular, the fire-induced release of mercury (Hg) into the environment is relevant due to its volatilisation and toxicity. The present study addresses this concerning issue by comparing the concentrations of Hg in topsoil (0-2 cm) and ashes in burnt and long-unburnt forest plantations (Ermida and São Pedro do Sul, North-centre of Portugal). Fire was classified as moderate in Ermida and moderate to high severe in S. Pedro do Sul. Sampling collection took place immediately and 4 months after the fire, the latter following an episode of heavy rainfall. Mercury analysis was performed in an Hg analyser (AMA 254 LECO Instrument), in which samples were thermally decomposed by controlled heating. The final decomposition products were passed through an Hg amalgamator heated to 700 °C and  $\text{Hg}^0$  was released and detected by absorption spectrometry at 254 nm. This technique allows eliminating the digestion procedure prior to analysis and is free from matrix interferences. The principal results obtained in this study were the following: (1) 30% of the Hg retained in eucalypt soils was released by the fire, corresponding to a loss of 1.0-1.1 g Hg per hectare of burnt soil; (2) levels of Hg in burnt eucalypt soils doubled the values registered in burnt pine soils for both areas; the Hg concentrations in ash revealed a similar pattern; (3) Hg concentrations in both soils and ashes differed significantly between the two burnt areas, possibly due to differences in fire severity; (4) rainfall caused a loss of 1.0 g Hg per hectare from ashes and a slight enhancement of 0.5 g Hg per hectare in the soil washed out. The difference between the previous estimations, 0.5 g Hg per hectare, corresponds to the quantity of Hg transported to the surrounding areas or eventually introduced into aquatic systems. Our results highlight that wildfires and subsequent rainfall play a key role in the mobilisation of mercury in the environment and point out the importance of further studies to assess the impact of Hg in aquatic systems downstream to burnt areas.

##### Effect of Different molecular weight fraction of dissolved organic matters on photo-degradation of MeHg in water

**M. Kim**, Seoul National University / Dept of Environmental Health; **A. Won**, Department of Environmental Health; **T. Kim**, Seoul National University; **K. Zoh**, Seoul National University / Department of Environmental Health

Methyl mercury (MeHg) is a potent neurotoxin that may pose a threat to ecosystem viability and human health. In aquatic systems, the photolytic degradation of MeHg is an important component in the MeHg cycle. Dissolved organic matter (DOM) is also affected by photo exposure leading to changes in DOM composition (e.g. loss of aromaticity), which can affect its bioavailability and its role in overall mercury (Hg) cycling. Recent studies have shown that DOM plays an important role during photo-demethylation of MeHg. Some studies reported that MeHg degradation rates decreased with increasing DOM concentration due to reduced penetration of light, whereas other researches reported that the binding of MeHg to thiol groups within DOM increased the photo-reactivity of the MeHg and its degradation rate. In addition, according to recent researches, significant differences in the MeHg degradation rate and the fate and bioavailability of MeHg. However, there is a still lack of knowledge regarding how MeHg reacts with different molecular size of DOM. Therefore, in this study, we investigated the effect of different molecular weight fractions of humic acid (as DOM) on the photo-demethylation of MeHg by (1) separating DOM into three fractions by molecular weight:  $\text{MW} < 3500 \text{ Da}$ ,  $3500 \text{ Da} < \text{MW} < 10000 \text{ Da}$ , and  $\text{MW} > 10000 \text{ Da}$ , (2) examining the effect of different DOM fractions on the photo-demethylation under various conditions, and (3) determining the photo-degradation kinetics of MeHg by different DOM fractions. The results showed that humic acid portion with  $3.5\text{K} < \text{MW} < 10\text{K}$  was most enriched, accounting for 62.8% of total DOC content. Among the fractions of humic acid, the smallest molecular weight fractions (MW

##### MERCURY IN MUSHROOMS: CONTENTS AND BIOACCESSIBILITY

**D. Velez**, Consejo Superior de Investigaciones Científicas / Conservación y Calidad de Alimentos; **C. Jadán**, C. Crespo, Consejo Superior de Investigaciones Científicas; **S. Serrano**, V. Devesa, Consejo Superior de Investigaciones Científicas **Carlos Jadán, Cristina Crespo, Susana Serrano, Vicenta Devesa, Dinoraz Vélez\*** Instituto de Agroquímica y Tecnología de Alimentos (IATA-CSIC). Av. Agustín Escardino nº 7, 46980 Paterna, Valencia (Spain). Corresponding author (\*): phone +34 963 900 022, fax +34 963 636 301, email deni@iata.csic.es Food is the main source of exposure to mercury for most of the population. The most problematic food matrices are seafood products, in particular large predatory fish (swordfish, tuna and albacore), which present contents that may exceed the maximum allowed in the regulations. It has also been detected high contents of

mercury in products of plant origin, especially mushrooms and derivatives. These foods are not controlled by the health authorities, as there is no legislation; however, in some cases they may suppose a risk for regular consumers. In general, food safety assessment of mercury in foods has been carried out on the raw product. However, the evaluation of the risk from mercury concentrations in raw food might be modified if cooking and bioaccessibility (the contaminant fraction that solubilises from its matrix during gastrointestinal digestion and becomes available for intestinal absorption) were taken into account. The aim of this study was to assess the contents of mercury in fresh, canned and dehydrated mushrooms marketed in Spain and determine the effects of cooking and of the process of gastrointestinal digestion on the risk associated with their intake. Mercury contents in dried mushrooms are larger ( $< \text{LQ}-4.4 \text{ mg/kg}$ ) than in fresh ( $< 0.04 \text{ mg/kg}$ ) and preserved mushrooms ( $< 0.5 \text{ mg/kg}$ ), inorganic mercury being the most abundant species. Cooking entails reductions in the contents of mercury, which is solubilized into the liquid of hydration or cooking. Despite these reductions, the consumption of a dietary portion (30 g) of dehydrated mushrooms after cooking can exceed the daily intake for inorganic mercury recommended by the World Health Organization ( $0.43 \mu\text{g/kg}$  body weight). The gastrointestinal digestion process produce a decrease in solubilization of most of the mercury present in the cooked mushrooms (bioaccessibility  $< 25\%$ ), which diminish the risk associated to mushroom consumption.

#### TU166

##### Is Hg uniformly distributed among soil aggregate size fractions?. A case study in spodic horizons in sub-Antarctic forest soils of Tierra del Fuego (Argentina)

**A. Gómez-Armesto**, University of Vigo / Plant Biology and Soil Science; **M. Pérez-Mills**, University of Vigo; **X. Pontevedra-Pombal**, University of Santiago de Compostela; **P. Pérez-Rodríguez**, M. Arias-Estévez, University of Vigo; **S. Diodato**, CADIC-CONICET; **A. Moretto**, CADIC-CONICET-Universidad Nacional de Tierra del Fuego; **E. García-Rodeja Gayoso**, University of Santiago de Compostela; **J. Nóvoa-Muñoz**, University of Vigo

Although the atmosphere plays a key role in the global Hg cycle, this metal has a limited time of residence before its deposition in the soil surface. Soils are recognized as the largest Hg sink, accounting up to 75% of the Hg present in the biosphere. The highest Hg concentrations are usually found in the uppermost soils layers, mainly due to Hg affinity for soil organic matter. However, it was also reported the presence of large concentrations of Hg in deeper soils layers, as occurs in podzols where spodic horizons (Bh, Bhs, Bs) become the last barrier against the mobilization of Hg towards groundwater and surface waters, which could increase notably the risk of environmental toxicity. The immobilization of Hg in podzol B horizons depends on the interactions between Hg and soil organic matter, metal-humus complexes or Al and Fe oxyhydroxides, but it is also closely related to soil aggregate size fractions. This study is focused in the distribution of total Hg ( $\text{Hg}_T$ ) in coarse sand, fine sand, coarse silt, fine silt and clay fractions of five Bs horizons of sub-Antarctic forest soils from Tierra del Fuego (Argentina). The total Hg content in the fine earth fraction ( $< 2 \text{ mm}$ ) ranged between 33 and  $98 \mu\text{g kg}^{-1}$ , whereas the clay size fraction showed the highest average value of total  $\text{Hg}_T$  ( $140 \mu\text{g kg}^{-1}$ ; range 94-183  $\mu\text{g kg}^{-1}$ ) followed by the fine silt fraction which had a range of  $\text{Hg}_T$  between 45 and  $109 \mu\text{g kg}^{-1}$ . In spite of this, clay and fine silt fractions only account on average for 32% of all  $\text{Hg}_T$ , mainly due to the low amount of these aggregate soil fractions in the studied horizons. On the contrary, both sand fractions showed a moderate content of  $\text{Hg}_T$ , with means of 79 and  $84 \mu\text{g kg}^{-1}$  for coarse and fine sand, respectively. This implies that 56% of  $\text{Hg}_T$  in these soils is associated to soil aggregates of sand size, whose mobilization will be easier after erosion events that could destroy the uppermost A and E horizons, leaving exposed the Bs horizons. This process can be expected in forest soils that undergo changes in its land use such as logging activities, which are spreading rapidly in some areas of Tierra del Fuego. However, in the spodic horizons  $\text{Hg}_T$  seems to be strongly bound to organic C, metal-humus complexes and Al and Fe oxyhydroxides, decreasing the risk of Hg mobilization towards the adjacent water courses and thus its potential transformation in methylated mercury species whose toxicity for the biota is widely known.

#### TU167

##### Discriminating primary sources of Hg in sub-Antarctic forest podzols from Tierra del Fuego (Argentina). Implications for Hg mobilization

**A. Gómez-Armesto**, University of Vigo / Plant Biology and Soil Science; **S. Peña-Rodríguez**, University of Vigo; **X. Pontevedra-Pombal**, University of Santiago de Compostela; **L. Cutillas-Barreiro**, M. Arias-Estévez, University of Vigo; **J. Vrsalovic**, CADIC-CONICET; **A. Moretto**, CADIC-CONICET-Universidad Nacional de Tierra del Fuego; **E. García-Rodeja Gayoso**, University of Santiago de Compostela; **J. Nóvoa-Muñoz**, University of Vigo

The weathering of soil parent material and the atmospheric deposition are the main sources of Hg accumulated in soils (up to 75% of the Hg in the biosphere). The origin of Hg in forests soils influences its mobilization and potential environmental toxicity. Atmospherically deposited Hg is retained in the surface soil layers by organic matter, metal-humus complexes, and Al and Fe oxyhydroxides. But these soil compounds also act as Hg carrier phases that facilitate Hg mobilization in the soil profile. Mercury in the parent material (lithogenic) occurs mostly in stable minerals (except for Hg sulfides) and its release to soil is strongly constrained.

However in the assessment of Hg toxicity in soils, total Hg ( $Hg_T$ ) content is often used as a key parameter leaving aside its distinctive origin. The origin of Hg, discriminating between atmospheric Hg ( $Hg_{Atm}$ ) and lithogenic Hg ( $Hg_{Lit}$ ), was assessed in six podzols from Tierra del Fuego (Argentina). Lithogenic Hg was estimated as:  $[Hg_{Lit}] = [Ti]_{soil} * ([Hg_T]/[Ti])_{rock/Chor}$  where Ti is a conservative element not influenced by atmospheric sources, *soil* refers to each soil layer and *rock/Chor* refers to soil parent material or the deepest C soil horizon. Atmospheric Hg is calculated as:  $[Hg_{Atm}] = [Hg_T] - [Hg_{Lit}]$  where the brackets indicate concentration of Ti ( $g\ kg^{-1}$ ) and Hg ( $\mu g\ kg^{-1}$ ). The mean  $Hg_T$  values ranges between 137 and 49  $\mu g\ kg^{-1}$  in O and A horizons, respectively. In O horizons,  $Hg_T$  comes mostly from atmospheric sources ( $Hg_{Atm}$  is 94% of  $Hg_T$ ), which is reduced to 54% in A horizons. The studied soils have a background Hg content (without Hg sulfides) and C horizons showed the lowest  $Hg_T$  values (average 25  $\mu g\ kg^{-1}$ ), presumably all from lithogenic origin. It was noticeable that spodic horizons (Bhs/Bs), which are subsurface horizons, showed the second largest  $Hg_T$  concentrations (average 52  $\mu g\ kg^{-1}$ ; range 15-97  $\mu g\ kg^{-1}$ ) of which up to 33% of  $Hg_T$  derived from atmospheric sources. This involves the mobilization of part of the Hg deposited in uppermost soil layers due to pedogenetic processes (podzolization), which is consistent with the low  $Hg_T$  concentration (mean: 21  $\mu g\ kg^{-1}$ ) and the high proportion of  $Hg_{Lit}$  (95% of  $Hg_T$ ) found in E horizons. The presence of these subsurface soil horizons enriched in  $Hg_{Atm}$ , such as in podzols, constitute an effective barrier against the transport of Hg to water courses, minimizing the risks of environmental toxicity associated to Hg release to groundwater and surface waters.

#### TU168

##### Ecotoxicological risks of soils surrounding an abandoned mercury mine

J. Borj, Universitat Politècnica de Catalunya (UPC) / Centre for Research and Innovation in Toxicology CRIT; B. Valles, Universitat Politècnica de Catalunya UPC / Centre for Research and Innovation in Toxicology CRIT; A. Navarro, M. Riva Juan, Universitat Politècnica de Catalunya UPC  
The abandonment of mercury mining areas is generally associated with a release of Hg into the environment. Due to its potential toxic properties, the mobilization of particulate and soluble Hg species is of major concern in areas surrounding Hg mines. The transport of mercury from soil is mainly caused by wind action, sediment transport, water leaching or atmospheric emissions. Once in the aquatic compartment, interactions with the aqueous phase and with associated solid media will influence the mobilization of mercury. In the present study, a representative number of soil samples containing mining wastes from an old abandoned mining area in the Valle del Azogue (Almería, Spain) were assessed to study the potential risk that their presence represent for terrestrial and aquatic organisms. Samples were analyzed by instrumental neutron activation analysis (INAA) and TD-ICP, showing a total mercury concentration in soils and wastes comprised between *Eisenia fetida* and arthropods from the species *Folsomia candida*. The toxicity to the aquatic compartment was assessed after leaching the sampled soils and through the growth inhibition test of *Pseudokirchneriella subcapitata* and the lethality test to *Daphnia magna*.

##### Transcriptome analysis of the earthworm Eisenia fetida exposed to mercury-contaminated soils collected in French Guiana using RNA-sequencing approach

C. COCQUERELLE, PRES Lille University North of France / LGCgE, University of Lille 1; N. Bousserhine, Université Paris-Est Créteil / Bioemco; F. Gimbert, University of Franche-Comte; F. VANDENBULCKE, LGCgE, Université de Lille 1 / LGCgE EA Univ Lille Fonctionnement des Ecosystèmes Terrestres Anthropisés Cité Scientifique SN Rdc F Villeneuve d'Ascq France  
As far as we know, mercury compounds have no biological function. They are toxic but their toxicity depends on their speciation. Most of the mercury released into the environment is inorganic mercury ( $Hg^{2+}$ ). Methyl-mercury is the most harmful mercury species because of its high bioamplification along food webs and its toxic effects. Because low background levels of mercury may induce harmful effects in the environment, many studies describe mercury concentrations and their potential impacts on organisms. Many of these studies were done on fishes and birds. Abundant literature is also available for marine and freshwater invertebrates and in a lesser extent on terrestrial invertebrates. Earthworms are suggested to be an appropriate tool to predict bioaccumulation in the terrestrial food chain. Studies demonstrated that inorganic mercury concentrations in biota did not exceed concentrations in the soil. In contrast bioaccumulation factor for methyl-mercury could reach 175 to 250 indicating an elevated bioaccumulation of organic mercury in natural population of earthworms. Earthworms have been investigated for very long as bioindicators of metallic and organic pollution and soil organic matter status, and they thus constitute appropriate terrestrial integrator organisms. However, while several studies have shown that earthworm specific richness/diversity and their density/biomass/abundance could be reduced in heavy metal polluted areas, to our knowledge no study investigated so far the detoxification and immune responses of earthworms following exposure to Hg contaminated natural soils. To do this, the ecotoxicologically important test-species, *Eisenia fetida* have been exposed 1 and 14 days to micro/mesocosms containing either Hg spiked OECD soil or natural Hg contaminated soil (collected in French Guyana) versus control soils. A transcriptome analysis by a next

generation sequencing (NGS) approach has been performed on coelomocytes (immune cells). This approach allowed us to identify transcripts of importance in the Hg challenge and allow the identification of genes which expression is affected by Hg in a controlled environment in *E. fetida*. Mercury and Methyl-mercury contents have also been quantified in worms. The aim of this transcriptomic approach is to underpin and to delineate the defence (immune and toxicant-mediated) function alterations in earthworms during exposure to Hg.

#### TU170

##### Enhanced relative methyl mercury concentrations within a valuable seagrass area in the brackish fjord Gunneklevfjorden, Norway

M. Olsen; F. Moy, Institute of Marine Research; E. Lydersen, Telemark University College; M. Schaanning, Norwegian Institute for Water Research  
Since early 1900 the brackish, land locked fjord Gunneklevfjorden in Norway has suffered from significant contamination due to industrial discharges. Between 1947 and 1988 approximately 80 tonnes of mercury were discharged into the fjord from a chloralkali plant. Plans for remediation of the fjord is now under development. Sediment profiles shows the contamination history and mercury concentrations peaks at 15 cm sediment depth with approximately 490 mg TotHg  $kg^{-1}$  (ppm). Termination of regular discharges of mercury has led to lower mercury concentrations in sedimenting material and our recent investigations have revealed 1.9 - 7.7 mg TotHg  $kg^{-1}$  (ppm) in surface sediments. Mercury in surface sediments is bioavailable to bottom dwelling and bioturbating organisms mainly in the organic form methyl mercury. Methyl mercury is known to bioaccumulate in aquatic food webs. Methyl mercury is formed by methylation of inorganic mercury primarily by sulfate reducing bacteria in the sediments. Methylation rates might be influenced by factors that influence bacterial activity, like pH and organic matter. Recent studies have demonstrated that the presence of live plants enhances bacterial mercury methylation rates. We hypothesize that relative methyl mercury concentrations are enhanced within the 70 000 m<sup>2</sup> area of seagrass found in shallow waters in Gunneklevfjorden compared to deeper areas without seagrass. To test our hypothesis that relative methyl mercury concentrations are enhanced within the area of seagrass, we measured relative methyl mercury concentrations in sediment cores and porewater samples from four stations in Gunneklevfjorden. The sediment cores were sliced and measures of each slice included TOC, pH, redox and sulphide in addition to total mercury and methyl mercury. In addition, total mercury and methyl mercury concentrations in sediment porewater were measured along a gradient of increasing depth and reduced vegetation density from within the seagrass area and into areas without seagrass. Our preliminary results show enhanced relative methyl mercury concentrations within the seagrass area, both in sediments and in porewater. The results also reveal more favorable conditions for bacterial activity within the seagrass area than outside. Remediation plans should take into consideration the possible influence of seagrass to bioavailability, seeking remediation actions that reduce bioavailability of mercury while preserving a valuable biotope.

#### TU171

##### Mercury concentration, enrichment and inventory in core sediments from an urban water supply reservoir in NW Spain

P.P. Rodríguez, Universidade de Vigo / Plant Biology and Soil Science; S. Peña-Rodríguez, University of Vigo; A. Gómez-Armesto, University of Vigo / Plant Biology and Soil Science; L. Cutillas-Barreiro, University of Vigo; P. Araujo-Nespereira, University of Vigo / Geotecnia and Hydrology; J. Nóvoa-Muñoz, University of Vigo  
Mercury is a global contaminant which is mainly stored in soils, but changes in land use (reforestation, agriculture, etc.) and forest fires facilitate its exportation at catchment level. A high risk of environmental toxicity is expected if this Hg reaches the surroundings of wetland ecosystems, where its transformation to highly toxic methyl-Hg is clearly enhanced. The concentration of total Hg ( $Hg_T$ ) in four non-disturbed core sediments from the banks of a reservoir which is the main water supply for a small town (Ourense, NW Spain) was studied. Two core sediments (A and B) were sampled close to the inflow of the reservoir, and cores C and D were sampled at the halfway of the wall of the reservoir. The sediment cores (48-54 cm depth) were sliced into 2 cm sections and air dried (40 °C). A small portion of each sample was oven-dried (105 °C) for bulk density calculation. Total Hg and Ti (for enrichment factor calculations) were determined in samples using an Hg analyzer and X-ray fluorescence, respectively. A sample of granite, the main rock of the reservoir catchment, was collected for analysis. In the cores A and B,  $Hg_T$  ranges between 73 and 229  $\mu g\ kg^{-1}$  without variations with the core depth. For cores C and D,  $Hg_T$  decreases steadily from 84-102  $\mu g\ kg^{-1}$  in the uppermost samples to 8-13  $\mu g\ kg^{-1}$  in the bottom sections. Since  $Hg_T$  concentration in the catchment rock was only 3  $\mu g\ kg^{-1}$ ,  $Hg_T$  in the cores (especially in A and B columns) must come from its mobilization from the uppermost soil layers of the reservoir drainage basin. This is consistent with the Hg enrichment factors ( $EF_{Hg}$ ) values in cores A and B (8-22) whereas for cores C and D the  $EF_{Hg}$  is < 4 for samples below 12 cm depth. The Hg inventory is 23-26 mg  $Hg_T\ m^{-2}$  for cores A and B, being much lesser (13-16 mg  $Hg_T\ m^{-2}$ ) in cores C and D, possibly due to a higher organic matter content in sediments of the cores A and B (9-15 %) which acts filtering the Hg that enters with river flow. This process is not seen in cores C and D. A negative side effect of the  $Hg_T$  accumulation in cores A and B is the high potential of the area for biogeochemical reactions that lead to the formation of highly toxic methyl-Hg (long-term

waterlogging and high in organic matter). The potential transformation of Hg in methyl-Hg in the studied reservoir deserves a detailed investigation as soon as possible at the light that, although after a careful purification, the water dammed is used for drinking.

#### TU172

##### **A regional analysis of the distribution of mercury in the aquatic ecosystem of the Limpopo Watershed, South Africa**

V. Somers et, NRE; M. Cuoto, Eskom; C. Walters, CSIR / Natural Resources and the Environment

In South Africa the magnitude of Hg pollution was relatively low on the agenda in 2000, although a study by Pacina *et al.* [1] has ranked the country as the second highest anthropogenic emitter. This data was largely based on the Hg emissions from coal combustion and artisanal gold mining, reporting that South Africa contributes more than 10% to the global Hg emission budget. South African Scientists have since then conducted further investigations and have reported that Hg emissions are significantly lower than previously reported [2]. The primary objective of the current study is to identify the main sources and transport mechanisms of Hg in the Limpopo Water Management Area (WMA), to establish a mass-balance for Hg and determine the fluxes between various ecosystem compartments. The Waterberg region is situated in this WMA and houses the building of the Medupi Power Station near Lephalale, which is the biggest dry-cooled coal-fired power station in South Africa and the world [3]. Various sources of site specific data for the Waterberg region in the Limpopo WMA have been gathered that includes Hg concentrations in water, sediment and biota. New data builds on the findings by Walters *et al.* [4] in which the Hg concentrations for the Limpopo WMA was identified to be: TotHg < 10 ng/L and MeHg < 1 ng/L in freshwater; while in sediment the TotHg < 10 ng/g and MeHg < 1.00 ng/g. The pathway for the wet and dry deposition of Hg is also investigated and an assessment of the roles of seasonal variability, wind direction and precipitation are also analysed. Analysis further involves the determination of the calculated flux of Hg across the sediment–water interface, water–air interface and water–biota transfer. Furthermore, the regional Hg budget and the factors contributing to major uncertainties associated with Hg emission estimates and Hg chemistry are also evaluated. It is believed that once the new dry-cooled coal-fired power station is in operation, changes in atmospheric Hg deposition to the aquatic ecosystems will occur, resulting in flux changes of Hg across the sediment–water interface, water–air interface and water–biota transfer. **References:**[1] Pacyna, E.G., et al. #### TU173

##### **Kinetics of mercury accumulation and transformation in periphyton**

P. Dranguet, Institut Forel, University of Geneva / Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences; S. Le Faucheur, Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences; V.I. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences

Periphyton is a melting pot composed of a biotic (microorganisms) and abiotic fraction (organic matter, polysaccharide matrix...) essential for the proper functioning of aquatic systems. Mercury (Hg) is a global pollutant, which dangerousness comes from its methylated form (CH<sub>3</sub>Hg) due its ability to biomagnify along the food chains. Periphytic communities are known to influence Hg cycle. For example some specific bacteria (such as sulfato-reducing bacteria) present in periphyton are able to methylate inorganic mercury (Hg<sup>II</sup>). Moreover, at the base of the food chain, periphyton might be one of its entry points into food webs. It is thus crucial to better understand the interactions between Hg and periphyton. The aim of the present study was thus to examine the kinetics of Hg accumulation and transformation by periphyton and to evaluate the role of periphyton composition in these processes. To that end, periphyton was cultured on microscopy slides with a flow-through microcosm containing Geneva Lake water during 85 days and 127 days. Formed biofilms were then exposed to 200 pM Hg during 10, 30 min, 1, 4, 6, 8 and 24 hours and examined for Hg content for each times. The composition of the two communities was analysed using pyrosequencing. Total Hg and non-extractable Hg<sup>I</sup> and CH<sub>3</sub>Hg (Hg obtained after cysteine washing) accumulation were measured after acid digestion by cold vapour atomic fluorescence spectrometry. Physicochemical parameters of exposure media (pH, temperature, anions, cations and dissolved organic matter concentrations) as well as Hg concentrations were also analysed at each exposure time. Total accumulated Hg in periphyton were comparable for both communities in the first hours of exposure. However, after 24h, these concentrations were 886±179 pM/g dry weight for the youngest periphyton and 1528±73 pM/g dry weight for the oldest periphyton. Non-extractable Hg contents were similar in both communities. The percentage of Hg strongly attached to periphyton represents thus around 48% for the 85 days periphyton and 34% for the 127 days periphyton. Moreover, chlorophyll a content decreased with increasing Hg accumulation, suggesting an impact on photosynthesis process. Further analysis on periphyton composition will allow us to better understand the influence of periphyton composition on

bioaccumulation and transformation processes.

#### TU174

##### **Mechanisms of Hg accumulation in the aquatic plant *Elodea nuttallii***

N. Regier, University of Geneva / Institute Forel Earth and Environmental Sciences; C. Cosio, Geneva University / Institute Forel Earth and Environmental Sciences

Biomagnification of Hg in food webs is still a big concern nowadays in aquatic ecosystems. In shallow waters the highly toxic methyl-Hg (MeHg) is formed and aquatic plants are the predominant primary producers playing a key role in Hg transfer in food webs. Mechanisms of Hg accumulation are still unclear with earlier data suggesting passive uptake, while few recent data suggest carrier mediated accumulation. The present study aimed at investigating the mechanism of Hg accumulation in a representative aquatic plant, *Elodea nuttallii*. High Hg tolerance and accumulation were observed in *E. nuttallii*. Competition with Cu resulted in a significant 97.2±0.6% inhibition of Hg uptake while other metals (Fe, Mg, Mn, Ca, K and Zn) had no significant effects on accumulation, supporting a putative role of Cu transporters in Hg uptake. RNAseq and RT-qPCR analysis further revealed a correlation between the level of expression of *EnCOPT1* gene and Hg exposure. As COPT1 is known to transport Cu from the surrounding medium inside cells in different organisms, we further tested the function of COPT1 in Hg accumulation in yeast and *Arabidopsis thaliana*. Analyses of *EnCOPT1* gene in yeast confirmed its ability to uptake Cu and confer tolerance to Hg. Lines of *A. thaliana* deficient and overexpressing COPT1 showed a clear correlation between the expression of COPT1 and accumulation of Hg. Results supports the hypothesis that Hg is accumulated through the Cu homeostasis network in plants, further suggesting that Hg accumulation is carrier mediated, and not passive in aquatic plants. Mechanistic understanding of bioaccumulation of Hg in primary producers will strongly contribute to environmental risk assessment of Hg and will help environmental managers to take appropriate decisions to limit Hg transfer in food webs.

#### TU175

##### **Mercury impacts towards periphytic communities**

S. Le Faucheur, Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences; A. Freiburghaus, University of Geneva / Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences; P. Dranguet, Institut Forel, University of Geneva / Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences; V.I. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences

Periphyton are microorganism communities, which grow onto hard substrata in natural waters. They have important roles in aquatic food chains as primary producers and in trace element cycling, notably mercury (Hg), which is known to be accumulated and transformed by periphytic microbes. In contrast, Hg effects towards biofilms are poorly known. The present study thus aimed to assess Hg impacts on periphyton and their sensitivity to Hg. To that end, periphyton were grown under controlled conditions using flow-through microcosms containing Geneva Lake water. Three of them were spiked with 20 pM, 200 pM and 2 nM Hg<sup>II</sup> whereas one was not contaminated and used as a control. After 7 weeks of colonisation, periphyton were analysed for their total Hg content and strongly bound Hg content (Hg<sub>n-ext</sub>, i.e. after a cysteine washing step). Their chlorophyll a content and ash free dry mass (AFDM) were also measured along with their abiotic and biotic fractions using microscopy and taxonomic composition using pyrosequencing. Modification of their sensitivity to Hg was assessed by further exposing grown periphyton to 2 nM Hg<sup>II</sup> for 24 h and evaluating damage on microbial membrane permeability using propidium iodide (PI) and cellular oxidative stress using CellRox® green. Total Hg content in control periphyton was found to be 0.33 ± 0.01 nmol/g dw and to increase by two times upon exposure to 200 pM Hg. Strongly bound Hg was also observed to increase, from 0.13 nmol/g dw in control periphyton to 0.47 nmol/g dw in periphyton exposed to 200 pM, representing 64% of the total content. At the highest Hg concentration, Hg<sub>n-ext</sub> represented only 10% of the total Hg content, suggesting that Hg bound to weaker binding sites at very high Hg concentrations. Modification of periphyton composition could not be observed with chlorophyll a content and AFDM measurements. However, microscopic analysis revealed a decrease of the biotic fraction in periphyton exposed to 2 nM Hg<sup>II</sup>. Taxonomic analysis further evidenced a shift in microbial communities from algal dominated (87%) to bacteria dominated communities (69% at 2 nM) with exposure to Hg. PI fluorescence was similar in control and Hg exposed periphyton. However, cellRox® green signal was lower in control periphyton than in Hg pre-exposed periphyton, suggesting that oxidative stress was higher in pre-exposed biofilms. The present study demonstrated the strong impacts of Hg on periphyton.

#### TU176

##### **Mercury bioaccumulation and effects on the transcriptome in the macrophyte *Elodea nuttallii***

R. Beauvais-Flueck, Institute Forel Earth and Environmental Sciences; V.I. Slaveykova, University of Geneva / Section of Earth and Environmental Sciences Institute Forel and Institute for Environmental Sciences; C. Cosio, Geneva University / Institute Forel Earth and Environmental Sciences

Mercury is one of the most harmful pollutants which can lead to important risk for

the environment at global scale. Moreover Hg exists in diverse forms, both inorganic (IHg) and organic, like methyl mercury (MeHg). Inorganic Hg and MeHg are very toxic and known to accumulate in primary producers, but MeHg is further biomagnified in the aquatic food chain, resulting in health hazard for higher consumers. *Elodea nuttallii* is a submerged plant rooted in sediments. Like other primary producers it plays an important role in Hg biogeochemical cycle in freshwater systems. Previous study on Hg accumulation in *E. nuttallii* highlighted high bioaccumulated concentrations but also important differences in the uptake kinetics and sub-cellular distribution of IHg and MeHg, and thus the possibility that these two Hg forms are taken up by different pathways or are regulated by different mechanisms in primary producers. The objective of our study was thus to assess the effect of Hg internalization on the level of gene expression using high-throughput sequencing, with the aim of increasing our understanding of the mechanisms behind Hg accumulation and toxicity. *E. nuttallii* was exposed two hours in a simplified artificial medium to increasing concentrations of  $1.0 \times 10^{-10}$  to  $1.0 \times 10^{-7}$  M IHg or  $4.6 \times 10^{-11}$  to  $4.6 \times 10^{-8}$  M MeHg. Although the tested concentrations do not have significant effects on photosynthesis, oxidative stress, or growth, the analysis of the transcriptome answer obtained by RNA-Seq enables us to investigate the molecular mechanisms of the response of this plant to Hg and to find interesting genes that can be used as biomarkers for IHg and/or MeHg exposure in the aquatic environment.

#### TU177

##### **Mercury in English freshwater fish - Which factors matter?**

M.D. Juergens, Centre for Ecology and Hydrology / Wallingford; A.C. Johnson, CEH Wallingford / Wallingford; A. Lawlor, Centre for Ecology and Hydrology; K.C. Jones, Lancaster University / Lancaster Environment Centre

**Mercury** Mercury was used in many industrial and agricultural applications in the past. In the UK today most deliberate uses have ceased, but it is still used in dentistry and some electrical components (mainly fluorescent lights), and it is also released as a trace component of fossil fuels. **The UK fish tissue archive** Fish accumulate chemicals from water and food over their lifetime, making concentrations higher (therefore easier to measure), less variable and more relevant to the potential threat to wildlife than water measurements. With this in mind, CEH and the Environment Agency are building a Fish Tissue Archive by annually collecting fish from a number of river sites and storing them long term at  $-80^{\circ}\text{C}$  to provide a resource for future retrospective monitoring of pollutants. **Results** We analysed a total of 144 roach and bleak (whole body homogenates) from the UK Fish Tissue Archive for mercury and found: Overall the mercury concentrations were in a relatively narrow range between 6 and 68  $\mu\text{g}/\text{kg}$  with more than 3/4 of the values above the EU Environmental Quality Standard of 20  $\mu\text{g}/\text{kg}$  fresh weight, but well below the food standard of 500  $\mu\text{g}/\text{kg}$ . Mercury concentration tended to increase with the size of the fish and was overall a little higher in bleak than in roach. After adjusting for fish size, site differences became apparent: In the upper reaches of rivers there was an increase of size-adjusted mercury concentration with distance from the source, but this increase did not continue in the lower reaches (lower reaches only available for the Thames). One explanation for this may be less favourable conditions for methyl-mercury transformation in the upper reaches.

**Conclusions** The Fish Archive is a suitable tool for monitoring mercury contamination. Although lower than in many other places, there is still some concern over mercury in English freshwater fish. Adjusting the contamination for size revealed site differences that were previously masked. Some of this data was published in: Juergens et al. 2013, The presence of EU priority substances mercury, hexachlorobenzene, hexachlorobutadiene and PBDEs in wild fish from four English rivers, STOTEN, 461–462, p.441–452.

#### TU178

##### **Mercury Concentrations in Freshwater Fishes on North Pacific Islands: the Influence of Military Sites, Atmospheric Deposition & Biotransport**

F.A. von Hippel, University of Alaska Anchorage / Department of Biological Sciences; L.A. Kenney, Alaska Natural Heritage Program / Biological Sciences; C. Eagles-Smith, FRESC; J. Ackerman, USGS / Western Ecological Research Center; R. Kaler, US Fish & Wildlife Service / Migratory Bird Management

Some islands in the Aleutian Archipelago and Gulf of Alaska have been heavily impacted by military activities since World War II and potentially exposed to long-range contaminant transport via atmospheric distillation, prevailing ocean currents, and biotransport. We evaluated mercury concentrations of 1,121 resident-freshwater fish samples of two species, the threespine stickleback (*Gasterosteus aculeatus*) and Dolly Varden (*Salvelinus malma*). Samples were obtained across a longitudinal gradient of 11 islands spanning over 3,000 km and including islands with and without a history of military occupation. Mercury concentrations for stickleback and Dolly Varden differed significantly among islands. There were no apparent longitudinal trends in mercury concentrations related to potential long-range transport from Asia, nor were there differences in fish mercury concentrations between military and non-military islands. Within islands, fish in lakes used by marine birds had higher mercury levels than those in non-marine bird lakes. Fish mercury concentrations were higher throughout our sampled islands than in lakes in mainland Alaska. At all islands, mean fish mercury levels exceeded Environment Canada's advisory level for fish-eating wildlife (0.033 mg/kg ww). These results provide the first mercury levels in resident-freshwater fishes across the Aleutian Archipelago, an area experiencing

effects of rapid climate change. The results also provide critical baseline data for wildlife management and human consumption advisories.

#### TU179

##### **Mercury in the big-scale sand smelt (*Atherina boyeri* Risso, 1810) of the Marano and Grado Lagoon (northern Adriatic Sea)**

N. Bettoso, A. Felluga, G. Piazza, E. Rancati, A. D'Aiotti, L. Faresi, G. Mattassi, ARPA FVG

The big-scale sand smelt, *Atherina boyeri* (Risso 1810), is a small, short-lived, euryhaline atherinid fish which mainly inhabits coastal and estuarine waters, including coastal lagoons, salt marshes and, more rarely, inland waters, over a wide range of salinities from freshwater to hypersaline conditions. It is common in the Mediterranean and adjacent seas, and is also found in the North-East Atlantic from the Azores to the North-West coast of Scotland. *A. boyeri* represents one of the most important fisheries resource in the Marano and Grado Lagoon, being caught by fyke nets, a traditional fishing gear in the northern Adriatic lagoons. The Marano and Grado Lagoon experienced an historical mercury (Hg) contamination due to both mining and chlor-alkali activities. As a consequence this environment suffers from a diffuse sediment contamination, which is actively transferred to the related trophic chain. The aim of this study was to investigate the total Hg concentration in the edible tissue of the sand smelt during spring 2012. Specimens were caught in 22 sampling stations and stored at  $-20^{\circ}\text{C}$  until the analysis. On each station 100 individuals were randomly selected and the total length (TL) was recorded. 40 g of fishes was homogenized for each sample and Hg analysis was performed using the EPA method 7473:2007. Mean TL of sand smelts in the sampling stations ranged from  $6.26 \pm 0.86$  cm to  $8.42 \pm 0.79$  cm (mean value 7.29 cm), whereas Hg concentration ranged from  $0.28 \mu\text{g g}^{-1}$  wet weight (ww) to  $0.85 \mu\text{g g}^{-1}$  ww (mean value  $0.52 \pm 0.18 \mu\text{g g}^{-1}$  ww). These preliminary data showed the level of Hg concentration in this species, caught during the breeding period. Further investigations are clearly required in order to assess Hg levels during other seasons and to verify the existence of a spatial gradient of bioconcentration in the Marano and Grado Lagoon.

#### TU180

##### **PBTK/TD model-based mortality risk assessment for tilapia species exposed to mercury/methylmercury**

Y. Cheng, Y. Lin, Y. Shu-Han, National Taiwan University / Department of Bioenvironmental Systems Engineering; Y. Yang, National Taiwan University; C. How, Y. Tseng, V. Liao, C. Liao, National Taiwan University / Department of Bioenvironmental Systems Engineering

Environmental mercury (Hg) is considered one of the most hazardous chemicals detrimental to aquatic organisms. Therefore, the overall objective was fourfold: (i) to quantify environmental Hg levels in six rivers across northern and southern Taiwan, (ii) to estimate tissue burdens in tilapia species based on the proposed physiologically-based toxicological kinetics (PBTK) model, (iii) to construct the dose-response relationships between tissue burden and mortality, and (iv) to estimate mortality risk for six rivers based on different estimated tissue burdens. Results indicated that in southern Taiwan, Luermen Creek had the highest mercury (Hg(II)) and methylmercury (MeHg(I)) levels of  $3.399 \times 10^{-5}$  and  $1.120 \times 10^{-6}$  mg  $\text{L}^{-1}$  and 2.024 and 0.079 mg  $\text{kg}^{-1}$  ww in water and sediment, respectively. Whereas in northern Taiwan, Tamsui River had the highest Hg level. Based on the established PBTK model, the highest and lowest tissue/organ burdens in Tilapia in Luermen Creek were found in kidney and muscle, respectively, of 0.135 and  $3.301 \times 10^{-4}$   $\mu\text{g g}^{-1}$  ww. Dose-response relationships revealed that muscle had the lowest half lethal dose ( $\text{LD}_{50}$ ) of  $3.21 \pm 2.88$  (median  $\pm$  se)  $\mu\text{g g}^{-1}$  ww ( $r^2 = 0.94$ ,  $p < 0.001$ ), whereas liver had the highest  $\text{LD}_{50}$  of  $7.15 \pm 9.10 \mu\text{g g}^{-1}$  ww ( $r^2 = 0.93$ ,  $p < 0.001$ ). The likely mortality risks were estimated to be 5.668% (95% CI: 0 – 35.060), 5.500 (0 – 50.278), and 5.500 (0 – 48.924) in gill, liver, and muscle, respectively. This study provides an integrated risk assessment framework to better assess the environmental impact of mercury/methylmercury exposure on mortality of tilapia species based on an integrated approach that links a water-sediment dynamic model, a PBTK model, and a probabilistic risk model.

#### TU181

##### **The sub-cellular partitioning of mercury in the liver of wild golden grey mullets (*Liza aurata*) - a case study of Ria de Aveiro (Portugal)**

O. Araujo, DIVOA; P. Pereira, Department of Biology and CESAM; M. Pacheco, University of Aveiro / Dept of Biology; J. Raimundo, IPMA / DIVOA

Mercury (Hg) has been identified as a severe environmental pollutant to the aquatic biota. However, little is known about its sub-cellular partition in wild fish. Thus, the current study aimed to evaluate the affinity of total mercury (tHg) to the whole liver and sub-cellular fractions of golden grey mullet (*Liza aurata*), namely granules (Gran), mitochondria (Mit), nuclei plus cellular debris (N+D), lysosomes plus microsomes (Lys+Mic), heat denaturable proteins (HDP) and heat stable proteins (HSP), under different environmental loads of Hg contamination. For this purpose, a field campaign was performed in June 2013 comprising fish capture in two sites of a Portuguese coastal lagoon (Ria de Aveiro): LAR located in the most contaminated area; R near the lagoon inlet and thus selected as reference site. In parallel with fish capture, surface sediment and water were collected in both sites. In whole liver, fish from contaminated area (LAR) accumulated approximately 2 times more Hg ( $0.098 \mu\text{g g}^{-1}$ ) than the individuals from reference area (R) ( $0.054 \mu\text{g g}^{-1}$ ). Similarly, Hg

concentrations in Gran, Mit, Lys+Mic and HDP fractions of liver from LAR (median values varying from 0.23 to 0.64  $\mu\text{g g}^{-1}$ ) were two to three times higher than sub-cellular fractions of individuals from R site (median ranging between 0.10-0.28  $\mu\text{g g}^{-1}$ ). Also, the partitioning of Hg among the sub-cellular fractions varied between individuals from R and LAR. At LAR, Lys+Mic was the main major fraction binding to the Hg while at R site no differences were observed for Lys+Mic, Mit and HDP. Moreover, levels in Mit, Gran and HDP were linearly correlated with Hg concentration in the whole liver while two different tendencies may be discerned for Lys+Mic and whole liver. This could be indicative that a certain threshold of accumulation was exceeded. The association of Hg to metal sensitive fractions (e.g. Mic, Mit and HDP) suggests that the metal detoxification mechanisms were not efficient in liver of *L. aurata* living under chronic exposures conditions.

#### TU182

##### **Temporal and spatial assessment of mercury in fish of the Madeira River, Brazil**

W.R. Bastos, Universidade Federal de Rondônia; J.G. Dorea, University of Brasília / Nutrition; J. Bernardi, Universidade de Brasília; L. Lautharte, M. Mussy, Federal University of Rondônia; L. Lacerda, Federal University of Ceará; O. Malm, Fed Univ Rio de Janeiro / Biophysics Institute

The Madeira River is the largest tributary of the Amazon River Basin and one of the most impacted by artisanal gold-mining activities, deforestation for agricultural projects, and recent hydroelectric reservoirs. We studied total Hg (and methyl-Hg) concentrations in 3,211 fish samples of 84 species (3 genders) of different trophic levels as a function of standard size. Species at the top of the trophic level (Piscivorous, Carnivorous) showed the highest mean total Hg concentrations (50.9 to 1,241.7  $\mu\text{g/kg}$ ), Planctivorous and Omnivorous species showed the intermediate total Hg concentrations (25.8 to 494.0  $\mu\text{g/kg}$ ), while Detritivorous and Herbivorous species showed the lowest range of mean total Hg concentrations (9.4 to 274.8  $\mu\text{g/kg}$ ). Significant correlations between size (standard length) and Hg concentrations were seen for Planctivorous ( $r=0.474$ ,  $p=0.0001$ ), Piscivorous ( $r=0.459$ ,  $p=0.0001$ ), Detritivorous ( $r=0.227$ ,  $p=0.0001$ ), Carnivorous ( $r=0.212$ ,  $p=0.0001$ ), and Herbivorous ( $r=0.156$ ,  $p=0.01$ ), but not for the Omnivorous species ( $r=-0.064$ ,  $p=0.0685$ ). Moreover, feeding habit of species influenced theratio of MeHg to total Hg (ranged from 70 to 92%). When adjusted for standard body length, significant increases in Hg concentrations in the last 10 years were species specific. Spatial differences indicate that significant difference but no time trends consistent with environmental contamination of past alluvial gold mining activities. Fish-Hg bioaccumulation is species specific but fish feeding strategies is the predominant influence in the fish-Hg bioaccumulation pattern. Despite spatial differences in fish-Hg concentrations, short term temporal changes indicate an increase in Hg bioaccumulation pattern of fish species collected before impoundment of areas under the influence of Santo Antonio Dam.

#### TU183

##### **Mercury in Arctic Barnacle goslings in contaminated terrestrial habitats**

N.W. van den Brink, Wageningen University / Dept of Toxicology; I.B. Scheiber, University of Groningen / Centre for Ecological and Evolutionary Studies Behavioural Ecology and Selforganization; M.E. de Jong, University of Groningen / Arctic Center; A. Braun, University of Groningen / Centre for Ecological and Evolutionary Studies Behavioural Ecology and Selforganization; M.J. Loonen, University of Groningen / Arctic Center

The Arctic is contaminated by mercury from different sources. Long-range transport brings mercury from lower latitudes to the Arctic via the atmosphere. Local human activities may result in contamination of confined areas. For instance, mining activities have resulted in elevated levels of mercury in the surroundings of the mining areas. Research on mercury in the Arctic has mainly focussed on marine ecosystems and receptors, which are regarded as being mostly at risk. On the other hand, risks of local contamination of terrestrial ecosystems by human activities have been studied less. In the current paper we will present a pilot-study, in which we herded goslings in a mine impacted site and a control site near Ny-Ålesund, Spitsbergen. Herding of the goslings made it possible to perform a controlled study under field conditions, assessing the accumulation of mercury in the two groups of goslings raised in the two areas. Soil in the mining area contained 5-6 times higher concentrations of total mercury in comparison to the control site (based on geometric means). This was reflected in elevated levels of mercury in the vegetation in the mining area (approx. 2.2 times higher compared to the control site). Each group of goslings grazed approximately 3-4 hours per day in their respective areas. At night and during bad weather conditions they were kept in pens. The goslings that grazed in the mine impacted area showed increased levels of total mercury in the liver relative to control goslings ( $p < 0.05$ ). Concentrations were relatively low, possibly due to growth dilution and deposition of mercury in the growing feathers. All goslings received supplemental food, hence effects of mercury on growth rate could not be assessed. Currently, biochemical analyses are underway in order to determine effects at the sub-individual level. Since mercury is a neurotoxin, our analyses focus on neurotoxic modes of action. Additionally, we exposed goslings to moderate stressors, and observed their behaviours. Combined results will be presented at the meeting.

##### **Impact of multi-stress on macrophyte vegetation in the Danube Basin: the experience from the Joint Danube Surveys (JDS 2 & 3)**

M. Novković, D. Cvijanović, S. Radulović, University of Novi Sad Faculty of Sciences / Department of Biology and Ecology; I. Teodorovic, University of Novi Sad

The aim of this study, undertaken within the frame of collaborative FP 7 project Solutions, was to select the most important stressors on macrophyte vegetation assemblages' diversity along the Danube, based on the Joint Danube Survey 2/3 databases. The influence of land cover types, basic physico-chemical parameters and pesticides were tested against i) vegetation structure, ii) macrophyte richness and iii) macrophyte production. Vegetation data matrix was compiled using the macrophyte functional groups. Canonical Correspondence Analysis (CCA) was performed in order to assess the impact of multiple environmental stressors on vegetation structure. All ordination-associated analyses were performed with the CANOCO 4.5 software package. Macrophyte richness and production were correlated with environmental variables using the Statistica 12. Macrophyte richness and production were moderately influenced by presence of wetlands and artificial land cover types in the riparian zone. In opposite, results of the CCA analysis revealed that the land use parameters do not influence vegetation structure directly. Basic water quality parameters and selected organic pollutants (Bentazon, Bezaflibate, Bisphenol A, Desethyl-atrazine, Diclofenac, Ibuprofen, Ketoprofen, Simazine), explained together approximately 35% of total variance of vegetation structure, while selected pollutants explained over 28 % of total variance. The SOLUTIONS Project is supported by the Seventh Framework Programme (FP7-ENV-2013) of the European Union under grant agreement no. 603437.

#### TU185

##### **Discriminating between the effects of chemicals and other influencing factors on the macroinvertebrate community and trait composition: data analysis from the 3rd Joint Danube Survey**

A. Focks, Alterra Wageningen University and Research Centre / Ecotoxicology Environmental Risk Assessment Team; h. haveco, Environmental Risk Assessment Team; W. Graf, BOKU - University of Natural Resources and Life Sciences Vienna / Institute for Hydrobiology Water Management; A. Schmidt-Kloiber, P. Leitner, BOKU - University of Natural Resources and Life Sciences Vienna; I. Teodorovic, University of Novi Sad; M. Paunovic, IBISS; P.J. van den Brink, Alterra and Wageningen University

In large rivers such as the Danube, a number of different factors can affect the composition of aquatic macroinvertebrate communities: hydromorphological conditions, nutrient levels, general water quality parameters such as SOM, pH or salinity, but also organic chemicals or metals. A prerequisite for an assessment of such influences is having enough data at hands with most important factors included to ensure robust statistical analyses. In the scope of the 3<sup>rd</sup> Joint Danube Survey (JDS3), for 68 sampling sites across the entire length of the Danube River an extensive dataset was collected. The data collection was organised by the International Commission for the Danube River (ICPDR) together with all 14 main Danube Basin countries and the European Commission. The data consists of hydromorphological parameters, water quality parameters and results from chemical target analysis for more than 300 organic chemicals and metals. In addition, data was collected for several biological groups, e.g. macroinvertebrates, fish or aquatic macrophytes. For our analysis we focused on the assessment of the taxonomic composition of the macroinvertebrate community. Abundances of macroinvertebrate species were sampled via kick & sweep method and microhabitat sampling techniques. The resulting community composition data were transformed into trait composition by using species-traits tables, amongst other sources from the freshwater ecology.info database. Multivariate statistical techniques were applied to determine the influence of the above mentioned water parameters on the taxonomic and functional composition of the invertebrate community with the objective to identify those factors that explain variations across the sampling sites. Further, we wanted to filter for the influences of different categories of explaining factors. Hence we applied the technique of variance partitioning, which can be utilised to partition explained variability in the data into a number of categories. As expected, the variability in the invertebrate composition was co-determined by quite a number of factors from different categories, and again hydromorphology was found to be most influential. Nevertheless, it was possible to identify the most influential chemical compounds as well. ##### **Can Trait-Based Approaches in Analysis of Fish Communities Help in Identification of Key Pollutants and Mixtures: The River Danube Case Study**

S. Sips, Faculty of Sciences / Lecotox Laboratory of Ecotoxicology; V. Jovanovic, Institute for Biological Research Siniša Stanković University of Belgrade; V. Bammer, Austrian Federal Agency for Water Management; L.

Pehlivanov, Bulgarian Academy of Sciences / Institute of Biodiversity and Ecosystem Research; H. Zornig, M. Schabuss, PRO FISCH OG; Z. Szalóky, Danube Research Institute / MTA Centre for Ecological Research; A. Focks, Alterra Wageningen University and Research Centre / Ecotoxicology Environmental Risk Assessment Team; I. Teodorovic, University of Novi Sad Species traits provide a reliable means to understand general rules in community ecology, along environmental or landscape gradients, as the river continuum concept, at least theoretically, links functional groups with the longitudinal gradients in habitat structure and productivity. Trait-based approaches are gradually replacing taxonomy-based approach in aquatic ecosystem status assessments, but mainly to study responses of fish species and communities to hydromorphological alterations and processes of fish species extinction, invasion and assemblage homogenization. Hydromorphological alterations, eutrophication and biological invasions for sure present key pressures to fish communities and overall ecological status of aquatic ecosystems, while adverse impact of chemical pollution on ecosystem integrity might remain hidden. The aim of the present study is to apply community composition and trait based approaches to detect and possibly quantify in situ ecological impacts of pollutants and their mixtures on fish communities and hopefully contribute to the process of identification of key or river basin specific pollutants and mixtures. The study is based on comprehensive monitoring dataset, acquired during Joint Danube Survey 3 (JDS 3) in 2013, which includes biological (focus on fish), hydromorphological and large chemical dataset (over 300 chemicals). Fish data were collected by ichthyological team of JDS 3 at 32 sampling sites along the Danube, from Kelheim (DE) to Sulina (RO). Altogether, 67 species belonging to 17 families were identified, however, preliminary analyses showed that taxonomic approach is not appropriate for reaching the objectives of the study. Therefore, characterization of longitudinal sectors of the Danube River was based on characteristic communities, i.e. environmental groups. Community composition data were transformed into traits, and a number of traits, such as maximum length, ecological guild, mobility, life history strategies, reproductive strategies, offspring care, number of eggs laid by mature individuals and the feeding habits have been selected for further analysis. Multivariate statistical techniques would be applied in attempt to explain variability and distinguish between chemical and other stressors which impact fish communities. Since the chemical data of JDS 3 became available only recently, the analyses are still underway. The study is being conducted in the framework of FP 7 SOLUTIONS Project (603437).

##### **Mutagenicity of Joint Danube Survey (JDS3) water samples using diagnostic strains of *Salmonella*/microsome assay**

D.A. Morales, School of Technology, UNICAMP / LEAL Laboratory of Ecotoxicology and Environmental Microbiology; F. Kummrow, Universidade Federal de São Paulo; M. Krauss, T. Schulze, W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis; G.d. Umbuzeiro, FACULTY OF TECHNOLOGY -UNICAMP / LEAL  
The *Salmonella*/microsome assay using strains with different metabolic capacities and DNA repair systems have proven to be useful to identify chemical classes of mutagenic compounds in environmental samples. YG1041 strain is more sensitive than its parental TA98 to nitro compounds and aromatic amines. Similarly, YG5185 is more sensitive to benzo(a)pyrene like substances in comparison to TA1538. The objective of this study was to evaluate the mutagenicity profile of surface water organic extracts from the Danube campaign (JDS3) collected in 2014. High volume water samples were collected and extracted using large-volume solid phase extraction during the Joint Danube Survey 2013 (<http://www.danubesurvey.org>). Dried extracts were re-suspended in DMSO and tested in the microsuspension protocol in dose responses experiments with a highest relative enrichment factor of 800X in the presence and absence of metabolic activation (S9). Blanks, negative and positive controls were included. 15 from de 22 samples presented mutagenic activity. The rank of strains sensitiveness was YG1041 > TA98 > TA1538. YG5185 did not detect any positive sample. In general organics containing a nitro group seems to be the major class present in the samples, except for some samples, which TA98 was most sensitive than YG1041. Although preliminary results indicate that *Salmonella* diagnostic strains can play an important role in the identification of mutagenic compounds in water samples. YG5185 was probably not a good choice because the extraction recovered more polar rather than non-polar compounds. YG7108, very sensitive for alkylating agents, should be included in next studies along with its parental TA1535 to verify their application mutagenic profile studies of water samples. *Acknowledgement:* The authors thank FAPESP Project 2013/16956-6, the International Commission for the Protection of the Danube (ICDPR), the NORMAN Network and the Solutions Project. We are particularly grateful to Margit Petre, Jörg Ahlheim and Peter Tarabek for technical assistance. D.A. Morales thanks CAPES for the PhD scholarship.

##### **Organic trace pollutants in the Danube Catchment - Results from Joint Danube Survey 3**

F.R. Storch, DVGW-Technologiezentrum Wasser / Analysis and Water Quality; H. Brauch, DVGW-Technologiezentrum Wasser

Pollution of surface water with anthropogenic chemicals is an issue concerning a wide range of aspects from ecotoxicology to drinking water production. Many waterworks rely either directly on surface water as a raw water resource, use river

water for artificial groundwater recharge or abstract bank filtrate. To provide a scientific basis for legislation and regulation and to give a snapshot of the state of water quality in the Danube River Basin, Joint Danube Survey (JDS) campaigns are held every 6 years. This study presents data of organic trace pollutants analysed in water samples taken in a longitudinal Danube profile during JDS 3 in the year 2013 [1] and from additional bank filtrate and groundwater samples. A set of 49 compounds was analysed which comprised benzotriazoles, artificial sweeteners, pharmaceuticals, iodinated X-ray contrast media, the stimulant caffeine and others. Elevated concentrations of biodegradable substances like caffeine and saccharine demonstrated the release of untreated domestic waste water, especially in Danube tributaries in the middle and lower catchment. A number of less biodegradable or rather persistent substances were detected in the Danube, its tributaries and even in bank filtrate. Among those, the artificial sweetener acesulfame had the highest concentrations (up to 2.9 µg/L). Further important pollutants were the industrial chemical 1-H-benzotriazole and tolyltriazoles (mostly below 400 ng/L), iodinated X-ray contrast media like amidotrizoic acid or iopamidol (up to 1.6 µg/L) and pharmaceuticals like carbamazepine (up to 140 ng/L). Concentration levels of the trace pollutants investigated were mostly lower in the Danube than in the Rhine, most likely due to higher dilution in the Danube. Danube tributaries, especially in the middle and lower basin, were more heavily polluted both with persistent and with biodegradable compounds, pointing to discharge of untreated wastewater. The general contribution of metropolitan regions on deterioration of water quality was illustrated by elevated concentrations of several compounds. [1] Joint Danube Survey 3 Final Scientific Report, eds. Liska I, Wagner F, Deutsch K, Sengl M, Slobodnik J. under review. Vienna, Austria: ICPDR – International Commission for the Protection of the Danube River. Thanks to D. Richter, colleagues from IAWD and water suppliers. Further, thanks to JDS3 team, I.Liska and J.Slobodnik representatively.

#### TU189

##### **An overview of the Danube water quality in the Novi Sad municipality during 2011-2013**

N. Milic, University of Novi Sad, Faculty of Medicine / Department of Pharmacy; I. Spanik, Slovak University of Technology in Bratislava; M. Milanovic, Medical Faculty, University of Novi Sad; O. Vyvierska, Slovak University of Technology in Bratislava; I. Mihajlovic; N. Grujic Letic, Pharmacy; D. Milovanovic, Faculty of Technical Sciences, University of Novi Sad; M.M. Turk Sekulic, Department of Environmental Engineering and Occupational Safety and Health; J. Radonic, Faculty of Technical Sciences; M. Vojinovic Miloradov, Novi Sad as the second largest city in Serbia faces the specific problem of the drinking water supply from several groundwater aquifers that could easily be affected by direct discharges of the municipal, industrial and agricultural wastewaters without any treatment into the Danube. Therefore, the main objective of the three year study was to gain more insight into the occurrence and concentration levels of emerging and priority pollutants present in the Danube surface water and wastewater of sewage discharges around the territory of Novi Sad in order to estimate the “emerging” status of this Danube section. The water samples were analysed using gas chromatography or high-performance liquid chromatography, while inorganic compounds were determined by atomic absorption spectroscopy and coulometric analyser. More than 150 organic pollutants were detected in the surface water and wastewater samples at all discharging municipal sites; phthalates, polycyclic aromatic hydrocarbons (PAHs), bisphenol A (BPA), caffeine, terpenes, fatty acids, industrial and lubricant oils and defoaming agents were most frequently identified. The detected concentration levels of some organic pollutants, such as pentachlorobenzene, dieldrin, endrin, p,p'-DDD, p,p'-DDT, 4-(1,1',3,3'-tetramethylbutyl)-phenol, di(2-ethylhexyl) phthalate and Se, Cr, Zn, Cu, Hg, Cd and cyanides, were above environmental quality standard values in the urban area of Novi Sad. The significant concentrations of caffeine were determined at the sampling sites near the wastewater discharges with the potential risk for the chronic effects. Furthermore, the endocrine disrupter BPA was frequently detected throughout the seasons at the concentration levels up to 692.6 ng/L. The conducted study of the surface water and wastewater quality in Novi Sad confirmed the significant pollution of the Danube section and serve as a good base for the selection of substances involved in the implementation of early warning system of the quality of raw water in the city of Novi Sad. This research has been financially supported by NATO Science for Peace Project ESP.EAP.SFP 984087.

##### **Integrated chemical and toxicological profiling of surface water samples from Swedish rural areas**

J. Lundqvist, Swedish University of Agricultural Sciences / Department of Biomedical Sciences and Veterinary Public Health; J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides; A. Oskarsson, Swedish University of Agricultural Science / Department of Biomedical Sciences and Veterinary Public Health

Water may be contaminated by e.g. pesticides, pharmaceuticals and other chemicals emitted from industrial/urban activities and consumer products. As part of a Swedish environmental monitoring program, we have collected surface water samples from small catchments in areas with heavy agricultural activity. The water samples have been analyzed for residues of 131 pesticides, using GC-MS and

LC-MS/MS. 87 of the analyzed pesticides were detected in different water samples. Further, the water samples were used for toxicological profiling. Oxidative stress response is a sensitive indicator of toxicity, responding to a wide variety of chemicals. The nuclear factor erythroid 2-related factor 2 (Nrf2) is a key regulator in the cellular defense against oxidative stress through release of detoxifying enzymes. To investigate the potential of the water samples to activate the Nrf2 pathway, human NCI-H295R cells were transfected with a reporter plasmid where the expression of luciferase is under the control of a promoter containing Nrf2 responsive elements. The water samples from the environmental monitoring program were extracted, concentrated and then analyzed for cytotoxicity by MTS test and oxidative stress response in the transfected NCI-H295R cells. No cytotoxic effects were revealed, but a large number of the samples exerted oxidative stress, even in the samples where all the detected pesticides were below the water quality standards as defined by the Swedish Chemicals Agency. In conclusion, we have established a reporter gene assay to measure oxidative stress response in concentrated water samples and detected effects in samples not displaying general cytotoxicity and with pesticide residue levels below the water quality standards.

#### TU191

##### **Depth profile of emerging and persistent organic pollutants, in front of the Three Gorges Dam 2012/13**

D. Deylering, J. Wang, Helmholtz Zentrum Muenchen / Molecular EXposomics; Y. Bi, Chinese Academy of Sciences / Institute of Hydrobiology; C. Peng, Institute of Hydrobiology; G. Pfister, HMGU-MEX; B. Henkelmann, Helmholtz Zentrum Muenchen; K. Schramm, Helmholtz Zentrum Muenchen / Molecular EXposomics. The Three Gorges Reservoir (China) formed by the impoundment of the Three Gorges Dam has a surface area of 1084 km<sup>2</sup>. The large volume of this water body affords high efforts in terms of the analysis of organic trace compounds. Therefore a sampling method was developed in the framework of the Yangtze project, for the enrichment of large quantities of water (up to 300 L) in order to detect compounds down to concentrations in the pg L<sup>-1</sup> scale. The sampling was conducted by actively pumping water through self-packed sampling cartridges with polymeric resin. The method was applied twice in the middle of the Yangtze River in front of the Three Gorges Dam in 2012 and 2013. Three different water depths were sampled in order to generate a depth profile of the investigated organic trace compounds. The samples were processed by two independent cleanup methods. One method focused on a wide range of persistent organic pollutants (POPs) including polycyclic aromatic hydrocarbons (PAH), organochlorinated pesticides (OCPs) and polychlorinated biphenyls (PCBs). The other method was optimized for the analysis of compounds with higher water solubility including perfluoroalkyl acids (PFAAs), active pharmaceutical ingredients and polar pesticides. POP analysis was carried out with gas chromatography and high resolution mass spectrometry. Compounds with higher polarity were analyzed with micro-scale ultra-performance liquid chromatography coupled to a quadrupole time-of-flight mass spectrometer. In general, analytes seemed to occur in comparable concentrations in different water depth. Individual pharmaceutical residues and polar pesticides were detected at concentration levels between 25 and 4500 pg L<sup>-1</sup>. PFAAs were found in a concentration range between 0 and 1300 pg L<sup>-1</sup>. PAH-levels ranged from 0-4000 pg L<sup>-1</sup>. OCPs could be detected at trace levels between about 0 and 70 pg L<sup>-1</sup>, individual PCB concentrations were in the low pg L<sup>-1</sup>-scale and thus mostly in the range of blank values.

#### TU192

##### **Determination of auramine dye in river water samples and ecotoxicological evaluation for aquatic organisms**

C.C. Azevedo, UNICAMP; C.C. Montagner, University of Campinas UNICAMP; G.d. Umbuzeiro, FACULTY OF TECHNOLOGY -UNICAMP / LEAL. Auramine (CAS Number: 492-80-8) is a diphenylmethane dye used in several industrial activities, such as, textile, paper, food and leather. Auramine is a probably carcinogen to humans according to IARC. Although, its production has been prohibited in some countries, auramine is still used and found in some products. Surface water pollution is a global concern, and these dyes can be released to the environment in waste streams from its production and use. Several other dyes have been found in the environment but there is no information about auramine in the aquatic system. Therefore, this study aimed to develop a method for determination of auramine in water samples, and to evaluate its toxicity for aquatic organisms. A method was developed based on liquid-liquid extraction (LLE) followed by high performance liquid chromatography-diode array detector (HPLC-DAD). Acute toxicity tests were performed with *Daphnia similis*, and chronic tests with *Ceriodaphnia dubia* and *Raphidocelis subcapitata*. HPLC-DAD conditions were: hypersil ODS-C18 column, methanol/0.1% formic acid (50:50, v:v) as mobile phase, flow rate set at 0.8 mL min<sup>-1</sup> with detection at 437 nm. The detection limit for the auramine dye was of 0.01 µg L<sup>-1</sup> was obtained for samples that were concentration 1000 times. The recovery was 92 % (n=3) for spiked river water samples (900 mL) containing 1.0 mg L<sup>-1</sup> of the dye were extracted with LLE using dichloromethane/methanol (2.5:1 v/v). EC<sub>50</sub> (48h) for *D. similis* was 2100 µg L<sup>-1</sup>, NOEC for *C. dubia*, 100 µg L<sup>-1</sup> and for *R. subcapitata*, 20 µg L<sup>-1</sup>. We conclude that the analytical method using LLE and HPLC-DAD was convenient and fast and is ready to be applied to real samples at quantification limits that are 2 000 times below the NOEC of the most sensitive organism tested. Real samples of effluents and water under the influence of industrial discharges are now being analyzed. The

toxicity data with fish embryo test will be conducted for the derivation of a proper PNEC to be used for the comparison with the occurrence data.

#### TU193

##### **Systematic suspect screening and identification of sulfa drug transformation products**

M. Majewsky, Karlsruhe Institute of Technology (KIT) / Engler Bunte Institut Chair of Water Chemistry and Water Technology; T. Glauner, Agilent Technologies / Sales Services GmbH HewlettPackardStr Waldbronn Germany; H. Horn, Karlsruhe Institute of Technology KIT / Chair of Water Chemistry and Water Technology

It has recently been shown that transformation products (TPs) of sulfamethoxazole (SMX) featuring transformations such as hydroxylation or nitration retain significant antibacterial effects and are suspected to contribute to the development of antibiotic resistance in bacteria. Due to the homologous series of sulfonamides and their common reactive sites, there is much to suggest that similar transformations occur for sulfonamide homologs other than SMX. Given that about a dozen of sulfonamide antibiotics are frequently occurring in surface waters, the screening for all transformation products using target methods would require to purchase or synthesize all potential TPs and would evidently cause unreasonably high costs and is therefore hardly realistic. For this reason and since accurate mass LC/MS is not widespread in control labs, the aim of the present study was to develop a generic scheme to predict the 28 most likely TPs of a sulfonamide by identification of the major transformation reactions and pathways. The mass shifts of each transformation were used to calculate the precursors for a targeted suspect screening with unit mass LC-MS/MS. The additional use of accurate mass LC/QTOF analysis allowed for the tentative identification of TP precursors by their molecular weight and isotopic pattern. Based on the structural elucidation of the parent sulfonamide product ion spectrum, mass shifts additionally allowed to predict five characteristic product ions for each derivative TP. The prediction scheme was developed using reference standards of SMX TPs and LC/QTOF for verification of the product ion formulae. The occurrence of specific predicted fragments also reveals if the transformation had occurred at the 4-aminobenzenesulfonamide moiety, which is common to all sulfonamide homologs or at the mostly heterocyclic moiety specific for each individual compound. In a final step, TP precursors and the according product ions were predicted for two arbitrarily chosen sulfa drugs (sulfapyridine, sulfamerazine) transformed during an activated sludge biodegradation experiment. Eight ecotoxicologically relevant TPs could be detected and were tentatively identified using LC-MS/MS. By use of accurate mass LC/QTOF in combination with the predicted fragmentation, confidence in the identification was largely increased and validity of the generic fragmentation scheme was confirmed.

#### TU194

##### **The combination of sediment and Cladophora for the screening of surfactant in freshwater river.**

H. Byers, EffectDirected Analysis; L. Krauskopf, M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; M. Schmitt-Jansen, UFZ - Helmholtz Ctr Environm. Research / Department of Bioanalytical Ecotoxicology; W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis

The wide use of surfactants in personal care product, pesticides, pharmaceutical on a global scale, makes their presence rather ubiquitous in the environment. Surfactants may be found in the aquatic environment at concentrations, which may be orders of magnitude above other micro-pollutants and result in notably high hazard quotients. Due to their amphiphilic properties surfactants are likely to sorb on surface. Previous work has shown their presence in sediment, but few have been investigating Cladophora as potential accumulation compartment. Cladophora are often found in nutrient rich river waters downstream of WWTP output, a known emission source of surfactant in the environment. The monitoring of chemicals like surfactants, in these algae will help to estimate the exposure and risks of the respective aquatic ecosystem. In a case study Holtemme River in Saxony-Anhalt (Germany), which is impacted by WWTP effluents has been sampled for sediment and Cladophora. The concentration of a broad range of surfactant including, e.g., QACs, betaine, PFCs, and LAS, was quantified in several compartments, such as sediment, Cladophora and phytobenthos community. The method used for this study includes sequential extraction by Pressuring Liquid Extraction, combined with further clean-up steps (Normal Phase and liquid-liquid extraction); the chemical analysis was performed by LC-ESI-MS/MS analysis. Longitudinal profiles of surfactants in the Holtemme River identified and confirmed point sources of surfactants and helped to identify hot spots for subsequent in-depth investigations.

#### TU195

##### **Identification of diphenyl-bis(trimethylsilyloxy)silane as an environmental contaminant**

A.H. Kierkegaard, M.S. McLachlan, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES. In an earlier model-based screening study aimed at identifying organosilicon chemicals present in the environment, three previously unknown environmental contaminants were identified. A phenyl substituted siloxane,

phenyl-tris-(trimethylsiloxy)silane, was the most abundant of the three, with concentrations in the range of 50 pg m<sup>-3</sup> in air and 0.5 ng g<sup>-1</sup> d.wt. in sediment from the Stockholm archipelago. Other phenyl substituted organosilicons have been prioritised as possible persistent and bioaccumulative chemicals based on their properties. To further explore this group of chemicals, several contaminated sediment and sewage sludge samples were screened. Full scan spectra of a number of semivolatile phenylated organosilicons were obtained from purchased standards and from mass spectral libraries. Common fragmentation patterns were identified and SIM descriptors for phenylated linear and cyclic siloxanes were selected. Sediment and sewage sludge were solvent extracted with dichloromethane/acetone and cleaned up with a purge & trap method on an ENV+ SPE-cartridge. The samples were analysed using GC/MS. From these analyses diphenyl-bis(trimethylsilyloxy)silane was identified and positively confirmed in sediment from Stockholm harbor and in sewage sludge from two sewage treatment plants in Stockholm.

## TU196

### Risk evaluation of Fipronil in freshwaters from State of São Paulo, Brazil

**C.C. Raimundo**, UNICAMP / Institute of Chemistry; A.J. Nogueira, University of Aveiro / Departamento de Biologia CESAM; A.F. Albuquerque, University of Campinas; G.d. Umbuzeiro, FACULTY OF TECHNOLOGY -UNICAMP / LEAL Fipronil is a broad-spectrum phenylpyrazole insecticide. It is used as active ingredient in pesticides formulation for agriculture applications and as parasiticide for pets. So fipronil is a contaminant that can be found in surface waters from both rural and urban areas, due to soil leaching effects and sewage input to receiving waters. The objective of this work was to assess the risk for aquatic life of fipronil in freshwaters of São Paulo State, Brazil. First we investigated the occurrence of fipronil in sub-nanogram per liter levels, in 42 samples of different water bodies located in both agricultural and urban areas from São Paulo State. Then we calculated a quality water criteria for the protection of the aquatic life using species sensitivity distribution (SSD). We compared the occurrence data with the calculated criteria to verify the risk of fipronil to aquatic life. Fipronil extraction was performed using 1-Liter samples using solid phase extraction. Quantification was performed by liquid chromatography coupled to mass spectrometry (LC-MS/MS). The Limit of Quantification for the analytical method (LOQ) was 0.8 ng L<sup>-1</sup>, considering the concentration factor of 1,000 times. Fourty two samples were collected during February to October 2014 from 16 different rivers and reservoirs from São Paulo State. A preliminary value for the PNEC was derived from the dataset available at the ECOTOX database. The HC5 (hazard concentration at 5 %) was calculated with the SSD Generator from EPA. The PNEC value was calculated according to the recommendations of the European Chemical Bureau and assessment factor of 2 was used Fipronil was present in 100 % of the samples in concentrations from 1.2 and 21.7 ng L<sup>-1</sup>. A value of 192 (84-437) ng L<sup>-1</sup> as HC5 (50 % CI) resulted, after application of the assessment factor of 2 in a PNEC (50 % CI) = 96 (42-219) ng L<sup>-1</sup>. The goodness of fit for the estimation of the HC5 was 0.973 (n=46). A risk Quotient (RQ) was calculated for each of the sampling sites dividing the measured environmental concentration (MEC) by the PNEC value. Although fipronil was present in 100 % of the freshwaters collected in São Paulo State, risk quotient was always under 1 but in some areas the MEC of fipronil raise concern for the coming future. Monitoring studies are needed to verify if the occurrence of fipronil, and its transformation products, are likely to raise environmental concern, not only in water but also in sediments and biota in the São Paulo State.

## TU197

### Risks to drinking water from Personal Care Products and Domestic Cleaning Products

**V. Benson**, WRc plc / National Centre for Environmental Toxicology; T. Dee, A. Ewence, R. Gee, WRc plc; T. Hall; W. Mark, L. Rockett, WRc plc; C. Watts, Chris Watts Associates Ltd  
Personal care products (PCPs) and domestic cleaning products (DCPs) are a diverse range of products that contain vast numbers of different chemicals. These chemicals may have the potential to reach drinking water supplies via release into the environment through typical use and entry to sewerage and subsequent treatment. This study presents an investigation into the potential for ingredients used in PCPs and DCPs to be present in drinking water as a result of their intended use. An assessment was also made as to the potential for people to be exposed to these ingredients at higher concentrations from drinking water and bathing than would be anticipated through the intended use of PCPs and DCPs. Data were collated on 692 chemicals and then prioritised as to their potential to reach drinking water supplies. This prioritisation was based on parameters such as the physico-chemical properties of the chemicals, the annual consumption tonnages of each chemical and whether studies were available in the public literature reporting their prior detection in drinking water. Thirty-three chemicals were subsequently identified as having a high potential for reaching drinking water supplies. The potential concentration of these chemicals in drinking water was then modelled, and the precautionary estimated exposure to these chemicals via drinking water and bathing was compared with the estimates of exposure to these same chemicals through their intended use. Out of the thirty-three prioritised chemicals, the models indicated that exposure via drinking water and bathing was significantly lower for nineteen chemicals than would be anticipated through their intended use. However, for ten of

the thirty-three prioritised chemicals, predicted levels of maximum exposure through drinking water and bathing were close to or greater than would be anticipated through their intended use. These ten prioritised chemicals included, chelating agents (phosphonates, EDTA), boric acid, surfactants (linear alkylbenzene sulphate and cocamidopropyl betaine), 2-(2-Butoxyethoxy) ethanol (DEGBE) and benzotriazoles. This provides a focus for further work that may be required to assess the potential for PCPs and DCPs to occur in drinking water in the UK. The research was funded by Defra and managed by the Drinking Water Inspectorate (DWI). The views expressed here are those of the authors and not necessarily those of the Defra or the DWI.

## TU198

### Orthogonal, parallel Fractionation of Androgens and Antiandrogens by Liquid Chromatography

**M. Muschket**, UFZ- Helmholtz Centre for Environmental Research / EffectDirected Analysis; M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; A. Bahlmann, Helmholtz-Zentrum für Umweltforschung UFZ / Effect Directed Analysis; W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis  
Effect Directed Analysis (EDA) is a powerful approach for the identification of potentially harmful compounds in environmental compartments like sediments or water. The success of EDA is essentially influenced by the fractionation procedure. This is classically performed in sequence of LC fractionation, biotesting and selection of active fractions for the next LC fractionation step until the complexity has been reduced to a small number of compounds, for which structure elucidation is carried out. We propose a parallel fractionation of a sample on orthogonal columns as a time-efficient alternative. Subsequently chemical and toxicological analysis is performed on fractions from the different separation systems. Here candidate peaks shared by bioactive fractions are selected and subjected to structure identification. To test the applicability of this approach, an EDA on androgens and antiandrogens was chosen as a case study. The selection of orthogonal columns was based on a set of 52 known or suspected androgens and antiandrogens. The retention times of these compounds were determined on 16 different stationary phases owning widely differing chemistries. Those three columns allowing for the best orthogonal separation were selected for parallel fractionation of a surface water sample.

Hollert, RWTH Aachen University / Institute for Environmental Research

The NORMAN network is a permanent self-sustaining network for the monitoring and biomonitoring of emerging environmental contaminants. The NORMAN working group on Bioassays (Bio WG) focuses on the application of bioanalytical tools for environmental quality monitoring. A main objective is to provide recommendations for the implementation of effect-based tools into regulatory frameworks. In this context, a blind interlaboratory study (ILS) was performed. The aim was to verify if a bioassay battery conducted in different laboratories following own protocols would produce comparable results when testing spiked surface water extracts. The lead in planning and organizing was taken by the Department of Ecosystem Analysis (ESA), RWTH Aachen University (DE). The ILS bioassay battery included acute-toxicity assays with organisms from different trophic levels (Algae, Daphnia, Zebrafish embryos) and mechanism-specific bioassays for estrogenicity (YES, ER-Luc cell lines) and mutagenicity (Ames fluctuation) assessment. Three to four participants performed each bioassay, including: BfG (DE), Waternet (NL), Waterproef (NL), INERIS (FR), IFREMER (FR), RECETOX (CZ), ISSEP (BE), ITM (SE), IVM-VU (NL), Entox/University of Queensland (AU), Ecotox Centre (CH), ESA-RWTH (DE). Clean water from a reference site was concentrated 10,000 times with large volume solid-phase

extraction. Four emerging pollutants were used for spiking: triclosan, acridine, 3-nitrobenzanthrone and 17- $\alpha$ -ethinylestradiol. Extracts were spiked with either single chemicals or a mixture, in concentrations aimed to produce full dose-response curves in bioassays. The spiked extracts were prepared, separated in aliquots, identified with codes, and sent to the participating laboratories. Standardized bioassay methods (OECD, ISO) were recommended but not mandatory, and biotesters could use their own protocols. Results were sent to RWTH, and a summary of the full ILS was provided to the ILS participants. In October 2014, a workshop was held at RWTH Aachen to present and discuss the ILS results. Bioassays produced mostly highly comparable results, even when protocols differed significantly. Suggestions for future improvements include harmonization of methods for data analysis and results evaluation. An important expected outcome of the ILS is the promotion of biotesting for water quality monitoring at the level of European policy-makers.

## TU200

### Acute aquatotoxicity screening of cellulosic products contained glyoxal, using multi-strain bacteria, daphnia, and zebrafish embryos

C. PARK, Korea Institute of Science and Technology Europe / Convergence Environment Team Environment Bio Group; M. Song, Samsung Fine Chemicals / Green Materials Development Team; N. Choi, Samsung Fine Chemicals / Green Material Development Team; S. Kim, KIST Europe / Chemical Management Lab. It is well known that cellulose ethers are water-soluble polymers derived from cellulose which is consisted natural organic compounds. These polymers have been specifically modified in a wide range of application, from construction products, ceramics, paints, personal care products, and pharmaceuticals. From June 2015, the information about the safety of cellulosic products contained additives such as a cross-linking agent (i.e., glyoxal) on the human- and environment health will need to response in EU CLP (classification, labelling and packaging) legislation. To screen the aqua-toxic effects of cellulosic products involved glyoxal with different concentration, the acute aquatotoxicity test using multi-strain environmental bacteria (microbial array for toxicity risk assessment, MARA), *Daphnia magna* (OECD test guideline 202) and zebrafish embryos (OECD test guideline 203) was conducted in this study. The acute aquatotoxicity using 3 different aquatic organisms (multi-strain bacteria, *Daphnia magna*, and zebrafish embryos) were limit and not significant. To better evaluate the aqua-toxic effects of cellulosic products contained cross-linking agents, the chronic toxicity test will be performed and the further studies regarding the toxic effects of cellulosic products by physical properties (e.g. solubility, viscosity, pH change, etc.) is also required.

## TU201

### Are phytoestrogens and mycoestrogens relevant emerging pollutants? - review of their sources, occurrence, in vitro and in vivo estrogenic activity

B. Jarosova, Masaryk University / Faculty of Science RECETOX; J. Javurek, Research Centre for Toxic Compounds in the Environment (RECETOX) / RECETOX Research Centre for Toxic Compounds in the Environment; O. Adamovsky, Masaryk University, Faculty of Science, RECETOX / Research centre for toxic compounds in the environment RECETOX; K. Hilscherova, Masaryk University, Faculty of Science, RECETOX / RECETOX Research Centre for Toxic Compounds in the Environment. Phytoestrogens and mycoestrogens enter surface waters from both natural and anthropogenic sources and could potentially contribute to estrogenic effects in aquatic biota. In this study, available data on their estrogenic potencies and detected concentrations reviewed from a number of studies were combined to elucidate whether these compounds could have significant influence on *in vitro* estrogenicity and *in vivo* effects in surface waters. Concentrations of phyto/mycoestrogens in surface waters varied greatly from undetectable or ng/L ranges to units or even hundreds of  $\mu\text{g/L}$ . The relative potencies (compared to E2) of individual phyto/mycoestrogens differed by orders of magnitude among individual *in vitro* assays and even among the same assays performed or evaluated according to different procedures. *In vivo* effective concentrations of waterborne phyto/mycoestrogens were available only for daidzein, formononetin, genistein, equol, sitosterol, and zearalenone. Despite the limited information available, the review confirmed that some phytoestrogens and the mycoestrogen can contribute significantly to *in vitro* responses and potentially also to *in vivo* effects in surface waters in areas with their greater concentrations. The review also indicates the potential extent of use of different assays to detect the phyto/mycoestrogens at their effective concentrations. The study was supported by the Czech National Science Foundation grant No. P503/12/0553 and EU FP7 project SOLUTIONS (grant No. 603437).

## TU202

### Use of fish farms to assess river contamination: combining biomarker responses, active biomonitoring, and chemical analysis.

J. Navas, INIA - Madrid; M. Fernández Cruz, Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA) / Departamento de Medio Ambiente Lab DETC; A. Quesada-García, INIA; M. Villarreal, Universidad Politécnica de Madrid; M. Gómez, University of Queensland; M. Hernando, Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA); F. Torrent, Technical Superior School of Forest Engineers Polytechnic University of Madrid; A. Valdehita, Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria

(INIA) / Departamento de Medio Ambiente Lab DETC

Aquatic organisms are often exposed to mixtures of low levels of pollutants whose presence and effects can pass easily unnoticed if only traditional monitoring strategies are employed. In this regard, the combination of different techniques is essential to detect the possible effects of trace levels of contaminants on fish. In this study biomarkers response, active biomonitoring (ABM) and chemical analysis were used. In environmental studies, cytochromes P4501A (Cyp1A) and Cyp3A and related enzyme activities (7-ethoxyresorufin-O-deethylase, EROD, and benzyloxy-4-[trifluoromethyl]-coumarin-O-debenzyloxyase, BFCOD, respectively) are commonly used as biomarkers for evidencing exposure to a variety of contaminants. Biomarker methodologies applied on fish farms has recently emerged as a realistic method to assess any exposure of fish to chemical compounds that could provoke subtle modifications in their physiological homeostasis. In two rainbow trout (*Oncorhynchus mykiss*) fish farms that are routinely sampled we observed a strong and increase in these activities at two different moments. In one case this increment was accompanied by antiestrogenicity phenomena. In order to shed light on the causes of this induction, in an ABM approach we transferred some fish to a fish farm with controlled conditions and examined them. EROD activity showed a decrease of 80% from the original values after only 7 days in the control farm, while BFCOD activity was also reduced after 15 days. Although not significant, a decrease in *cyp1A* and *cyp3A* mRNA levels was also observed. To determine the presence of pollutants, water and sediment samples from the river feeding the fish farms were analyzed by two-dimensional gas chromatography-time-of-flight mass spectrometry (GC  $\times$  GC-TOF-MS). Trace levels of polycyclic aromatic hydrocarbons (PAHs) and personal care products were detected in sediments, indicating that the observed effects in fish should be caused by (the combination of) accompanying substances. The methodology here described has proven useful in detecting trace levels of contaminants in water courses and evidencing their influence on biota.

## TU203

### Estimating baseline toxicity and in-vivo and in-vitro bio-partitioning of complex mixtures of nonpolar analytes using GCxGC

D. NABI, Masdar Institute / iWater; J. Gros, LMCE; J.S. Arey, EPFL / LMCE. Existing estimation methods are generally not successful for the estimation of aquatic baseline toxicity and bio-partitioning properties of the hundreds to thousands of potentially bioaccumulative contaminants found in complex mixture of nonpolar analytes. Ideally, these estimation approaches should be targeted at compounds actually measured in environmental samples. In the present study, we showed that aquatic baseline toxicity and bio-partitioning properties can be mapped onto the separation space offered by comprehensive two-dimensional gas chromatography (GC $\times$ GC). We used GC $\times$ GC chromatogram retention information to estimate baseline toxicity and bio-partitioning properties for a diverse set of non-polar halogenated and hydrocarbon compounds that undergo negligible or limited hydrogen bonding interactions. When compared to the experimental data our model exhibited root mean square error (rmse) of 0.32 log unit for 96-hour median lethal concentration (-log LC<sub>50</sub>) endpoint for fathead minnow. We also show that *in-vivo* and *in-vitro* bio-partitioning properties can successfully be calculated by parameterizing the multiphase biopartitioning model using GC $\times$ GC-estimated bio-partition coefficients. The predictive performance of our model in both cases was comparable to that of Abraham solvation model with the added advantage that it can be applied to thousands of chemicals separated by GC $\times$ GC in real environmental samples. Thus, GC $\times$ GC can be used as a powerful tool for the risk assessment and fate modeling for complex mixtures of nonpolar organic compounds in environmental media. **Keywords:** comprehensive two dimensional gas chromatography, bio-partitioning properties, baseline toxicity, complex mixtures

## TU204

### Risk assessment associated with the presence of emerging organic micropollutants originated from municipal wastewater in the aquatic environment: the case of Greek rivers

V.S. Thomaidi, University of the Aegean / Department of Environment; A.A. MAZIOTI, Aegean University / Environment; A.S. Stasinakis, University of the Aegean / Department of Environment; N.S. Thomaidis, University of Athens / Department of Chemistry

The purpose of this study was to estimate the environmental risk associated with the presence of emerging organic contaminants, released from treated municipal wastewater, in rivers. For this reason, 25 Greek rivers were chosen as a case study. After literature review, the concentration levels of emerging contaminants that had been detected in Greek Wastewater Treatment Plants (WWTPs) were recorded and the experimental acute toxicity data of these compounds (EC<sub>50</sub> or LC<sub>50</sub> values) for 3 different aquatic organisms (fish, *daphnia magna* and algae) was collected. In cases that no experimental toxicity data was available, ECOSAR model (U.S.EPA) was used. Taking into account the Maximum Measured Environmental Concentration (MEC), the Predicted No Effect Concentration (PNEC) and the Dilution Factor (DF), Risk Quotients in rivers (RQ<sub>r</sub>), were calculated. The possible hazard due to the mixture of target micropollutants was estimated as well, using baseline toxicity data from ECOSAR program. According to the results, monitoring data was available for 207 emerging contaminants, belonging to 8 different groups: pharmaceuticals, illicit drugs, phenolic endocrine disruptors (EDCs), perfluorinated compounds,

benzotriazoles, benzothiazoles, artificial sweeteners and siloxanes. The rivers with DF equal to 2 and 3 presented the highest possibility for ecological threat due to the presence of 22 and 19 emerging contaminants, respectively. Amongst target compounds, triclosan presented  $RQ > 1$  for all studied rivers (DF up to 2388), indicating a possible ecological risk for algae regardless wastewater dilution. Additionally, decamethylcyclopentasilane (in daphnia magna), caffeine (in algae) and nonylphenol (in fish) presented RQ values higher than 1, for 23 (DF  $\leq 1910$ ), 22 (DF  $\leq 913$ ) and 20 rivers (DF  $\leq 824$ ), respectively. The class of emerging pollutants with the highest ecological risk was EDCs, since 4 substances (nonylphenol, nonylphenol diethoxylate, nonylphenol monoethoxylate and triclosan) presented high RQ values even after wastewater dilution. The mixture of the emerging contaminants presents a serious risk in all studied rivers, as the mixture's RQ had values far higher than 1 (98 for fish, 123 for daphnia magna and 42 for algae), even in river with the highest DF. EDCs present the greatest contribution to the toxicity of the mixture (99 % in fish and daphnia magna and 98 % in algae).

## TU205

### **Risk Based Prioritisation of Pharmaceuticals in the environment in Iraq** O. Abdullah, York University / Environment; A. Boxall, University of York / Environment Department

Numerous studies have shown that residues of pharmaceuticals occur in the natural environment, raising concerns about their impact on non-target organisms or human health. One region where little is known about the exposure and effects of pharmaceuticals in/on the environment is Iraq. Due to the high numbers of pharmaceuticals used by the public health sector in Iraq (hospitals and care centres), there is a need for a systematic approach for identifying substances that should be monitored in the environment in Iraq and assessed in terms of environmental risk. In this study a risk-based prioritization approach was used on 99 pharmaceuticals in use in Iraq. Initially, information on the amounts of pharmaceuticals used in Iraq was obtained with the top use medicines found to be paracetamol, amoxicillin and metformin HCl with annual consumption exceeding 20 tonnes. Predicted environmental concentrations (PECs) and predicted no-effect concentrations (PNECs), derived from ecotoxicity end-points, were then used to rank the pharmaceuticals in terms of risk to different environmental compartments. Amoxicillin, valproic acid and paracetamol were identified as highest priority in surface waters and sediment. Paracetamol, captopril and glibenclamide were identified as highest priority in drinking water, in terms of risk for both adults and children. Amoxicillin, erythromycin and amiodarone HCL were identified to pose the greatest risk in the terrestrial environment. Future work will focus on understanding the occurrence, fate and effects of these substances in the environment in Iraq.

### **Performance of modified SimpleBox after optimization by using multimedia monitoring data for exposure assessment required by the new chemical management law in Korea**

H. Kim, Department of Environmental Studies and Environmental Planning Institute; D. Lee, Seoul National University / Graduate School of Environmental Studies

SimpleBox was modified and optimized for application in Korea by using concurrent multimedia (air, water, sediment, and soil) monitoring data of 37 chemical compounds from 4 chemical groups (volatile organic compounds, polycyclic aromatic hydrocarbons, polychlorinated dibenzo-p-dioxins and dibenzofurans, and polybrominated diphenyl ethers). A total of 14 environmental parameters were identified from sensitivity analysis for optimization. Eight different monitoring datasets were used for optimization and their performance was compared based on bias, skewness, and the degree of association of prediction with observation. Selecting monitoring data of chemicals such that the chemicals collectively cover a wide range of physicochemical properties was found to be important in the optimization to improve the overall prediction performance. If the coverage for physicochemical properties was wide enough, use of different monitoring datasets did not substantially vary the overall optimization performance. Use of a dataset of a single chemical group improved the performance only for that chemical group while deteriorating performance for other chemical groups. Over 94% of the 8344 observed concentration ratios for the 37 compounds was predicted within a factor of 30 by the optimized SimpleBox, suggesting its applicability to the exposure assessment purpose.

## TU207

### **Evaluation of Long Range Transport Potential of Volatile Compounds in POPs Assessment**

S. Xu, Dow Corning Corporation / Health and Environmental Sciences

This presentation is concerning the challenges and methods for the accurate evaluation of long-range transport potential (L RTP) of volatile compounds that are different from the traditional POPs. High L RTP is a characteristic of persistent organic pollutants (POPs). Therefore, evaluation of L RTP is one of the key steps in screening chemicals for potential POP candidates. The objectives of the Stockholm convention on POPs are to prevent adverse health in humans and adverse impact to the environment. The assessment endpoints are unacceptable toxic effects in humans or organisms in the environment as a result of a combination of POP properties that result in exposures that approach or exceed thresholds of adverse

effects in near field and remote regions. In some past assessments of volatile and semi-volatile compounds, "the half-life in air  $> 2$  days" or even the presence of a compound in the remote part of atmosphere were the only evidence used to judge L RTP. In this presentation, we examine environmental modeling results and experimental data of volatile compounds from the literature and conclude that atmospheric half-life alone is not enough for L RTP assessment for some of the volatile compounds; although it works well with the known POPs. Deposition potential can be used to more accurately predict the risk of volatile compounds imposed to humans and environment at the far field. "Detected in the Arctic" is not necessarily an indication of high L RTP of the chemical, but may reflect the usage patterns, emission rates and scenario, and sampling and analytical details that have little to do with the transport processes.

## TU208

### **Calculating 'exposure potential' - parsimonious application of the unit-world concept**

D. van de Meent, RIVM / DMG; J. Struijs, Laboratory for Ecological Risk Assessment; A. Striffler, J. Baumeister, denkbare; D. Stüttler, Umweltbundesamt; N. Aust, Federal Environment Agency (UBA) / Biocides

Parsimony has proven its value in understanding and predicting environmental fate of chemicals. The most prominent example is the unit-world-based mass balance modeling of exposure of man and ecosystems to chemical substances, which provides insight how and why chemicals with different physical and chemical properties behave differently. The concept has recently been rediscovered by the German Federal Environment Agency (UBA), who now calculate 'exposure potentials' of chemicals in air, water and soil for regulatory purposes. Exposure potential of a substance - the same entity is known and used in Life Cycle Impact Assessment (LCIA) as 'environmental fate factor' - is defined as the steady-state mass in the environment (kg), per unit rate of release (kg/d) into it. It is calculated by means of a 'simple, simple box treat' (simple<sup>2</sup>boxtreat): a minimalized (i.e. air, water, soil only) unit-world model, scaled to mimic the typical REACH region, to which a sewage treatment plant model has been added. Developed originally at RIVM and Radboud University for teaching environmental exposure assessment modeling, the simple<sup>2</sup>boxtreat is now used by UBA risk assessors to understand and predict how transport and transformation affect exposure levels of (new) chemicals in the environment. The simple<sup>2</sup>boxtreat is used on a routine basis, embedded in UBA's KnowSEC decision support system. The tool is made available to environmental science students and other users via RIVM's website ([www.rivm.nl](http://www.rivm.nl)). The poster describes and explains the simple<sup>2</sup>boxtreat model and illustrates this with a regulatory case study.

## TU209

### **Overview of the Prioritisation Process under the Water Framework Directive**

L. Ceriani, European Commission DG Joint Research Centre / Institute for Environment and Sustainability IES; R. Negrão Carvalho, Institute for Environment and Sustainability / Institute for Environment and Sustainability IES; A. Ippolito, EFSA - European Food Safety Authority / Institute for Environment and Sustainability IES; D. Marinov, JRC, EC / Institute for Environment and Sustainability; R. Loos, European Commission DG Joint Research Centre / Institute for Environment and Sustainability; T. Lettieri, European Commission - Joint Research Centre / Institute for Environment and Sustainability

The objective of the European Water Framework Directive (WFD) is to achieve good chemical status by monitoring priority substances (PS) at Union level which should not exceed Environmental Quality Standards (EQS). Annex I of the Directive 2013/39/EU lists forty-five PS and Priority Hazardous Substances (PHS), which have been selected amongst those which present a significant risk to or via the aquatic environment. The revision of the PS list has been launched recently with the aim of identifying new substances of concern. The scientific and technical methodology for the current review has been developed by the JRC in consultation with DG ENV and the sub-group of experts of the Working Group Chemical. In fact, a defined prioritisation scheme has been created for both the modelling and monitoring-based exercises. The two exercises will be run in parallel, and will consider more than six-thousands of substances, collected from several publications and databases. More specifically, substances having monitoring data from at least four Member States will be considered for the monitoring-based exercise, based on the Spatial, Temporal, and Extent of exceedances frequencies approach (STE approach), developed by the JRC. Whilst all other substances will undergo through the modelling-based scheme, which encompasses firstly a screening phase, based on defined hazard and exposure criteria, and secondly a modelling-based risk assessment (RA). In both the monitoring and modelling-based exercises, the RA will be done separately for surface water, sediment, biota and human from secondary poisoning, and drinking water. Connections between the two exercises are expected in more than one step, and challenges are likely to be faced, while handling different classes of substances, like pharmaceuticals, mixtures, and inorganic compounds.

## TU210

### **A novel device for on-site large volume solid phase extraction for chemical and effect-based monitoring of water resources**

T. Schulze, A. Kloth, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; A. Bahlmann, Helmholtz-Zentrum für Umweltforschung UFZ /

Effect Directed Analysis; M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; K. Walz, MAXX Mess und Probenahmetechnik GmbH; W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis

For the implementation of multi- and non-target as well as effect-based analysis in monitoring strategies an innovative and automated solid phase extraction (SPE) based active sampling device was developed. While no or only low enrichment is required for the analysis of micro-pollutants in water due to the improved sensitivity of modern analytical equipment, enrichment of large amounts of water is necessary to conduct *in vitro* and *in vitro* bioassays or even effect-directed analysis. The newly developed mobile device permits the on-site collection of large water volumes up to 1000 L. This approach avoids the storage and transport of large volumes as well as the preparation of the sample in the laboratory. Furthermore, time-, discharge- or flow-proportional or event based sub-sampling of the water body over days or weeks is made possible in order to yield representative samples. In this paper we present the results of the evaluation of the chemical performance of the large volume solid phase extraction device for 50 L (LVSP50) device in laboratory and field scale [1, 2]. A novel device for the on-site large volume solid phase extraction was developed and tested in laboratory and field scale. The laboratory test showed very good recoveries for a broad range of compounds. The field test resulted in methodical detection limits in the lower ng/L range. The device will help to improve monitoring of organic pollutants in water resources in the future. [1] Schulze T, Krauss M, Bahlmann A, Hug C, Walz K-H, Brack W. 2014. Onsite large volume solid phase extraction – how to get 1000 litres of water into the laboratory? , SETAC Europe 24th Annual Meeting, 11-15 May 2014, Basel. #### TU211

##### High throughput toxicity screening of the priority substances in water quality assessment

E. Simon, Centre Ecotox; M. Naderman, Biodetection Systems BV; B. van der Burg; A. Brouwer, Biodetection Systems BV; P. Behnisch, BioDetection Systems; B. van Vugt-Lussenburg, Biodetection Systems BV

The list of routinely monitored chemicals in European water bodies is compiled based on certain selection parameters (e.g. production volume, occurrence, posing significant risk to or via the aquatic environment), however, their toxic potency (involving broad range of toxic pathways) has not been investigated extensively before. In addition, water samples can contain many toxic compounds, their metabolites and degradation products which are not included in current regulations. Bioassays can be used to assess the effect of the entire mixture of compounds, thereby reducing uncertainty in safety evaluation. In order to harmonize and combine current monitoring practices (chemical analytics) with innovative effect-based bioanalytical tools with our study we aimed at the: i) Compilation of the extensive toxicity profile of the routinely monitored substances (priority and priority hazardous substances; and substances that are under review for being included in the priority compounds' list) in the European water bodies to identify the toxic pathways picked up by these priority substances. ii) Comparison of the toxicity pathways induced by the routinely monitored substances with the bioanalytical results of water samples and the relevant toxicity pathways for water quality assessment iii) Establishment of overlap and complementarity of the chemical- and biological analytical data. A total number of approximately 90 compounds are currently being screened in the high throughput *in vitro* reporter gene bioassays (CALUX® panel of 24 assays) covering a wide range of toxic endpoints, such as endocrine disruption, xenobiotic metabolism, genotoxicity, oxidative stress, disturbances of lipid metabolism. Preliminary results with 24 compounds revealed so far the importance of endocrine - (particularly the activation of the estrogen receptor, and antagonistic activity on the androgen- and progesterone receptors) and xenobiotic metabolism-related (activation on the aryl hydrocarbon receptor) pathways of the routinely monitored substances. Detailed comparison of these results of the environmentally relevant samples and regulated substances will be presented to identify strength- and weaknesses of both approaches.

#### TU212

##### Screening for pharmaceuticals and other emerging pollutants in sediments of major European estuaries

L. Beckers, R. Massei, EffectDirected Analysis; L. Schinkel, J. Prothmann, M. Krauss, W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis

Pharmaceuticals and many other chemicals that became pollutants of emerging concern in the environment are indispensable goods in our society. They are so far not included in systematic monitoring programs and their fate in and effect to the environment is largely unknown. Due to their physico-chemical properties these substances may accumulate in sediments. Thus, sediments serve as a large sink. In this study sediments from 13 river estuaries in Europe are analyzed for the extent of contamination with pharmaceuticals and other emerging pollutants. A wide range of target compounds covering different chemical and effect classes was selected considering predicted persistence and bioaccumulation potential (EpiSuite), physico-chemical properties such as log  $K_{ow}$  and  $pK_a$  values, production volumes

and information on authorization and sales amounts in the EU. Additionally, compounds detected in previous sediment studies were included. A multi-target method has been developed using pressurized liquid extraction and clean-up by adsorption chromatography and liquid-liquid extraction. For the analysis of sediment samples a novel screening approach using liquid chromatography – high resolution mass spectrometry and gas-chromatography-mass spectrometry was employed. These techniques do not only allow for target analysis but moreover for suspect screening of metabolites. For the target pharmaceuticals the method detection limits ranged between 0.2 – 52.6 ng/g. The recovery varied from less than 20% to greater than 100% whereas most compounds showed a recovery greater than 50%. The matrix effect ranged between -78% to 65% with a median suppression of -8%. So far, sediments from the Danube delta (Ukraine and Romania) as well as from the Po River in Italy have been subject to target analysis for pharmaceuticals. In total, eight out of 60 target compounds were detected in the sediment samples including amitriptyline, citalopram, fluoxetine, miconazole, propranolol, sertraline, terbinafine and tramadol. The study will contribute to the knowledge of the fate of pharmaceuticals and other emerging chemicals in the environment and shed light on the question whether pollution patterns are river basin specific or if an EU-wide contamination is observed.

#### TU213

##### Quantitative structure-biodegradation relationship (QSBR) development and thermodynamic analysis to understand the biodegradation rates of chemicals

K. Acharya, Newcastle University / Environmental Engineering; J. Dolfing, Newcastle University / School of Civil Engineering and Geosciences; P. Meynet, Newcastle University / CEGS; W. Mroczek, Newcastle University / School of Civil Engineering Geoscience; D. Werner, Newcastle University / Civil Eng and Geosciences; R. Davenport, Newcastle University / School of Civil Engineering and Geosciences

QSBRs are a relatively recent form of Quantitative Structure Activity Relationship (QSAR) used to predict the rate and/or transformation product of microbial degradation. The majority of QSBRs are developed for congeneric chemicals, and mostly incorporate information of their physicochemical properties, but neglect information about the microbial communities participating in their degradation. The broad aim of this study is to develop a new QSBR for a diverse set of aromatic pollutants that have some structural similarity using physicochemical properties of the chemicals and the information of the specific degrading communities. Twenty five aromatic chemicals were selected (20 training set and 5 validation set). First order biodegradation rate estimated using Ultimate Biodegradation rating and Ultimate Biodegradation rating in time from Biowin3 model were used as a response variable. Nine molecular descriptors independent of each other were initially selected as explanatory variables. Multiple Regression Analysis (MRA) was performed using MINITAB 17 Statistical Software, where best subsets regression approach was used to identify the best predictors for the model. In addition, thermodynamic analysis of the biodegradation pathways of individual chemicals was performed using the group contribution method, where the Gibbs free energy of individual reaction in the degradation pathway until aromatic ring cleavage was calculated. The QSBR model [Adjusted  $R^2 = 0.907$  and  $R^2$  (predicted) = 0.81] developed using MRA incorporated five descriptors (sigma, molar refractivity, 1<sup>st</sup> and 2<sup>nd</sup> order valence connectivity indices and van der waal Volume). Most notably, total fragment coefficient which is one of the variable in the Biowin3 model; if included in this model, the  $R^2$  (predicted) increases to 0.914. The thermodynamic analysis of biodegradation pathways of chemicals revealed the reaction involving removal of functional groups as well as cleavage of aromatic ring have large negative Gibbs free energy change compared to other reactions in the pathways. Information on the energy yield and the enzyme catalyzing the biodegradation reaction will be instrumental in predicting the activity of degrading microorganism, which might ultimately be used in QSBR together with those descriptors above. Therefore, future studies will focus in improving the robustness of the QSBR model by incorporating the quantitative information of degrading microbial communities in the model.

##### Towards a reliable environmental impact assessment of personal care products (P)

#### TU214

##### SPE-LC-(APPI)-MS/MS analysis of selected anthropogenic infochemicals in Mediterranean rivers

D. Garcia-Sillero, IDAEA-CSIC / Analytical Environmental Chemistry; D. Molins-Delgado, Environmental Chemistry; S. Diaz-Cruz, IDAEA-CSIC / Environmental Chemistry; D. Barcelo, IQAB-CSIC / Institute for Environmental Assessment and Water Research

Keywords: Infochemicals, PCPs, chromatography, insect repellents The manipulation of the odour perception of organisms by anthropogenic substances which may result in ecologically relevant behavioural disorder is known as *infochemical effect*. It plays an important role in life history, habitat finding, food recognition and survival<sup>1</sup>. Among the synthetic chemicals potentially interfering such functions we find insect repellents. The widespread application of these compounds to human skin and the subsequent wash-off has been lead to detect concentrations of up to several µg/L in surface waters. In these fresh waters, insect

repellents might affect aquatic non-target organisms disturbing their behaviour and distribution pattern (communication among individuals, etc.).<sup>2</sup> These personal care products (PCPs) have been typically analysed by GC-MS<sup>3</sup>. The aim of this work was to develop and validate a new method for the analysis of 6 synthetic insect repellents of human use in water. The method is based on solid phase extraction-liquid chromatography/ tandem mass spectrometry (SPE-LC-MS/MS) using atmospheric pressure photoionization (APPI) as ionization mode. The insect repellents that have been analysed so far are compounds such as DEET and Bayrepel (Picaridin) extensively used for decades<sup>4</sup>. In the present study we also analysed a new group of repellents, that appear to be good substitutes for DEET. The performance of the method along with an example of their applicability will be presented. References Kalayci et al., World J Microbiol Biotechnol (2014) 30:407–411. ## TU215

### Identification and assessment of photo transformation products of the UV filters Octocrylene, Benzophenone-3 and Ethylhexyl methoxycinnamate present in grey water intended for water reuse

F. Jentsch, University Lüneburg / INUC; O. Olsson, Leuphana University Lüneburg; K. Kuemmerer, Leuphana University Lüneburg / Institute of Sustainable and Environmental Chemistry

Especially in arid areas decentralized grey water reuse is an important measure to save water. Grey water has a low load of pollutants and therefore has a high potential for reuse such as for irrigation, toilet flushing or laundry. Classical biological treatment of grey water is not able to eliminate micro pollutants such as UV filter substances that originate from personal care products (PCP) [e.g. Eriksson et al. 2010]. However, the discharge of UV filters should be prevented due to their hormonal activities [Kunz and Fent 2006] and potential of bioaccumulation [Balmer et al. 2005]. As long as full mineralization is not achieved, the suggested photo-oxidation process can result in the formation of transformation products (TP) that may continue to pose environmental or health concerns. For this reason the UV-C treatment as potential post treatment method of UV filters in grey water was investigated. The primary elimination of three selected UV filters – Octocrylene, Benzophenone-3 and Ethylhexyl methoxycinnamate and identification and evaluation of their photo-TPs was done. Photolysis studies were carried out in a photo reactor by exposing spiked solutions to light of a medium pressure mercury vapor lamp. The primary elimination of the UV filters was analyzed by HPLC-UV/VIS. Moreover, the formation of TP was followed by HPLC-MS/MS analysis. The biodegradability, sorption and toxicity were assessed for the proposed photo-TPs using quantitative structure activity relationships (QSARs). Based on these results, the applicability of photo-oxidation of the selected UV filters was evaluated by investigation of the degree of mineralization, biodegradability, structure and toxicological assessment of the formed transformation products. The new derived information on the degradation efficiency of the selected PCPs as well as the risk assessment of the formed transformation products extends the knowledge on sustainable grey water treatment options. ## TU216

### Method Comparison for the Analysis of Cyclic Volatile Methyl Siloxanes in Surface Water and Waste Water Treatment Plant Effluent

S.M. Knoerr, Dow Corning Corporation / Health and Environmental Sciences; Y. Horii, Center for Environmental Science in Saitama; K. Kobayashi, N. Suganuma, Silicone Industry Association of Japan; J.A. Durham, Dow Corning Corp. / Health and Environmental Sciences; T.H. Schramke, Dow Corning Corporation / Health and Environmental Sciences

Cyclic volatile methyl siloxanes (cVMS) are common ingredients in many consumer products, including personal care products such as hair conditioners and anti-perspirants. The wastewater stream represents a major post-use disposal route and the cVMS may subsequently enter the environment through the waste water treatment plant's (WWTP) effluent. In order to understand the role of WWTP emissions of cVMS into the environment, it is important to be able to accurately quantify cVMS in aqueous matrices. This study compared two different methodologies measuring the amount of cVMS in effluent and surface water while also underlining the importance of quality control samples to verify the integrity of the sampling, storage, processing, and analysis of the samples. The first method utilized a low density polyethylene sequestrant to minimize the loss of the cVMS from the aqueous sample followed by a solvent extraction. The second method was processed with a purge and trap style analysis with the cVMS captured on a solid sorbent and then extracted. Both analyses were conducted using gas chromatography/mass spectrometry with a isotopically labeled internal standards. The two different methodologies, analyzed at multiple laboratories will be presented along with a statistical analysis of the results.

### Occurrence And Environmental Impact Of Organic UV Filters In Urban Aquatic Ecosystems

D. Molins Delgado, Environmental Chemistry; J. Távora, S. Diaz-Cruz, IDAEA-CSIC / Environmental Chemistry; D. Barcelo, IQAB-CSIC / Institute for Environmental Assessment and Water Research

Organic UV Filters (UV-F) constitute a diverse group of chemicals used as a protection against the harmful effects of the UV sunlight. We can find them in many daily use products such as personal care products or as additives in polymeric materials that need protection against sunlight. The quantities of these substances that enter the environment are particularly important because, in opposition to many other emerging contaminants, PCPs have an uncontrolled flow to the receiving environment, through activities like swimming and bathing, spraying and excretion. As a consequence of their continuous release into the environment and their poor degradability and limited elimination in WWTPs [2] they are considered persistent contaminants [1]. Therefore, the study and understanding of these substances in the environment is of major importance because of their potential to bioaccumulate and consequent toxicity, with potential negative impact especially on biota, or even on humans [3, 4]. The aim of this work is to analyse the impact of UV-F in the urban environments of Barcelona city and its surroundings in terms of occurrence and ecotoxicological potential risk posed by the target PCPs in the sampling sites. Eight UV-Fs were selected on the basis of their high production rates, extensive use and potential ecotoxicological effects. Surface water and wastewater were analysed to assess the levels of the target UV-Fs, as well as to estimate the removal efficiency of the treatment stations and the potential risk posed by levels audited. The analytical method applied was based on automated on-line Solid Phase Extraction and High Performance Liquid Chromatography-Quadrupole-Linear Ion Trap tandem Mass Spectrometry (SPE-HPLC-QqLIT-MS/MS) [1]. ### Sediments as a sink for UV-Filters: The case study of Upper Iguaçu basin, Curitiba (Brazil)

A. Mizukawa, Federal University of Paraná / Department of Hydraulics and Sanitation; J. Valle-Sistac, IDAEA-CSIC / Environmental Chemistry; D. Molins Delgado, Environmental Chemistry; J.C. Rodrigues de Azevedo, Federal University of Paraná / Department of Hydraulics and Sanitation; S. Diaz-Cruz, IDAEA-CSIC / Environmental Chemistry; D. Barcelo, IQAB-CSIC / Institute for Environmental Assessment and Water Research

The Upper Iguaçu basin has political and economic importance for the state of Paraná (Brazil), because it is the main source of water supply for Curitiba, capital of Paraná State. Population growth and uncontrolled occupation of irregular areas are a major problem in this region, leading to the degradation of aquatic ecosystems. Studies using caffeine concentration as a tracer for anthropic activities were conducted in the region [1] indicating intense anthropogenic influence, attributed to the presence of domestic sewage. Recently, researches on emerging organic micropollutants, such as UV-filters, stimulated their scientific interest. These contaminants are used in personal care formulations to absorb solar radiation to protect against its harmful effects, also used in many industrial processes and stability of products. Several studies revealed their potential toxicity and endocrine disrupting capacity, showing adverse effects on fecundity and reproduction in organisms [2]. Many UV filters are high lipophilic and low degradable, tending to accumulate in sediments [3], sewage sludge [4] and aquatic organisms [5]. In the present study the occurrence of UV filters was investigated for the first time in sediment samples from Iguaçu basin. Seventeen sediment samples were analyzed to determine 20 UV filters and derivatives. Samples were collected in 3 urban rivers, Belém, Palmital and Atuba River, in two sampling campaign in 2014 in Metropolitan Region of Curitiba. The contaminants were extracted using pressurized liquid extraction with in-cell purification (PLE) and analyzed by liquid chromatography-tandem mass spectrometry (HPLC-QqLIT-MS/MS). Acknowledgements: Mizukawa thanks CAPES foundation, Ministry of Education of Brazil, for the scholarship (Process number 0137-14-6). We also thank the Generalitat de Catalunya (Consolidated Research Group “2014 SGR 418 - Water and Soil Quality Unit”). ## TU219

### Size and amount of microplastics in toothpaste

A.J. Verschoor, RIVM / Centre for Safety of Substances and Products; J. Herremans, RIVM National Institute for Public Health and the Environment /

Centre for Safety of Substances and Products; W.J. Peijnenburg, RIVM / Center for Safety of Substances and Products

Microplastics may be used in cosmetics; for example in rinse-off products such as soap, shower and bath products, facial cleaners and toothpaste. The main reason to add microplastics in these products is their abrasive or polishing effect, and sometimes also shimmering effect. The microplastics in rinse-off products enter household wastewater. Some studies in The Netherlands have shown that these particles may pass the sewage treatment plants and enter the surface water, where they are consumed by aquatic organisms. The ecological risk assessment of microplastics in the aquatic environment has to deal with many uncertainties in relation to fate and effects. However, the large-scale presence and persistence of (micro)plastics are undebated and from a precautionary point of view, actions to reduce plastic debris and microplastics are taken world-wide. The size of microplastics is considered as a potential criterion for allowance and enforcement. However, only limited information is publicly available about the actual particles sizes and amounts of microplastics in rinse-off products. Company information and public literature was collected regarding the size of microplastics in facial scrubs and bath glitters. In addition laboratory tests were performed on three toothpastes from different brands to investigate the size and amount of polyethylene speckles. The poster describes the methods used for analyses of particles size distribution and chemical confirmation of polymer identity, and will present an overview of the collected data..

## TU220

### **Photochemical transformation of climbazole under artificial UV light and sunlight: Identification and evolution profile of photodegradation by-products**

G. Alvarez-Rivera, Department of Analytical Chemistry Nutrition and Food Science; M. Majewsky, Karlsruhe Institute of Technology (KIT) / Engler Bunte Institut Chair of Water Chemistry and Water Technology; M. Delay, Karlsruhe Institute of Technology KIT; M. Llompart, C. Jares, University of Santiago de Compostela / Department of Analytical Chemistry Nutrition and Food Science; H. Horn, Karlsruhe Institute of Technology KIT / Chair of Water Chemistry and Water Technology; M. Lores, University of Santiago de Compostela / Department of Analytical Chemistry Nutrition and Food Science

Climbazole (CMZ) is an imidazole anti-fungal agent widely used in daily life in pharmaceuticals and personal care products (PCPs) like lotions, conditioners, and particularly as an active ingredient of antidandruff formulations. These products can contain up to 2.0 % (w/w) of CMZ, equivalent to approximately 15 g/L in antidandruff shampoos. Like other PCPs, CMZ is continuously released in bath water and recreational waters reaching the environment due to incomplete removal during waste water treatment. Recently, CMZ was detected in effluents of a conventional German wastewater treatment plants (WWTP) at concentrations of approximately 0.5 mg/L. Furthermore, ecotoxicity studies demonstrated its exceptionally high toxicity toward selected aquatic organisms and terrestrial plants. UV light is an established free-chlorine method for water and waste water disinfection and a developing method for waste water purification, which can be used in combination with strong antioxidants in the so-called Advanced Oxidation Processes (AOPs), such as heterogeneous photocatalysis (UV/TiO<sub>2</sub>). Photolytic or photocatalytic treatment of CMZ can lead to the formation of multiple phototransformation products, which might exhibit similar enhanced ecotoxicological potential relative to that of the parent compound. Additionally, It can be expected that photodegradation also occurs in aquatic environments under natural sunlight. Photodegradation studies about CMZ are rather scarce in literature. In this work, the photolytic and TiO<sub>2</sub>-assisted photocatalytic behaviour of CMZ in water was evaluated using two experimental systems: a lab-scale photoreactor equipped with a 1000 W Xe short-arc lamp (254nm) as well as a solar simulator. Photoproducts identification strategy was based on LC-MS/MS in two main steps: a) monitoring of suspect ions in SIM(+) mode, and b) fragmentation of suspect ions, showing photoproduct-like kinetic profile, in product ion scan (PIS) mode at different collision energies. Six major transformation products were tentatively identified as photochemical breakdown by-products, with nominal [M+H]<sup>+</sup> masses of 69, 181, 183, 167, 275, and 259 Da. To our knowledge, the photoinduced transformation of the cosmetic preservative CMZ into degradation by-products is proposed in this study for the first time. These results might involve environmental implications due to the formation of photoproducts with unknown toxicological properties.

## TU221

### **Ecotoxicity and mixture effects of ultraviolet filters toward selected aquatic organisms**

D. Molins Delgado, Environmental Chemistry; S. Diaz-Cruz, IDAEA-CSIC / Environmental Chemistry; D. Barcelo, IIQAB-CSIC / Institute for Environmental Assessment and Water Research

UV Filters (UV-F) constitute a heterogeneous group of chemicals used as a protection against the harmful effects of the UV solar radiation. We can find them in a wide range of compounds such as personal care products or as additives in polymeric materials that need protection against sunlight. Nowadays, these emerging pollutants are considered persistent due to their continuous release into the environment [1]. Thus, the study and understanding of these substances in the environment is of major importance because of their potential to bioaccumulate and consequent toxicity, which may have a negative impact on the receiving

environment, especially for biota, or even humans [2]. Some studies performed mostly *in vitro* but also in *in vivo* have shown that many of these compounds can produce adverse effects on reproduction, disrupting the normal development on fishes and rodents [3, 4]. For instance, 4MBC has similar estrogenic effects than those of 17- $\beta$ -estradiol in mammals and amphibious species [5]. Despite that, the knowledge on the potential chronic or acute toxicity to biota of these compounds is still scarce [6]. This study aims to determine the EC<sub>50</sub> values of the selected UV-F through a series of toxicological assays on three aquatic species (*Daphnia Magna*, *Selenastrum Capricornutum* and *Vibrio Fischleri*) and to explore the potential synergetic effects in UV-F mixtures. The results indicated that PCPs have EC<sub>50</sub> values of mg/l of concentration, being slightly more harmful in simpler organisms. Mixtures of PCPs presented normally lower toxicities. *Acknowledgment* - The authors acknowledge the Generalitat de Catalunya (Consolidated Research Group: Water and Soil Quality Unit 2014-SGR-418). ## TU222

### **Ecotoxicological evaluation of the insect repellent DEET. Sub-lethal effects on two aquatic insect species.**

D. Campos, Department of Biology and CESAM; C. Quintaneiro; C. Gravato, University of Porto / Laboratory of Ecotoxicology; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; J.L. Pestana, CESAM & University of Aveiro / Department of Biology and CESAM

N, N-diethyl-meta-toluamide (DEET) is an active ingredient present in many insect repellents, and due to its effectiveness against insects and arthropods it has been widely detected in different matrices such as effluents, surface water, groundwater and even drinking water. Despite questions on its ecological effects information concerning DEET's toxicity in the aquatic environment is still limited and focused on acute effects on model species. Our main objective was to assess the effects of DEET on these non-target species using sub-lethal endpoints. For that we have chosen two aquatic insect species, the caddisfly *Sericostoma vittatum* and the midge *Chironomus riparius*, both common in Portuguese freshwaters, with an important role in detritus processing in streams and already used in different ecotoxicological assays. *C. riparius* larvae were exposed to a gradient of concentrations (8, 12, 18, 27 and 40.5 mg/L) of DEET according to OCDE guidelines to assess effects on growth, emergence and adults size. *S. vittatum* were exposed to a gradient of concentrations (8, 18 and 40.5 mg/L) of DEET to assess effects on feeding behaviour and biochemical responses. Effects on biochemical responses for *C. riparius* were evaluated over 48 hour exposures in concentrations of 8, 18 and 40.5 mg/L of DEET. The feeding rates of *S. vittatum* were significantly reduced by exposure to 40.5 mg/L of DEET. DEET exposure reduced *C. riparius* larvae growth and delayed emergence of adults (LOEC of 18 mg/L). Body size of adult midges was also significantly reduced with exposure to DEET. Concerning the biochemical responses exposure to DEET caused a reduction in AChE activity. Our results indicate that it's unlikely for environmental concentrations of DEET to cause ecological deleterious effects in aquatic insects. However, and based on DEET' mechanism of action indirect effects (such as predator avoidance and foraging) are to be expected in the aquatic environment. The results will be also discussed based on the sensitivity of the different aquatic insects as well as on the ecological relevance of the different ecotoxicological endpoints.

## TU223

### **TRICLOSAN IMPAIRS BYSSUS PRODUCTION**

R. Panzuto, Biologia; C. Agnisola, University of Naples Federico II / Biologia; S. Aiello, University of Naples Federico II / Biologia; C. Raimondo, University of Naples Federico II / Biologia; P. Creti, University of Salerno; L. Esposito, University of Naples Federico II / Biologia; C.M. Motta, University Federico II of Naples / Department of Biology; B. Avallone, University Federico II of Naples Triclosan (TCS) is an antimicrobial widely used in many consumer products, being a component of personal care products, textiles and plastics. In recent years its presence as a contaminant has been demonstrated in milk, as well as in waste waters and, as a consequence, in fresh and sea waters. This has raised an increasing concern for human and environmental health, and cytotoxic and genotoxic effects have been demonstrated in several aquatic organisms. In this study, mussels have been exposed for 1-7 days to an environmental concentration (1.25 µg/l) of triclosan. The effects have been determined by measuring byssal thread regeneration after cutting and by analysing byssus gland morphology, by light and electron microscopy. Results have clearly demonstrated that TCS alters collagen production and assembly resulting in a significant decrease in both production and mechanical resistance of the byssal threads. Considering that mussels utilise byssus to anchor to the substrate, it can be concluded that TCS may significantly alter the fitness of these animals in the natural habitats.

## TU224

### **Preening with Personal Care Products: A lack of chronic or reproductive**

#### **toxicity with Decamethylcyclopentasiloxane (D5) in Japanese quail**

E.M. Mihaich, ER2; J.M. Stafford, Smithers Viscient; K. Kobayashi, N. Suganuma, Silicone Industry Association of Japan (SIAJ)

Decamethylcyclopentasiloxane (D5) is used in personal care products, such as shampoos, skin creams, and deodorants, as well as in industrial applications and as an intermediate in the production of siloxane polymers. Due to its high volatility and high Henry's Law constant the majority of D5 volatilizes into the air, either during use or as a result of wastewater treatment. However, with very low water solubility and high log Kow, the presence of D5 in wastewater effluents and ultimately sludge, with subsequent land application, represents a potential route of distribution to the terrestrial environment. In addition to direct exposure to the land-applied sludge, terrestrial vertebrates could potentially be exposed to compounds with high log Kow via a secondary diet route, either through uptake into plants or terrestrial invertebrates and/or uptake into aquatic organisms that might be exposed to the chemical in the aquatic environment. Thus, it was of interest to evaluate the effects of D5 on a higher vertebrate that could be exposed to D5 both directly in the environment and indirectly via the food chain. To assess this, Japanese quail (*Coturnix coturnix japonica*) were exposed to D5 via the diet for 20 weeks, following OECD guideline 206, and effects on adult health, reproduction, and hatchling success were evaluated. No statistically significant differences were detected in adult body weight gain, adult feed consumption, egg production, embryo viability, embryo survival, eggs hatched, hatchling survival or eggshell thickness. The No-Observed-Effect Concentration (NOEC), based on adult and hatchling body weight, adult feed consumption, eggshell thickness and all reproduction endpoints, was determined to be 1000 mg D5/kg feed (143.5 mg D5/kg body weight/day). The Lowest-Observable-Effect Concentration (LOEC) was determined to be > 1000 mg D5/kg feed. These dietary concentrations are significantly higher than known environmentally-relevant concentrations, and D5 is easily metabolized and excreted in terrestrial vertebrates, providing evidence that direct and indirect exposure to D5 does not pose any risk to avian receptors.

#### **TU225**

##### **QSAR study of UV filters and their chlorine-induced degradation reactions**

J. Santos, M. Miranda, CIQUP University of Porto / Department of Chemistry and Biochemistry; J. Esteves da Silva, Department of Chemistry and Biochemistry  
Ultraviolet (UV) filters are the primary constituents of sunscreens but are also presented in cosmetics and pharmaceuticals. They absorb UVB (290-320 nm) and/or UVA (320-400 nm) radiation and therefore protect against its effects on human skin and health. Their importance and application implies significant stability, however, they are known to undergo degradation, photo-induced upon exposure to UV-radiation, and disinfection-induced upon exposure to disinfecting agents such as chlorine in swimming-pool water. The consequence of such reactions is the production of potentially eco-toxicological by-products such as free radicals, photo-isomers and disinfection by-products (DPBs). Quantitative structure-activity relationships (QSARs) represent a prominent field of scientific investigation, since isolated structural information, even from different contexts of work, can be therefore associated, turning what was once isolated knowledge into deeper interconnected data. QSAR studies fundamentally rely on concepts like molecular structure and the corresponding molecular descriptors, which can then be used to determine and predict, through theoretical, statistical and computational approaches, the biological activity or behaviour of different compounds. This work aims at applying QSAR techniques to analyse molecular descriptors of the UV filters currently approved and regulated in the EU and USA, ascertaining their potential to react with chlorine. Density functional theory (DFT) has been used to obtain molecular descriptors such as electronegativity, hardness, softness and electrophilicity index. Geometry optimizations of the investigated molecules were performed using the wB97X-D functional and the 6-31G(d) basis set. Unsupervised and supervised classifications strategies and linear and non-linear calibration techniques will be used in this QSAR analysis. This approach will allow the analysis of interconnecting relations between the filters, as far as their reactivity towards disinfecting agents such as chlorine. Also, it predicts which compounds will less likely undergo degradation, and will therefore be more advantageous as filters, as well as those which will likely degrade more significantly, yielding potentially harmful by-products.

#### **TU226**

##### **Chemical scoring of synthetic musks and siloxanes in aquatic environments**

N. Ratola, LEPAE- University of Porto / Physics of the Earth; V. Homem, University of Porto / LEPABE/DEQFEUP; J.A. Silva, LEPAE University of Porto; L. Santos, Faculty of Engineering - University of Porto / Chemical Engineering; A. Alves, Faculty of Engineering - University of Porto  
Due to the lack of information available on the levels and presence of emerging pollutants, there are no certainties about their total impact on the environment. So, chemical scoring and ranking should be developed as a screening tool for a future risk assessment studies. Several methods have been proposed to estimate the relative impact of different pollutants on the environment, but most of them do not include environmental fate, exposure data or health effects. Thus, in order to evaluate the overall impact of synthetic musks and siloxanes, a new risk-based ranking and scoring system ranking approach is presented, combining indicators of environmental toxic effects, bioaccumulation, and data of potential exposure. Synthetic musks are used as fragrance additives and fixative compounds in

numerous personal care and household products, like perfumes, shampoos, detergents, etc. About 77% of these contaminants are drained into the sewer system and reach the wastewater treatment plants (WWTPs), where they are usually not completely removed, risking the subsequent contamination of natural waterways. In fact, some studies have been reporting their presence in aquatic matrices (rivers, lakes, sea water, etc). Some studies in the literature suggest that siloxanes can cause toxic effects in aquatic organisms and their presence was quantified not only in waters, but also in other environmental media, such as air, sediments, sludge and soil. They are broadly used in personal care products and also in industrial applications. They are also persistent and very lipophilic, which makes them susceptible to bioaccumulation. With this innovative chemical scoring and ranking methodology, some compounds were acknowledged as "potentially relevant", a crucial choice to reduce the number of analysis/monitoring studies for future environmental risk assessment (ERA) evaluations. Acknowledgements: This work was funded by FEDER funds through the Operational Programme for Competitiveness Factors – COMPETE, ON.2 - O Novo Norte - North Portugal Regional Operational Programme and National Funds through FCT - Foundation for Science and Technology under the projects: PEst-C/EQB/UI0511, NORTE-07-0124-FEDER-000025 - RL2\_ Environment&Health, EXPL/AAG-MAA/0981/2013 and grant SFRH/BPD/76974/2011.

##### **Estimating environmental exposure concentrations for formulated consumer products at broad geographic scale - application of iSTREEM® for fragrance materials**

D. Ferrer, P.C. DeLeo, American Cleaning Institute; K.E. Kapo, C.M. Holmes, Waterborne Environmental, Inc.

In recent years, attention to anthropogenic chemicals in the environment has expanded beyond conventional industrial chemicals and plant protection products to include those used in everyday consumer products such as pharmaceuticals, cleaning products and personal care products (PCPs). Among the challenges in understanding the potential environmental impact of ingredients found in PCPs and other formulated consumer products is the estimation of environmental exposure concentrations. Formulated consumer products typically have an end-of-life disposal "down-the-drain" leading to widespread geographic release via treated wastewater effluent to aquatic environments. The American Cleaning Institute developed iSTREEM®, a publicly-available, web-based computer model that generates predicted environmental concentrations (PECs) of chemicals used in products typically disposed of "down-the-drain." iSTREEM® estimates concentration in the effluent of more than 10,000 wastewater treatment plants throughout the continental United States, their resultant mixing zones and downstream river reaches (more than 25,000) and at 1,700 downstream drinking water intakes (<http://www.cleaninginstitute.org/science/istreem.aspx>). By estimating freshwater exposures, the model illustrates the national distribution of PECs, where the greatest potential chemical risks may lie and how to best develop environmental monitoring programs. Likewise, it is a tool that can be utilized in setting public policy regarding freshwater discharges and pollution prevention. In this presentation, we examine the widely used fragrance ingredient HHCB (1,3,4,6,7,8-Hexahydro-4,6,6,7,8,8-hexamethylcyclopenta-γ-2-benzopyran) which was the subject of a recent risk assessment by the U.S. Environmental Protection Agency. We compare the national distribution of in-stream exposure concentrations predicted by the model to national monitoring data, and provide a screening level risk assessment based on a PEC derived from the model output. iSTREEM® provides conservative aquatic exposure estimates for "down-the-drain" chemicals and the results may be used to conduct screening level risk assessments of chemicals found in formulated consumer products in the United States. Likewise, the modeling approach shows promise for providing similarly reliable exposure estimates for major geographies around the world.

#### **TU228**

##### **Households as important source of biocidal active substances in influents of sewage treatment plants**

S. Wieck, Leuphana University of Lüneburg / Institute for Sustainable and Environmental Chemistry; O. Olsson, Leuphana University Lüneburg; K. Kuemmerer, Leuphana University Lüneburg / Institute of Sustainable and Environmental Chemistry

Insect repellents, disinfectants, preservatives – several biocidal active substances (BAS) that fall under the Biocidal Products Regulation (EU) 528/2012 (BPR) are designated for the use in households. However, it is widely unknown which BAS are used in what amount in households. Consequently, the contribution of BAS from households to the pollution of wastewater is unclear. Additionally, e.g. preservatives that are used in cosmetic products do not fall under the BPR but under the Cosmetic Products Regulation (EC) 1223/2009. This leads to the situation that the total amount of BAS used in households might not be evaluated under the BPR because a fraction of the use can fall under a different regulation depending on the function of the respective product. As exposures resulting from different regulatory areas are not aggregated during current environmental risk assessments, the risks of these BAS might be underestimated. The objectives of this contribution are therefore (i) to show the BAS that can be found in households and (ii) to describe the cases where BAS might enter the sewage system without falling under the BPR and thus are not evaluated under its risk assessment scheme. Interviews were

conducted to obtain more detailed information and data on the different uses of BAS in 80 households in a selected study site in Germany. Households were questioned regarding their use of biocidal products, plant protection products, washing and cleaning agents and cosmetics by a standardised questionnaire. Additionally, the products that were present in the households were registered with the help of a barcode scanner. During the interviews emphasis was laid on the use pattern of biocides but also of other product groups (e.g. because of preservatives that are also used in cosmetic products) that might enter the sewage system to record the BAS used in other regulatory backgrounds. This contribution presents information on the BAS that were found in these households and the usage pattern of biocidal and cosmetic products. Based on these results the emission of BAS from households to influents of sewage treatment plants is discussed. Herewith, the study extends the knowledge on the potential sources of BAS in wastewater and demonstrates how they distribute over the different regulatory areas, which highlights gaps in the current environmental risk assessments.

#### TU229

##### **IFRA ENVIRONMENTAL STANDARDS: RISK AND HAZARD ASSESSMENT UPDATE FOR 2015**

A. Lapczynski, RIFM / Environmental Specialist; D.T. Salvito, Research Institute for Fragrance Materials, Inc. / Department of Environmental Science; M. Vey, IFRA

To assure safety of fragrance ingredients in consumer products, International Fragrance Association expanded the fragrance industry's self-regulatory safety program with the development of IFRA Environmental Standards for both risk and hazard in 2008. Fragrance material risk assessments for these Standards are incorporated in the Research Institute for Fragrance Materials' (RIFM) testing program in coordination with its Expert Panel. To identify materials for risk assessment refinement, fragrance materials were screened using the RIFM Environmental framework and 2008 IFRA volume of use survey as reported for both Europe and North America. The Framework for this evaluation was published in *Environment Toxicology and Chemistry* (Salvito et al., 2002, 1301-1308). In addition, hazard assessment on these materials was also performed and reviewed. As a result nearly 3,000 materials were screened with preliminary risk quotients estimated to rank priority materials for risk assessment refinement. In an effort to provide greater transparency to the IFRA Environmental Standards, RIFM reports the most recent results of these additional tests (for both risk and hazard assessments) at both the annual SETAC NA and Europe meetings. These studies include persistence testing (ready biodegradation tests and die-away studies), bioaccumulation, and acute and chronic aquatic toxicity. Incorporating these new data in a second tier risk and hazard assessment for these materials will also be presented.

#### TU230

##### **The Fragrance Materials' Industry Approach to Environmental Risk Assessment: 12 Years of Progress**

D.T. Salvito, Research Institute for Fragrance Materials, Inc. / Department of Environmental Science; A. Lapczynski, RIFM / Environmental Specialist; C. Sachse-Vasquez, Research Institute for Fragrance Ma; T.W. Federle, The Procter & Gamble Company / Environmental Stewardship and Sustainability  
Fragrances used in consumer products (e.g., cosmetics, soaps and detergents, fine fragrances, and air care products) are composed of discrete organic chemicals and natural complex substances. There are over 2,000 materials in commerce used to prepare these fragrance compounds. Their use in consumer products results in their disposal down the drain to become components of domestic wastewater. They exhibit a wide range of structural classes and physical-chemical properties (e.g.,  $K_{ow}$ , water solubility). The Research Institute for Fragrance Materials (RIFM) published their screening-level framework for aquatic risk assessment 12 years ago (Salvito, Senna and Federle; 2002). This approach uses quantitative structure activity relationships (QSARs) to model removal during sewage treatment and toxicity to freshwater aquatic organisms. These QSARs are based on a material's physical chemical properties and its reported volume of use. The resulting model outputs were used to calculate the ratio of Predicted Environmental Concentration (PEC) to Predicted No Effect Concentration (PNEC). Negligible environmental risk is defined by a resultant PEC to PNEC ratio below one. The framework incorporates procedures for using other available information as well as an optimized strategy for generating new data that are needed to refine and improve the risk assessments. The predicted PECs and PNECs were compared with those based upon measured data. RIFM continues to present at SETAC progress made in the risk assessment of fragrance materials through *de novo* studies, and thereby building an environmental database of persistence, bioaccumulation, and ecotoxicity information that demonstrate the continued safe use of these materials in consumer products. Presented here is a retrospective analysis of 12 years of use of this framework.

## **Leaving the comfort zone. The challenge of measuring nanoparticles in complex matrices (P)**

#### TU231

##### **Development of single particle ICP-MS for the detection of silver**

##### **nanoparticles in a complex matrix**

k. mylona, C. Toncelli, HCMR / Institute of Oceanography; A. Tsiola, Institute of Oceanography; I. Kalantzi, M. Kagiorgi, Hellenic Centre for Marine Research / Institute of Oceanography; P. Pitta, Hellenic Centre for Marine Research Crete / Institute of Oceanography; S. Pergantis, University of Crete / Department of Chemistry; M. Tsapakis, Institute of Oceanography

The expected increase in aquatic exposure levels of engineered nanomaterials (ENMs) due to increased production has impelled the development of novel analytical techniques able to detect and characterize them in environmental samples at ng/L concentrations. Single particle ICP-MS (SP-ICPMS) has been presented as a unique tool for detection and characterization of these nanomaterials at such concentration range. This technique is able to provide information about the elemental chemical composition of nanomaterials as well as their number concentration, size, and the number size distribution. Because its dynamic range can be extended up to the micrometers region, polydispersed systems as well as aggregation or agglomeration processes may be studied. In addition, dissolved forms of the constituent elements of the nanoparticles can be detected and determined. Recently, several groups have worked at the optimization of detection capabilities and output refining of SP-ICPMS and, as a result, significant advances in the accuracy of the technique have been reported. However, analysis of different matrix types without the need for any sample pre-treatment, which could potentially create artifacts via NP aggregation, dissolution or partial retaining, are still cumbersome due to signal suppression caused by the matrix. In this study, we have developed an analytical methodology suitable for the detection of AgNPs by SP-ICPMS in a seawater matrix. In particular, a microflow injection system has been developed and coupled via a makeup flow to a conventional pneumatic nebulizer. Online dilution of the seawater samples flowing at 50  $\mu\text{L}/\text{min}$  was achieved by mixing it with a de-ionized water makeup flow at 1 mL/min approximately 2-3 mm before the tip of a conventional pneumatic nebulizer. The introduction of the seawater samples into SP-ICPMS is carried out via a fused silica capillary (100  $\mu\text{m}$  i.d. and 200  $\mu\text{m}$  o.d.) and a 19.7  $\mu\text{L}$  injection loop. In order to know the transport and ionization efficiency, only the reference nanomaterial was taken into account, thereby eliminating the need of using dissolved silver as additional standard reference. The originality of the analytical method opens new perspectives for the correct assessment of fate and transformation of a strong dynamic redox system, such as the silver nanoparticle/dissolved silver one, in seawater matrix at realistic environmental concentrations (i.e. from 200 ppt onwards).

#### TU232

##### **Transformation and fate of silver nanoparticles in seawater: use of single particle ICP-MS in complex matrix**

C. Toncelli, k. mylona, HCMR / Institute of Oceanography; I. Kalantzi, Hellenic Centre for Marine Research / Institute of Oceanography; M. Tsapakis, Institute of Oceanography; S.A. Pergantis, University of Crete / Chemistry  
Silver nanoparticles are of great concern as their production is expected to rise in the following years and very little is known about their fate and transformation at realistic exposure levels. Indeed, modeling studies showed an expected range of silver nanoparticle concentration varying from 0.1 to 100 ppt whereas many preliminary investigations focused on much higher concentrations due to lack of sensitive techniques able to detect at such low concentrations. Single particle ICP-MS represents a unique tool for detection and characterization of nanoparticles in environmental matrix, as it enables the analysis on a "particle-by-particle" basis, therefore remarkably reducing the concentration limit of detection. Moreover, it can be used as preliminary screening method for the assessment of their number concentration, size, and the number size distribution. However, its use in seawater analysis of silver nanoparticles is cumbersome due to signal suppression caused by the matrix. On the other hand, our study developed an on-line dilution method, which, albeit slightly increase the concentration limit of detection, allows a neat analysis of silver nanoparticles at concentrations levels starting from 200 ppt with the same detection limit in NP size reported in de-ionised water (25-30 nm). This method has been applied for microcosm studies of four different silver nanoparticles of different sizes (i.e. 60 and 40 nm) as well as capping agents (branched poly(ethylenimine) vs. poly(vinylpyrrolidone)). Each of the nanoparticle was individually deployed in 10 L oligotrophic seawater and their transformation was detected during two days exposure. The tanks were allowed to float in a large swimming pool in order to mimic realistic exposure conditions and each of the experiments was performed in three replicates in order to control the variability of the conditions, such as exposure to sunlight, extent of stirring, variation in organic matter composition, biota variations. All the nanoparticles investigated in this experiment showed a decrease in size over time, thereby demonstrating that dissolution was predominant over aggregation at such diluted conditions, despite the high ionic strength of the medium. BPEI coatings hindered dissolution to a greater extent compared to what was observed for the PVP capped NPs, probably due to electrostatic interaction between the positive charges of the BPEI coating with the anion complexes of dissolved silver with chlorides.

#### TU233

##### **Nanocount: user friendly spICP-MS data analysis software**

G. Cornelis, University of Gothenburg / Department of Chemistry and Molecular Biology

Interest in applying single particle ICP-MS (spICP-MS) in risk assessment of inorganic engineered nanomaterials (ENM) has been increasing because it is currently the only technique capable of measuring number-based particle size distributions of ENM at environmentally relevant number concentrations in complex environments. However, the large size of spICP-MS datasets makes data treatment cumbersome, even though the basic spICP-MS calculations are relatively straightforward. Moreover, advanced data-treatment algorithms such as deconvolution are required to measure the lowest sizes possible where considerable overlap between dissolved and particulate signals exists. The application of such algorithms requires software. Nanocount© is a spICP-MS data treatment software platform that can accept data from any ICP-MS off-line and offers large flexibility in currently available data-treatment algorithms such as  $n \times \sigma$ , K-means clustering and deconvolution using different noise models, to distinguish dissolved and particulate signals in spICP-MS datasets. In addition, it allows different approaches to calculate nebulisation efficiency and Nanocount© also has many options to account for signal drift, because spICP-MS requires extremely stable signals. Finally, many options are available to customize the calculated particle size distributions. While software such as Nanocount© may increase accessibility of spICP-MS, it is demonstrated in the current paper using spICP-MS data from 15 nm Au ENM, how different data-treatment approaches in spICP-MS can lead to different results. Current validation of spICP-MS analysis focuses on experimental protocols and finds wide variability in the obtained results. It is argued here that a large portion of this variability can be explained by differences in data treatment. There is thus a need for data treatment validation and standardisation, in addition to standardisation of the experimental approach.

#### TU234

##### **Development of an UHPLC-QTOF MS method for the analysis of fullerenes in soil and sediment matrices**

A. Carboni, IBED; R. Helmus, University of Amsterdam; J. Parsons, K. Kalbitz, P. de Voogt, University of Amsterdam / IBED

Fullerenes are carbon based nanomaterials receiving attention for their potential use in emerging nanotechnology. Their occurrence in the environment is expected to increase as a result of their application (e.g. in cosmetics, electronics) as well as unintentional production (e.g. by-product of combustion processes). In addition, natural processes may account for their presence in the environment. To date, few methods are available for the analysis of these emerging contaminants in environmental matrices. Most of the research focused on aqueous compartments (e.g. surface and grey water) more than in soil and sediments. Furthermore, most of the analytical methodology available are characterized with high detection limits and are not suitable for the analysis of expected trace levels within the environment. In the present work we developed a method for the analysis of C60 and C70 fullerenes in soil and sediment matrices. Fast chromatographic separation with HUPLC ( $R_s > 1.5$ ) was achieved with the use of biphenyl stationary phase whereas detection with Ion Booster-Q-TOF high resolution mass spectrometry granted high sensitivity and mass resolution. The detector response showed high linear dynamic range with detection and quantification limits of 0.6 ng/L and 1.9 ng/L respectively. The developed method was then validated for the analysis of fullerenes spiked into soil and sediments extracts ( $n=6$ ) with differing properties such as texture and organic carbon content. Particular attention was paid to the matrix effect and post-column infusion and standard addition experiments showed that the method is suited for the analysis of the majority of the matrices included in the present study. Furthermore, signal suppression in very complex matrices (e.g. high carbon content) could be by simple modification in the mobile phase composition. Although fragmentation could not be obtained for the fullerenes, the application of high collision energy provided a “background clean-up” that resulted in extremely clean and reliable  $MS^2$  spectra, where only the precursor ion was visible, in all the samples. Finally, it was shown how the method is suitable for the analysis of other fullerenes such as functionalized derivatives.

#### TU235

##### **Environmental survey of fullerenes in urban and industrial soils**

A. Carboni, IBED; R. Helmus, University of Amsterdam; J. Parsons, K. Kalbitz, P. de Voogt, University of Amsterdam / IBED

Fullerenes are considered as some of the most promising materials in nanotechnology and their increasing production and application is cause of concern for both toxicological and environmental aspects. To date, data reporting their occurrence in the environment are scarce and often contradicting. Possible pathways for their release are expected to be 1) the direct release from materials that contain them, 2) unintentional production (e.g. during combustion processes) and 3) because of natural phenomena. Furthermore, modelled scenarios as well as experimental data suggest that soil may act as a sink for these chemicals but still few data are available to support this thesis. In the present work, soil samples were collected in five different industrial and urban locations across the Netherlands. The samples were processed and analyzed with a recently developed method that allowed the detection at concentrations in the range of the expected environmental concentrations (i.e. ng/kg). C60 fullerene was detected in samples from different locations whereas C70 was not present in any of the samples analyzed. In addition to C60, one product of transformation that preserves the C60 cage was identified in few of the samples analyzed. These data will contribute to understanding the sources and pathways of contamination by fullerenes in soils.

#### TU236

##### **ASYMMETRICAL FLOW FIELD-FLOW FRACTIONATION HYPHENATED TO ORBITRAP HIGH RESOLUTION MASS SPECTROMETRY FOR THE DETERMINATION OF (FUNCTIONALISED) AQUEOUS FULLERENE AGGREGATES**

P.S. Bauerlein, KWR / Analytical and Environmental Chemistry; E. Emke, KWR Watercycle Research Institute; P. de Voogt, University of Amsterdam / IBED; P. Herrero, E. Pocurull, Universitat Rovira i Virgili

We report on the technical implementations of coupling an asymmetric flow field-flow fractionation (AF4) instrument to a high resolution mass spectrometer (Orbitrap) using an atmospheric photoionisation interface [1]. This will allow for the first time online identification of different fullerenes in aqueous samples after their aggregates have been fractionated in the FFF channel. It is now possible to analyse fullerene aggregates firstly with non-destructive techniques such as UV-Vis or MALS and subsequently use MS to identify and quantify the fullerenes. Quality parameters such as limits of detection (LODs), limits of quantification (LOQs) or linear range for the mass spectrometer were evaluated and they were in the range of hundreds ng/L for LODs and LOQs and the detector response was linear in the range tested (up to ~ 20 µg/L). Crucial for this setup are the use of the slot pump to reduce the flow to the detectors as well as the gas dopant device, which introduces toluene. Toluene is needed for enhancement of the ionisation of fullerenes. The low detection and quantification limits make this technique useful for future environmental or ecotoxicology studies in which low concentration levels are expected for fullerenes and common on-line detectors such as UV or MALS do not have enough sensitivity and selectivity. Possibly this FFF-MS setup could also be used for other organic particles. [1] P. Herrero, P.S. Bauerlein, E. Emke, E. Pocurull, P. Voogt, Asymmetrical Flow Field Flow Fractionation Hyphenated to Orbitrap High Resolution Mass Spectrometry for the Determination of (Functionlised) Aqueous Fullerene Aggregates, J. Chromatogr. A 1356 (2014) 277-282.

##### **Analytical challenges in identification of nanometer plastics**

S.A. Kools, KWR Watercycle Research Institute; P.S. Bauerlein, KWR / Analytical and Environmental Chemistry; P. Kooij, KWR Watercycle Research Institute; P. de Voogt, University of Amsterdam / IBED; W. Siegers, KWR Watercycle Research Institute

Plastics fragments may affect life and analysis of particles is in the attention of many. To underpin research on sources of plastic fragments, our research aims to detect and identify plastics in water matrices. We focus our work on the smaller scale fragments as low as the nanometer scale as these particles could be a greater threat to the aquatic environment and drinking water production. Yet, such data on very small scale fragments is limited. Eventually, we want to be able to identify them and trace their tracks in the environment. This will help to understand how they spread in the environment. We use two methods for the characterisation and identification of plastic particles. The first method identifies the type of plastic. For this we use a pyrolysis GC/MS. Based on the chromatogram and the mass fragments we can name the type of plastic. For further characterisation we make use of an FFF coupled to a MALS detector. The FFF separates the different particles based on their size and the size is determined by the light scatterer (MALS). We showed polyethylene and polystyrene, down to 100 nm. We are able to identify plastic particles in mixtures as well as in commercial and environmental samples. In this research, we present data on developments and applications.

#### TU238

##### **Applying a generic sample preparation approach to isolate nanomaterials from food and cosmetics**

M. Velimirovic, University of Vienna / Department of Environmental Geosciences; S. Wagner, University of Vienna / Department of Environmental Geoscience; F. Von der Kammer, Vienna University / Department of Environmental Geosciences; T. Hofmann, University of Vienna / Department of Environmental Geosciences

The applicability of a generic scheme to systematically develop methods for detection, characterization, and quantification of engineered nanoparticles (ENPs) in a complex matrix was tested using real products. We selected two sample types and applied the generic sample preparation scheme: 1) a powdered tomato soup which contains the anti-caking agent  $SiO_2$  (E551), and 2) a sunscreen which contains  $TiO_2$  as UV-filter. Our research focused on sample preparation, aiming to achieve a complete separation of ENPs from the respective matrix without altering the ENP size distribution and with minimal loss of ENPs. The generic multi-step sample preparation procedure includes: I) homogenization of the sample; II) ENP separation from the matrix; III) ENP enrichment if necessary, and IV) ENP stabilization. The preparation procedure was evaluated by pre-defined quality criteria, which are mass recovery and change in size distribution. The mass recovery was calculated by elemental analysis of Si and Ti, respectively. The size distribution of the isolated ENPs was determined by asymmetric flow field-flow fractionation (AF<sup>4</sup>) coupled to multi-angle laser light scattering (MALLS) and inductively-coupled plasma mass spectrometry (ICP-MS). The size distribution was compared to the size distribution of pristine particles. We demonstrated that for both sample types the generic sample preparation scheme is valid. For  $SiO_2$  in tomato soup, complete matrix removal and Si mass recovery > 90% was achieved

using acid digestion supported by heat (90°C) and hydrogen peroxide as oxidation agent. After careful enrichment procedure where acid was evaporated by multiple washing steps with MilliQ water at 90°C total SiO<sub>2</sub> recoveries were close to 100%. The size distribution of commercially available pristine E551 was comparable with the size distribution of the SiO<sub>2</sub> particles isolated from the commercial tomato soup. For TiO<sub>2</sub> in sunscreen, TiO<sub>2</sub> ENPs could be isolated by a combination of ultra-centrifugation and solvent washing. Recoveries were sufficiently high to perform FFF-MALLS-ICPMS analysis indicating only a slight shift of the size distribution towards larger diameters. Currently, total TiO<sub>2</sub> recoveries are improved by adaptation of ultra-centrifugation and washing steps. The proposed generic sample preparation scheme and the applied quality criteria are a very important contribution towards standardized method development in the field of ENPs in consumer products to determine release potential and quantities.

### **Pilot study about the behavior of different sized noble metal nanoparticles in *Daphnia magna* and related exposure media**

S. Brandsma, Institute for environmental studies (IVM); P. Krystek, MiPlaza, Philips Research Europe; P. Leonards, VU University, Institute for Environmental Studies / Institute for Environmental Studies IVM

As a new approach, exposure scenarios with different noble metal nanoparticles were setup. The particles are chosen based on their elemental composition (silver, gold and platinum) and the particles sizes of 5 to 50 nm i.d. *Daphnia magna* was exposed for a period of 24 hours. To localize the nanoparticles a microEDX technique was used. EDX images of the whole daphnia's showed the main locations were agglomerates of nanoparticles were present in the body. The uptake in *Daphnia* and the nanoparticle stability in the exposure media were studied. Various analytical approaches were evaluated and presented in detail.

## **TU240**

### **Development of a 'best practice' for algae testing of nanomaterials based on available recommendations from the scientific literature and other available guidance**

A. Brinch, DTU Technical University of Denmark / Department of Environmental Engineering; S.F. Hansen, Technical University of Denmark DTU / DTU Environment; N.B. Hartmann, Technical University of Denmark (DTU) / DTU Environment

Ecotoxicological data is a fundamental information requirement in different chemical legislations such as the European chemical legislation, REACH and the Biocidal Products Regulation (BPR). However, standard test guidelines for the ecotoxicity testing of NMs are lacking. Work is ongoing within the OECD WPMN to amend and develop new test guidelines specifically for nanomaterials. Until then, however, registrants and regulators must rely on currently available guidance and recommendations from other sources. Here we collect and analyse this readily available information from various sources including scientific literature and OECD guidance documents. On this basis we suggest a best practice for how to conduct appropriate ecotoxicity testing of NMs in order to provide reliable data for the risk assessment of NMs. Specific focus is on the OECD algal growth inhibition test and CuO nanoparticles (NPs). The elements of the best practice consist of specific recommendations regarding stock suspension preparation and characterisation, exposure suspensions preparation and the procedure for conducting the algal growth inhibition test. The main focus is on characterization of the NP suspensions and the test parameters before and during the test and specific investigations of the stability and degradation of the NPs in the test systems. Some components have subsequently been tested experimentally. It was found that both the OECD algal test medium and a low ionic strength media resulted in stable and relatively monodisperse dispersions. However, higher growth inhibition was observed in the low ionic strength media. Measurements of dissolution showed that dissolution measurements where method dependent (dialysis membrane vs. DGT) and revealed that *in situ* measurements of dissolution is key as the presence of algae increases dissolution of CuO nanoparticles. The developed best practice may serve as inspiration for future algal growth inhibition testing of nanomaterials and may also feed into development of OECD test guidance documents. This would help to facilitate the provision of more reliable test data in terms of both appropriate test design and study documentation for algae testing of NMs.

## **TU241**

### **Characterization of sepia ink eumelanins through SEM and DLS**

D.E. Gomez, The University of Exeter / College of Engineering Mathematics and Physical Sciences; M. Paradelo, University of Vigo / Plant Biology and Soil Science; P.P. Rodríguez, Universidade de Vigo / Plant Biology and Soil Science; J.L. Periago, University of Vigo / Plant Biology and Soil Science; I. De La Calle, University of Vigo / Analytical and Food Chemistry  
Eumelanins are black and insoluble pigments that give dark hue to several organic components. These molecules have suitable characteristics and structure to be used as colloidal tracers in soil experiments: they are easily obtained and quantified, have constant composition and properties, and are safe for humans and the environment (Cheng et al., 1994). In this work we have compared two techniques frequently used for determining particle size: scanning electron microscopy (SEM) and dynamic light scattering (DLS). SEM images showed quasi-spherical particles, slightly rough, and a variable size close to 100 µm. They are in the upper limit of the

classification as nanoparticles. DLS analysis were performed using a Cordouan Technology VASCO-2 particle size analyzer. The original ink sample (7.3 mg/mL) was diluted in water: 1/10, 1/100 and 1/200. Polydispersity index (PDI) has been calculated according to the Cumulants method (Kopel, 1972; Fiske, 2001), being 0.2960 (for 1/10 dilution), 0.1320 (for 1/100 dilution) and 0.02120 (for 1/200 dilution). Size distribution was obtained taking into account the number of the particles of each hydrodynamic diameter (nm). Results showed that 10% of the particles have a diameter less than 149±40 (CV=26 %) nm, 50 % of the particles have a diameter less than 181±20 (CV=11%) nm and 90 % of the particles have a diameter less than 211±18 (CV=8 %) nm. Similar results were obtained and the majority of the particles are in a range of 100 to 200 nanometers, but with the DLS the size is a bit larger. This may be because the diameter determined by DLS is a hydrodynamic size, and is bigger than the dry particle size. Bibliography Cheng J, Moss SC, Eisner M, Zschack P. 1994; 7: 255 – 262 Koppel D. ### **Solubility of ZnO nanoparticles. Comparison of AGNES and DGT**

c. rey-castro, University of Lleida / Chemistry; S. Cruz-Gonzalez, Universitat de Lleida; C. David, Universitat de Lleida / Department of Chemistry; J. Galceran, Universitat de Lleida / Department de Química; J. Puy, Chemistry  
Solubility measurement is important for the characterization of nanomaterials and their risk assessment. If a nanomaterial is dissolved, then it is no longer considered as *nano* for regulatory purposes [1]. OECD and ISO guidelines refer to the measurement of total solubility, rather than the speciation of dissolved material. However, in relation to nanoZnO, recent reports in the literature support the free ion species being linked to the toxicological effects [2]. The assessment of solubility usually requires solid/liquid separation steps, *e.g.* filtration and centrifugation. However, these steps may be hindered by inefficient particle removal, time-consuming operation, etc. Thus, there is a need for analytical techniques specifically suitable for environmental testing that can separate nanoparticles from dissolved species, and discriminate among the solute forms. Two of these techniques have been applied to the study of nanoZnO solubility: Absence of Gradients and Nernstian Equilibrium Stripping (AGNES) and diffusion gradients in thin films (DGT). AGNES has proved suitable for the measurement of free Zn<sup>2+</sup> concentrations in nanoZnO dispersions [3], with the advantage of a fast analytical response, able to follow the dissolution kinetics. The determination of other Zn species, however, is not straightforward. On the other hand, DGT allows the measurement of the dissolved (and labile) species, although the extent of nanoparticle penetration and dissolution inside the DGT device and its influence on the metal accumulation is still a matter of controversy. This work analyses the performance of DGT devices in ZnO dispersions and presents a conceptual framework integrating the speciation information yielded by this technique with the data on free Zn<sup>2+</sup> concentration provided by AGNES. The work leading to these results has received funding from the European Union Seventh Framework Programme (FP7-NMP.2012.1.3-3) under grant agreement no. 310584 (NANOREG). ## **Nanoparticle (NP) speciation and its consequences for NP environmental fate and effects (P)**

## **TU243**

### **Adsorption of 3-nitrobenzanthrone by Graphene Oxide: the role of Oxidative Debris**

T. HSIN YU, LEAL Laboratory of Ecotoxicology and Environmental Microbiology; D.S. Teodoro-Martinez, INSTITUTE OF CHEMISTRY UNICAMP / Laboratory of Solid State Chemistry; G.d. Umbuzeiro, FACULTY OF TECHNOLOGY -UNICAMP / LEAL; V.R. Coluci, SCHOOL OF TECHNOLOGY UNICAMP / LEAL Laboratory of Ecotoxicology and Environmental Microbiology

Graphene oxide (GO) is a very promising material because it is easy to process, water soluble, and chemically versatile due to the presence of oxygenated groups on its surface. Oxygenated groups like –COOH, –C=O, and –OH are important for the GO reactivity and for further functionalization. During preparation of GO sheets by exfoliating graphite with a mixture of potassium permanganate and concentrated sulfuric acid (modified Hummers method), complex mixtures of highly oxidized polyaromatic carboxylated fragments – oxidative debris (OD) – are produced. While these debris, that are strongly bound to GO surface, act as surfactant and help stabilizing aqueous GO suspensions, they also change GO surface properties such as the capacity of adsorbing molecules by noncovalent functionalization. This capacity is especially important for remediating environmental pollutants. Here we study the role of OD on the GO capacity to adsorb organic pollutants. GO with two different concentration of debris were studied (as-produced GO – aGO-L2 and aGO-L4). These samples were chemically treated to yield to debris-free GO (dfGO). We used the *Salmonella typhimurium* mutagenicity assay (Ames test) to

indirectly probe the GO adsorption capacity by looking at revertants induction caused by non-adsorbed testing molecules (pollutants) on GO surfaces. We selected an important mutagenic pollutant produced from incomplete combustion of fossil fuels (3-nitrobenzanthrone (3-NBA)) as the testing molecule. We observed that GO can adsorb 3-NBA and this adsorption is dependent on the amounts of OD on the GO surface used in the test, which indicates that OD indeed reduce the GO adsorption capacity. DfGO samples were 50% up to 85% more effective to adsorb 3-NBA than samples with debris whereas aGO-L2 samples, which has around 50% less OD than aGO-L4, were 20% more effective than aGO-L4 samples. While the presence of OD on the GO surface is interesting to increase the GO stability in water, the OD inhibit stronger interactions between 3-NBA and GO. Our data strongly indicate that OD are important molecules on the GO structure that should be taken into account in future studies. The authors acknowledgments São Paulo Research Foundation FAPESP (2012/19982-5) for financial support.

## TU244

**Comparative evaluation of methods to quantify dissolution of nanomaterials**  
**N.B. Hartmann**, Technical University of Denmark (DTU) / DTU Environment; S. Kruse, Department of Environmental Engineering; A. Baun, DTU Environment / Department of Environmental Engineering

Effects and behaviour of nanomaterials in the environment depends on the materials' specific physical and chemical properties and for certain nanomaterials (e.g., Ag, ZnO and CuO) aqueous solubility is of outmost importance. The solubility of metals salts is normally described as a maximum dissolved concentration or by the solubility constant (Ksp). For nanomaterials it is essential to also assess solubility kinetics as nanomaterials will often not dissolve instantaneously upon contact with artificial aqueous media or natural waters. Dissolution kinetics will thereby influence their short and long-term environmental fate as well as laboratory test results. This highlights the need to evaluate and improve the reliability of methods applied to assess the solubility kinetics of nanomaterials. Based on existing OECD guidelines and guidance documents on aqueous dissolution of metals and metal compounds, the aim of this project was to conduct systematic experiments contributing to a better understanding of how nanomaterials solubility can be tested and evaluated under the auspice of the OECD framework. The focus was to evaluate the performance of three different techniques used to separate the dissolved and non-dissolved fraction of nanomaterials, namely: dialysis membranes (MWCO 8-10 and 50 kD), Diffusive Gradients in Thin films (DGT) and ultracentrifugation. The release of Cu ions from CuO nanoparticles (primary nominal size < 50nm) was used as a case study. Micron sized CuO was used as a "non-nano reference" and CuSO<sub>4</sub> and CuCl<sub>2</sub> were used as ionic Cu references. In a comparative study of the three methods we found a good reproducibility between replicates and a good recovery (88-99% of nominal concentrations). However, we observed a large difference in results between the three applied methods. Preliminary results showed that by using the DGT method the measured dissolved fraction was 5-7 times higher compared to using ultracentrifugation and dialysis membranes. Possible explanations include metal-specific interactions with the dialysis membranes as well as the DGT unit influencing the dissolution equilibrium by acting as a 'sink' for Cu ions. These are issues that require further investigations. Based on these first results we would recommend ultracentrifugation as the most suitable method as it also offers the advantage of being 'material-independent' when correctly adjusted for particle sizes and density.

**Aggregation dynamics of silver nanoparticles in ecotoxicological test media**  
**G. Metreveli**, Institute for Environmental Sciences Group of Environmental and Soil Chemistry; B. Frombold, Universität Koblenz-Landau / Institute for Environmental Sciences Group of Environmental and Soil Chemistry; F. Seitz, Inst. for Environmental Sciences / Institute for Environmental Sciences; A. Grün, Universität Koblenz-Landau / Institute of Integrated Natural Sciences Department of Biology; A. Philippe, Universität Koblenz-Landau / Institute for Environmental Sciences Group of Environmental and Soil Chemistry; R.R. Rosenfeldt, University of Koblenz-Landau, Institute for Environmental Sciences / Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; W. Manz, German Federal Institute of Hydrology; G.E. Schaumann, University of Koblenz-Landau / Institute of Environmental Sciences For the ecotoxicological testing of engineered nanoparticles (ENPs), specially designed and standardized test media (TM) are usually used. Due to high ionic strength of the TM, the aggregation of ENPs is frequently promoted. Thus, the differences in chemical composition of TM and the broad concentration range of ENPs applied in ecotoxicological studies can result in discrepancies of ecotoxicological impact of ENPs and can lead to a biased interpretation of the experimental data. In this work, the aggregation dynamics and dissolution of citrate coated silver nanoparticles (Ag NPs) in three TM in absence and presence of natural organic matter (NOM) were investigated. A partial dissolution of Ag NPs was observed in all media in absence, as well as in presence of NOM. The release of silver ions from Ag NPs was controlled by the interplay of protecting mechanisms and stabilizing effects of NOM, as well as by complexation and re-sorption of released ions. In each TM, Ag NPs aggregated in a reaction-limited regime. The

aggregation mechanisms and dynamics were controlled by the ion composition, presence of specifically interacting organic compounds (vitamins, proteins), NOM quality and concentration of Ag NPs. Electrostatic stabilization by NOM was most effective at low Ca<sup>2+</sup> and Mg<sup>2+</sup> concentrations. At high Ca<sup>2+</sup> and Mg<sup>2+</sup> concentration, NOM accelerated aggregation due to formation of bridging-determined aggregates. Bridging-determined aggregation was much more pronounced for Ca<sup>2+</sup> than for Mg<sup>2+</sup>. The results of this study demonstrate how the composition of the TM, concentration of Ag NPs, and the duration of the ecotoxicological tests can affect the dissolution and aggregation status of Ag NPs. These findings underline the requirement to carefully interpret associated ecotoxicological data. The results obtained in this study can also be used for tuning the aggregation and coating properties of Ag NPs in different TM. For example, the reduction of the Ca<sup>2+</sup>/Mg<sup>2+</sup> ratio in ranges acceptable for the organisms will reduce the aggregation rate of nanoparticles. The further amendment of TM with NOM will result in different types of colloidal stabilization. The addition of specifically interacting organic compounds like vitamins or proteins may further strengthen the organic coating.

## TU246

**FullereneC60 loading interferes of the growth and emergence rate of the Midge Chironomus riparius**

**G.C. Waissi-Leinonen**, University of Eastern Finland; I. Nybom, Department of Biology; K. Pakarinen, University of Eastern Finland / Department of Biology; E. Petersen, National Institute of Standards & Technology; J. Akkanen, University of Eastern Finland / Department of Biology; M.T. Leppanen, Finnish Environment Institute / Laboratory Centre; J.V. Kukkonen, University of Jyväskylä / Biological and Environmental Science

The suitability of test methods for use with nanomaterials is a topic of significant research interest. There are several uncertainties when assessing nanomaterials, such as fullerene(nC<sub>60</sub>), potential toxicity to aquatic invertebrates because of their unique chemical properties which substantially differ from those of hydrophobic organic chemicals and dissolved metals. Aims of this study were to investigate the method for measuring the body residues on *Chironomus riparius* and to study if sediment associated fullerene had an impact on larval development and emergence rate. A benthic invertebrate *C. riparius* larvae were exposed to nC<sub>60</sub> with two different exposure methods; 1) masses in the sediment top layer creating an environmentally realistic method and thus simulating a sensitive exposure route for *C. riparius* feeding habits and 2) using fullerene spiked sediment which is commonly used method in ecotoxicology. Body residues after acute and chronic exposures were analysed and larval growth and development rate assessed. Body residues were lower in the exposure method 1 after 15 d exposure than after 10 d which may stem from changing in behaviour of larval feeding habits during the development time or possibly after 10 d time larvae have reached steady state. Using the exposure method 2, larval growth and emergence rate were affected by fullerenes. Findings indicated that presence of fullerene interferes organisms even at the lowest tested (method 2, 0.5 mg/kg) concentration. Overall, these results pose that there is possible ecotoxicity towards benthic organisms that fullereneC<sub>60</sub> may cause leading changes in ecotoxic parameters used here.

## TU247

**Acute and chronic effect of titanium dioxide nanoparticles functionalized by esterification with ligands bearing -COOH, -NH<sub>3</sub> and PEG groups on mobility and reproduction of Daphnia magna.**

**Z.A. Gajda-Meissner**, T.F. Fernandes, Heriot-Watt University / School of Life Sciences; M.G. Hartl, Heriot-Watt University / Centre for Marine Biodiversity and Biotechnology School of Life Sciences

Modifications of titanium dioxide nanoparticles (nTiO<sub>2</sub> NPs) for different applications may change their physicochemical properties, such as surface charge. Assessments of the extent to which such modifications influence nTiO<sub>2</sub> on acute and chronic toxicity are needed to understand the potential environmental risks these variously modified nanoparticles may pose. Assessment of the effects of various nTiO<sub>2</sub> surface modifications on mobility and reproduction of *Daphnia magna* was thus the aim of this study. *Daphnia* acute toxicity tests were performed according to the OECD guideline 202, using synthetic medium (M7). The acute tests were conducted using seven test compound concentrations (0.1-100 mg L<sup>-1</sup>) and untreated control (M7). After exposure for 24 h and 48 h the immobilization rate for individuals was calculated. The 24 h and 48 h EC<sub>50</sub> (immobilization) values were calculated using SigmaPlot® software. *Daphnia magna* reproduction tests were performed according to the OECD guideline 211. Neonates were exposed for 21 d under the following concentration of nTiO<sub>2</sub>: 0 (control), 0.03, 0.1, 0.3, 1, 3mgL<sup>-1</sup>. The chronic effects endpoints monitored were criteria used to evaluate the reproduction of *D.magna* including total living offspring per adult animal. The survival and body length of adult animals were documented during the exposure period. After incubation for 24 hours high nTiO<sub>2</sub> concentrations of 100mgL<sup>-1</sup> and 30mgL<sup>-1</sup> caused less than 20% and 10% immobilization, respectively, and no significant mortality was found. EC<sub>50</sub> values were greater than 100 mgL<sup>-1</sup>. After 48 hours of exposure to nTiO<sub>2</sub>+PEG significant immobilization was observed (EC<sub>50</sub> 40.07mgL<sup>-1</sup>). The results demonstrated that nTiO<sub>2</sub> (core) without modification, nTiO<sub>2</sub>+PEG group and nTiO<sub>2</sub>+NH<sub>3</sub> surface treatment, even at the low concentrations of 0.1 mg L<sup>-1</sup>, 0.3 mg L<sup>-1</sup> and 1 mgL<sup>-1</sup>, respectively, showed significantly (p

## TU248

### Evaluation of environmental toxicity for surface-modified silver nanoparticles on aquatic organisms

Y. Jung, Convergence Environment Team; S. Baik, KIST Europe / Convergence Environment Team; C. PARK, Korea Institute of Science and Technology Europe / Convergence Environment Team Environment Bio Group; S. Kim, KIST Europe / Chemical Management Lab

With the increased use and application of surface modified silver nanoparticles (AgNPs), many concerns have been raised for their toxicity after releasing and discharging to aquatic ecosystems which may pose possible risks to the environment. Therefore, in this study, ecotoxicological evaluation of surface-modified AgNPs on aquatic organisms was conducted. Aquatic organisms for the ecotoxicological evaluation were luminescent bacteria and *Daphnia magna*, and four different surface coated AgNPs with the same core diameter of about 20 nm were used. Surface coating materials for AgNPs were citrate (Cit), tannic acid (Tan), polyethyleneglycol (PEG), and branched polyethylenimine (BPEI) and  $\zeta$  potentials of those NPs were -27.1 mV, -10.7 mV, -20.5 mV, and 18.3 mV, respectively. For an acute (15 min) ecotoxicological screening test, luminous microbial array for risk assessment (LumiMARA), which consists of 2 fresh water and 9 marine bacteria, was applied. The tendency of toxic effects for target AgNPs on the marine bacteria are following order; BPEI-AgNPs > PEG-AgNPs > Tan-AgNPs > Cit-AgNPs, resulting on the positively charged AgNPs with higher salt stability showed more toxic on those marine luminescent bacteria. The other acute (48 h) ecotoxicological test was conducted using *Daphnia magna* as the aquatic organisms in accordance with OECD guideline 202. Mortality and immobility of *Daphnia magna* exposed to target AgNPs were investigated. 50% effective concentration ( $EC_{50}$ ) and 50% lethal concentration ( $LC_{50}$ ) of BPEI-AgNP on *Daphnia magna* were calculated as 20.38  $\mu\text{g/L}$  and 64.19  $\mu\text{g/L}$ , respectively, and  $EC_{50}$  for Cit-AgNP was calculated as 110.64  $\mu\text{g/L}$ . However, there is still insufficient understanding of main factors which influence the organisms. The NPs size, surface coating materials or ions released from NPs as well as reactive oxygen species (ROS) can contribute to toxicity of AgNPs to the organisms. Furthermore, regarding the safety of AgNPs with environmentally relevant conditions, it is necessary to deliberate more complicated matrix considering pH, ionic strength, organic matters, etc. Prior to the critical assessment of the mechanism, we tried to identify the quantification and size distribution of AgNPs taken up by organisms in the test media by inductive coupled plasma mass spectrometry (ICP-MS).

## TU249

### The eco-corona mediated uptake and impacts of so-called "Future Nanoparticles" on *Daphnia magna*

F. Nasser, University of Birmingham / Geography Earth and Environmental Science; E. Valsami-Jones, The Natural History Museum; I. Lynch, University of Birmingham / Geography Earth Environmental Science

Nanoparticles (NPs) can be defined as having at least one external dimension between 1-100nm. Due to their small size, NPs have a large surface area to volume ratio giving them unique characteristics that differ from bulk material of the same chemical composition. As a result these novel materials have found numerous applications in areas such as drug delivery, medicine and electronics. Previous research has been conducted on legacy NPs such as silver which acts as an antimicrobial agent; gold which is used in cancer therapy and; carbon nanotubes which provides heightened capacity for drug delivery. On the horizon is research on so-called "future or next generation NPs" which are being developed to display a variety of shape, morphology, behavioural and other properties that are not provided by legacy materials. There is extremely limited research on the interaction of future NPs with the environment or biological organisms, or indeed on whether existing approaches to assessing quasi-spherical or rod-shaped materials are applicable to or relevant for such advanced architectures and hybrid compositions. Nanoparticles may adsorb substances from the environment to form an ecocorona, which ultimately changes the NP identity and how it can interact with organisms. New nanomaterial shapes or architectures may impact what bio- or eco-molecules can adsorb to its surface and can considerably change NP interactions with organisms and/or their membrane receptors. Optimisation of protocols has been performed using simple COOH- and  $\text{NH}_2$ -modified spherical polystyrene nanoparticles (intended as negative and positive controls, respectively) in order to assess the secretion of biomolecules in response to the presence of nanoparticles and their impact on nanoparticle uptake. Impact of nanoparticle shape (morphology) is also assessed using gold NPs of a range of morphologies (rods, stars, prisms etc.) to determine the impact of NP shape on the initial ecocorona composition, the NP interaction with *daphnia magna*, and the "final" ecocorona following exposure to *daphnia magna* in order to fingerprint the ecocorona evolution.

### Effects of nano-stressors on oxidative stress in crustaceans: enzyme activity in the tissues of *Potamonautes warreni*

C. Walters, CSIR / Natural Resources and the Environment; E.J. Pool, University of The Western Cape; V. Somerset, NRE

The increasing use of nanotechnology emphasizes the need to understand and clarify the environmental impacts of nanomaterials (NMs). Silver nanoparticles

(AgNPs) are one of the most prevalent manufactured NMs used in a variety of consumer products. As such, their widespread applications will inevitably lead to their increased release into the environment. Reactive oxygen species (ROS) are the most studied biomarkers to evaluate the biochemical alterations by contaminants (such as NMs) on aquatic organisms. Studies on oxidative stress in crustaceans and other aquatic organisms have widely been used as ecotoxicological indices to assess the environmental risk produced by chemical and environmental stressors.

Antioxidant enzyme responses and oxidative stresses were assessed in the gills and hepatopancreas of the freshwater crab *Potamonautes warreni* following exposure to AgNPs at room temperature. Responses were evaluated through activities of antioxidant enzymes, i.e. superoxide dismutase (SOD), catalase (CAT) and glutathione S-transferase (GST). The results indicated inhibition of SOD activity with increase AgNP concentration and was generally higher in the gills when compared to the hepatopancreas. For the latter, the converse was true for GST. In the gills, GST activity followed the trend: 100  $\mu\text{g/mL}$  group < control group < 10  $\mu\text{g/mL}$  group, while the hepatopancreas had the following trend: 10  $\mu\text{g/mL}$  group < 100  $\mu\text{g/mL}$  group < control group. CAT activities initially increased and subsequently decreased with increasing AgNP concentration. Collectively, the results suggest that the antioxidant defences of *P. warreni* were significantly affected by exposure to environmentally-relevant concentrations of AgNPs.

## TU251

### Absorption and distribution of ingested silica nanoparticles in *Blattella germanica*: a potential carrier in the development of nanopesticides

I. Biagioni, M. Ochoa-Zapater, Universitat de Valencia / Dpt Biología Funcional y Antropología Física; A. Ribera, Universitat de Valencia / Instituto de Ciencia Molecular; A. Torreblanca, University of Valencia / Department of Animal Biology; F. Romero, Universitat de Valencia / Dpt Química inorgánica; I. Varo, Spanish Research Council (CSIC) / Biology culture and pathology of marine species; M. Garcerá, Universitat de Valencia / Dpt Biología Funcional y Antropología Física

The rapid advances in nanotechnology have provided a wide range of nanomaterial with unique properties that open new possibilities of application in medicine, agricultural productivity and pest control. Nanoparticles can be used in agriculture as insecticide carriers in order to improve efficiency, reduce environmental pollution and the impact on non-target organisms of conventional pesticides. Mesoporous silica nanoparticles could be promising candidates as carriers due to the tridimensional open network structure that allows to store and controllably release active agents. We investigate penetration, absorption and distribution of mesoporous silica NPs marked with the fluorophore rhodamine B in the digestive tract of the model insect *Blattella germanica*. Silica NPs administration was carried out through food and insects were frozen at different exposure times at  $-80^\circ\text{C}$ . Finally, insects were dissected and analyzed using an Olympus FV1000 fluorescence confocal microscope with 10x and 60x objectives. It was confirmed the presence of silica NPs in the alimentary canal. Furthermore NPs were observed in the enteric caeca suggesting that silica nanoparticles could cross the peritrophic membrane in *Blattella germanica*. It is likely the presence of silica NPs in other organs although it has not been confirmed yet.

## TU252

### Effect of freshwater algal growth stage on physicochemical properties, transformations, and toxicity of iron nanoparticles

A.S. Adeleye, University of California, Santa Barbara / Bren School of Environmental Science Management; L.M. Stevenson, Ecology Evolution and Marine Biology; Y. Su, Tongji University / State Key Laboratory of Pollution Control and Resources Reuse; R.M. Nisbet, UCSB / Ecology Evolution and Marine Biology; A.A. Keller, Bren School of Environmental Science and Management

A number of pilot and full scale field studies have shown that nanoscale zero-valent iron (nZVI) and its derivatives are promising for remediation of several important environmental pollutants. However, there is still a lot of uncertainty about the implications of injecting high concentrations of these engineered nanomaterials (ENMs) into the natural environment. The implications of ENMs in the environment are controlled mainly by the ENMs' physicochemical properties, stability, transformation, and the bioavailability of their different transformation products. In this study, the physicochemical properties of sulfide/silica-modified nZVI (FeSSi) were compared in both fresh algal media (Day 1 media) and media in which *Chlamydomonas reinhardtii* had been grown for 11 days (Day 11 media) in order to elicit the effect of organic matter produced by the freshwater algae. In addition, dissolution and transformation of FeSSi particles were investigated for a month in Day 1 and Day 11 media inoculated with *C. reinhardtii*, while monitoring the response of both sets of cultures. Hydrodynamic diameter and zeta potential data suggested that FeSSi particles were coated by organic matter in the Day 11 media, which increased the particles' colloidal stability. This was confirmed by aggregation and sedimentation kinetics experiments. Dissolved Fe detected in Day 1 media was an order of magnitude higher than that in Day 11 media; and X-ray diffraction analyses confirmed slower oxidation of FeSSi in Day 11 cultures. Regarding toxicity, lesser impact of FeSSi was observed on algal growth rate in Day 11 media than in Day 1 media. This study shows that the growth stage of algae at which they are exposed to ENMs may have a strong effect on the physicochemical properties, transformations, and toxic effects of the particles.

## TU253

### DNA changes in *Pseudomonas putida* induced by zirconium oxide nanoparticles using RAPD analysis

M. Zaleska-Radziwiłł, Warsaw University of Technology / Department of Biology; N. Doskocz, Warsaw University and Technology / Department of Biology  
Unique properties of nanoparticles, such as, among others, their small size, a large mechanical resistance, a high surface to volume ratio, a higher chemical reactivity, make usable products produced by nanotechnology extremely attractive compared with those obtained by traditional methods. With the arrival of nanomaterials and their wide application there is a great risk of exposure of organisms in ecosystems to this type of contamination. Research has been conducted to determine the genotoxicity of zirconium oxide nanoparticles towards *Pseudomonas putida* bacteria using RAPD-PCR method (*Random Amplification of Polymorphic DNA*). The results were compared with the effects of the impact of the macro form of the compound on DNA. The PCR reaction used the following primers: OPA 2, OPA 10, OPA 9 and OPA 18 of a random nucleotide sequence. On the basis of RAPD profiles using primer OPA 2 and OPA 10 the research demonstrated mutagenic action of the tested nano-compound. The obtained profiles of RAPD bands are different from the negative control by over 16,7 % to 7,3 % for primer OPA 2 and by 14,3 % for primer OPA 10. Using the remaining primers RAPD bands the profiles for the samples with the nano-compound and the negative control varied to a small extent. This study showed a decrease in the genetic stability of DNA (GTS, %) after treatment of the bacteria nano-ZrO<sub>2</sub> as compared with the negative control. GTS value for the nano-ZrO<sub>2</sub> was 78,1 % (1000 mg/l, 100mg/l, 10 mg/l). In the remaining concentrations of nano-ZrO<sub>2</sub> GTS remained was 82,3 %. The results showed that the nano-ZrO<sub>2</sub> can induce modifications of the genetic material to a greater extent than the same compounds in the macro form.

## TU254

### Acute effects of gold nanoparticles and fluoxetine on *Mytilus galloprovincialis*

L.G. Luis, CESAM & Department of Biology / Department of Biology; A. Barreto, CESAM / Department of Biology; T. Trindade, University of Aveiro / Department of Chemistry; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; M. Oliveira, Laboratory of Ecotoxicology and Ecology  
One of the main challenges that ecotoxicologists currently face is to understand how contaminants of emerging concern such as human pharmaceuticals and nanoparticles will affect the health of the environment and ultimately human health. This study was designed to investigate the acute effects of gold nanoparticles (GNP) with a citrate (cGNP) or a polyvinylpyrrolidone (PVPGNP) coating alone or in combination with the antidepressant fluoxetine, on biomarkers of neurotoxicity, oxidative stress and damage, biotransformation and energetic metabolism of the mussels *Mytilus galloprovincialis*. Mussel specimens with 4.3±0.4 cm (mean length ± standard deviation) were caught in a reference site and allowed to acclimate for 2 weeks, without feeding, to the laboratory conditions, in 80 L glass aquaria containing continuously filtered artificial saltwater (35 g.L<sup>-1</sup>) in a temperature controlled room (20 °C). Animals were exposed to gold (ionic form), GNP (cGNP or PVPGNP), or fluoxetine, and mixture of fluoxetine and PVPGNP in 96 hours bioassays with medium renewal every 24 hours. Overall, data suggest that GNP may alter the assessed biochemical responses (e.g. cholinesterase, glutathione S-transferases, glutathione reductase and Status of lipid peroxidation) either alone or in combination with the fluoxetine concentration. **Keywords:** biomarkers, gold nanoparticles, *Mytilus galloprovincialis*, pharmaceuticals.

Luis has a fellowship from FCT (BI/U188/6881/2014); M. Oliveira has a post-doc fellowship from FCT (BFRH/BPD/85107/2012) supported by the European Social Fund and national funds from the “Ministério da Educação e Ciência (POPH – QREN – Tipologia 4.1)” of Portugal.

## TU255

### Fate of dissolved and nanoparticulate silver in fresh and brackish waters using a radiolabeling technique

E. Pelletier, University of Quebec, Rimouski / ISMERUQAR; I. Desbiens, University of Quebec, Rimouski / ISMER; C. Roleau, Peches et Océans Canada  
The chemistry of silver nanoparticles (AgNP) in natural waters is far more complex than first expected with the presence of poorly characterized dissolved and particulate organic matter and natural inorganic colloids (< 450 nm). Basic data such as adsorption/desorption coefficients and aggregation/attachment efficiencies are not available and cannot be predicted theoretically. In an attempt to provide new data on the adsorption/desorption of silver ions (Ag<sup>+</sup>) and aggregation/attachment of AgNP in natural waters with added clay particles, a series of laboratory experiments was conducted using gamma-emitting <sup>110m</sup>Ag as a radiotracer to prepare citrate-coated <sup>110m</sup>AgNP (20 nm) and solutions containing free ions <sup>110m</sup>Ag<sup>+</sup>. Very early mixing process of river waters (containing Ag<sup>+</sup> or AgNP, dissolved organic matter and clay suspension (Na-Montmorillonite Swy-2)) with coastal waters was mimicked by adding between 0.3 and 4% of natural unfiltered coastal waters (29 PSU) to the freshwater suspension and the % retention of <sup>110m</sup>Ag on 0.45

µm MCE filter was determined as a function of time. Desorption of Ag<sup>+</sup> and disaggregation/dissolution of AgNP were determined by adding a few mg of clay particles (previously exposed to <sup>110m</sup>Ag<sup>+</sup> or <sup>110m</sup>AgNP in freshwater for 18 to 24h) to river, brackish and coastal waters and amount of <sup>110m</sup>Ag was determined in filtrates as a function of time. As expected, the % adsorption of <sup>110m</sup>Ag<sup>+</sup> on clay particles and filter decreased sharply (from 75 to 10%) as ionic strength increased slowly at the beginning of the mixing with coastal waters due to the formation of silver chloro-complexes. However, the addition of only 0.3% of coastal waters to freshwater suspension of AgNP induced a strong and quick aggregation/attachment to clay particles and over 80% of <sup>110m</sup>AgNP were recovered on filters with no obvious changes with time. When clay particles with already adsorbed <sup>110m</sup>Ag<sup>+</sup> are added to river and brackish waters, a large proportion (65-90%) of labelled silver is recovered in filtrates indicating an important desorption even in freshwater. Similarly, when clay particles with already adsorbed <sup>110m</sup>AgNP are added to river, brackish and coastal waters, between 75 to 90% of labelled <sup>110m</sup>Ag is recovered in filtrates indicating an important disaggregation of AgNP going through filter and/or a dissolution process during the 24h adsorption period. These data are being incorporated in a model of the environmental fate of AgNP at the river/ocean frontier.

## TU256

### Effects of different feeding media and nano-TiO<sub>2</sub>-particles on the food uptake of *Caenorhabditis elegans*

K. Samet, HAW- Hamburg / Medical Engineering; J. Angelstorf, Hamburg University of Applied Sciences; S. Heise, Hamburg University of Applied Sciences / Life Sciences

Even though the amount of industrially manufactured nano-particles used in e.g. consumer products has been increasing steadily over the last years, information on ecotoxicity is limited. Simulating the accumulation of nano-scale titanium dioxide (n-TiO<sub>2</sub>) in rivers, Gottschalk et al. (2009) calculated an accumulation of 1.4 mg / kg a year in European sediment. This is 1000 times higher than the accumulation of other nano-materials. Lowest observed effect concentration of n-TiO<sub>2</sub> to reproduction of *C. elegans* was 10 mg / L. n-TiO<sub>2</sub> agglomerated in the nematode's intestine in the absence of bacteria. Bacterial cells showed a potential protective function to the intestinal cells of *C. elegans* against accumulation with n-TiO<sub>2</sub>. A fluent defecation was observed as indicated by the uptake and transport of microspheres along the intestine (Angelstorf et al. 2014). This study focuses on the mode of action of n-TiO<sub>2</sub> during exposure of the nematode *Caenorhabditis elegans* and the discrimination between the effect of bacterial cells and their extracellular polymers on n-TiO<sub>2</sub> in the nematode's intestine. Results of different feeding experiments, indicating the effect of different combinations of n-TiO<sub>2</sub>, exopolymers and bacterial cells on the uptake, agglomeration and toxicity of n-TiO<sub>2</sub> could help to elucidate one mode of action of nano-scale titanium dioxide in organism. Following the standardized bioassay ISO 10872 with n-TiO<sub>2</sub> in a concentration of 100 mg / L as test-material and different feeding experiments with the bacteria *Escherichia coli* resulted in digestive problems observed by the uptake and transport of microspheres as indicator for the digestion process in the nematode's body. Digestive problems and growth inhibition were observed in the test-organism during exposure to n-TiO<sub>2</sub> with and without extracellular polymers as feeding medium. Feeding nematodes with extracellular polymers caused also an inhibition in growth compared to the nematodes fed with bacterial cells. As indicated by the uptake of microspheres the attenuation of n-TiO<sub>2</sub> agglomeration in the intestine of *C. elegans* was not caused by bacterial exopolymers but probably by bacterial cells.

## TU257

### Interaction of Nanomaterials with Telomere in *Caenorhabditis elegans*

N. Chatterjee, Q.N. Choudhry, University of Seoul; J. Choi, School of Environmental Engineering Graduate School of Energy and Environmental system Engineering

Alterations in telomere, DNA-protein structures that cap the ends of chromosomes, dynamics and length are associated with genomics instability, cancer and various age related diseases. Evidences are rapidly increasing that telomere homeostasis might be affected by environmental and occupational exposures of chemicals, such as, air pollution (i.e. particulate matter (PM), benzene/ toluene, polycyclic aromatic hydrocarbons (PAHs), N-nitrosamines, pesticides, lead, chromium, arsenic, etc). Now-a-days, it is well established fact that the enormous nano-biological interactions could possess a potential threat to environmental and human health due to the increasing use of nanomaterials. The aim of the present study was to investigate the effect of engineered nanomaterials on telomere homeostasis in the *in vivo* *Caenorhabditis elegans*, the nematode, models. We screened the life span of the *trt-1* (the telomerase mutant) and *mrt-2* (possess shortening of telomere with each generations) mutants with several nanomaterials (metallic nanoparticles – AgNP, AuNP; carbon nanomaterials – MWCNTs, graphene nanos, oxide nanomaterials – TiO<sub>2</sub>, SiO<sub>2</sub>) with. Among all the tested nanomaterials SiO<sub>2</sub> and single layer graphene oxide (SLGO) were found as the most sensitive one to cause decrease in life span of the telomere related mutants. Moreover, both SiO<sub>2</sub> and SLGO displayed lipofuscin accumulation, an aging biomarker, in a dose dependent manner in both *trt-1* and *mrt-2* strains. Taken together, our results showed that nanomaterials could accelerate telomere shortening and in turn aging or age related diseases. **Acknowledgement:** This work was supported by the ‘Basic Science Research Program (2013R1A1A2057534)’ through the National

#### TU258

##### **The influence of soil properties on particle fate of silver nanoparticles and their toxicity to *C. elegans* and *E. coli***

C. Schultz, Centre for Ecology and Hydrology; M. Matzke, Centre for Ecology & Hydrology (NERC) / Molecular Ecotoxicology; J.M. Unrine, University of Kentucky; D. Spurgeon, Centre for Ecology & Hydrology; C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology

Due to their high reactivity manufactured nanoparticles will likely undergo various transformations after entering the environment. Such transformations will affect their fate and behaviour, such as dissolution, agglomeration and sedimentation, which can in turn influence their bioavailability and resultant toxicity. It is therefore important to consider the effect of environmental properties on nanoparticle chemistry and form to understand how exposure relevant particles are presented to, and taken up by, organisms. The effect of soil properties on the toxicity of two silver nanoparticles (AgNPs) to *C. elegans* and *E. coli* strain OP50 was investigated by performing exposures in pore waters extracted from soils of different chemistry. Soil properties assessed were soil organic matter content (4.18% vs. 16.70%) and pH (pH 4.8 vs. 6.1 vs. 7.2) and the particles used were a small 3-8 nm un-functionalised AgNP (3-8Ag) and a larger 52 nm PVP-coated AgNP (52PVP). Effects on the nanoparticle agglomeration state and stability over time was assessed using asymmetric field flow fractionation (AF4) and UVvis absorbance measurement. Nematodes were exposed as gravid adults to a range of concentrations of the particles as well as ionic silver for 72 h and their reproductive toxicity was subsequently assessed. The results of the nematode toxicity tests showed ionic silver had a higher toxicity than the tested AgNPs, with EC<sub>50</sub> concentrations being at least a magnitude lower across all the tested pore waters, whereas there was little difference in toxicity between the two AgNPs and no distinct pattern between soils. Increasing soil organic matter content significantly decreased the toxicity of 3-8Ag while it increased that of AgNO<sub>3</sub>. Soil pH of the extracted pore waters significantly changed the toxicity of ionic and both silver nanoparticles, with highest toxicity observed at the lowest pH, for both AgNPs there was a 10 fold decrease in EC<sub>50</sub> concentration. The bacterial toxicity testing is still ongoing. Nanoparticle characterisation with UVvis spectroscopy revealed only a slight agglomeration dynamics independent of soil properties for 3-8Ag, while higher organic matter and low pH appeared to stabilise the 52PVP particles in suspension. Overall both soil organic matter content as well as pH had a nanoparticle dependent effect on fate as well as toxicity to *C. elegans*, however, there appears to be no clear connection between the measure particle properties and their effect.

#### TU259

##### **The Effects of Silver Nanoparticles and Silver Nitrate on Plants, Collembola and Earthworms in Soil**

J. Velicogna, Biological Assessment and Standardization Section; J. Princez, Environment Canada / Biological Assessment and Standardization Section; E. Ritchie, Environment Canada; R.P. Scroggins, Environment Canada / Biological Methods; H.V. McShane, McGill University / Dept of Natural Resource Sciences A suite of soil toxicity tests were completed to examine and compare the effects of commercially available 20 nm PVP (0.3%) coated silver nanoparticles (AgNP) to ionic silver (Ag<sup>+</sup>, as AgNO<sub>3</sub>) in a sandy-loam field soil. Plant tests examined effects on emergence and root and shoot growth (length and dry mass) of *Elymus lanceolatus* and *Trifolium pratense*. Invertebrate tests examined survival and reproduction in *Folsomia candida* and *Eisenia andrei*, as well as bioaccumulation for *E. andrei*. *Elymus lanceolatus*, *T. pratense* and *F. candida* were more sensitive to the Ag<sup>+</sup> exposures, relative to the AgNP for all measured endpoints. However, effects on juvenile production and dry mass of *E. andrei* were comparable upon exposure to both Ag<sup>+</sup> and AgNP, and were the most sensitive test organisms in general. For example, *E. andrei* reproduction was significantly affected when exposed to ≥49 mg/kg AgNP, whereas the EC<sub>50</sub> was 29 mg/kg Ag<sup>+</sup> (when exposed to AgNO<sub>3</sub>). When considering bioaccumulation metrics, for both forms of Ag (AgNP and Ag<sup>+</sup>), a rapid uptake was observed in earthworms when exposed to 4 mg/kg Ag during the first week of the uptake phase. The bioaccumulation factor at the end of the uptake phase (i.e., day 21) was 0.71 and 0.80 for AgNO<sub>3</sub> and AgNP, respectively. Silver in tissue remained significantly higher than background levels throughout the elimination phase with 48 and 96% remaining in the AgNO<sub>3</sub> and AgNP exposed worms, respectively. Transmission electron microscopy (TEM) confirmed that AgNP were present in tissue at the end of the 21 day uptake phase. Further efforts will be directed towards the evaluation of AgNP in biological tissue, and will include a comparison and evaluation of AgNP when added to soil through the application of contaminated biosolids, the route through which AgNP are likely to enter into the environment.

##### **Toxicokinetics and Toxicodynamics of Silver Nanoparticles in *Enchytraeus crypticus***

E. Topuz, VU University Amsterdam / Department of Ecological Science; C. van Gestel, VU University Amsterdam / Ecological Science

Silver nanoparticles (AgNPs) are used in numerous consumer products and may

end up in ecosystems [1], especially in sediments due to agglomeration over time, depending on surface water properties [2]. AgNPs that enter wastewater treatment plants mostly partition in the sewage sludge fraction during treatment [3]. Since in many countries sewage sludge is applied to soil it is urgent to investigate effects of AgNPs on soil organisms. Investigation of the relationship between the toxicity and internal concentration of organisms might be more beneficial since external concentration is affected by environmental conditions [4]. Enchytraeids are essential for the functioning of the ecosystem and sensitive to the numerous stressors [5], with *Enchytraeus crypticus* being a suitable model for soil ecotoxicity testing [6]. The aim of this study is to investigate the toxicokinetics and toxicodynamics of AgNPs in *Enchytraeus crypticus*. By performing experiments in water and soil, results will provide insight on the role of porewater in the exposure of *Enchytraeus crypticus* to AgNPs. Citrate coated and polyvinylpyrrolidone coated AgNP are tested to compare the effects of coating materials on the survival of *Enchytraeus crypticus*. AgNO<sub>3</sub> is tested as an ionic control. For the first experiments, quartz sand is used as a test medium to avoid the effects of soil properties on the bioavailability of AgNPs [4]. The effect of exposure time on the bioaccumulation and toxicity of AgNPs and AgNO<sub>3</sub> is determined. Animals and test media are analysed for total silver concentrations to assess uptake and elimination rate constants. LC50s are calculated and the relationship between survival and time is analysed applying a logistic survival model. Survival will also be related to internal Ag concentrations in the surviving animals. In the later experiments, enchytraeids are exposed to the same AgNPs and AgNO<sub>3</sub> in different soils and by measuring Ag concentrations in the animals, results of solution and soil experiments are linked together. #### TU261

##### **Toxicity and bioaccumulation of Ag NPs in the isopod *Porcellionides pruinosus***

P.d. Tourinho, University of Aveiro / Department of Biology CESAM; P.V. Silva, Department of Biology CESAM; C. van Gestel, VU University Amsterdam / Ecological Science; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM; S. Loureiro, Universidade de Aveiro / Biology

Silver nanoparticles (Ag NPs) are widely used in nanotechnology industry and consumer products. Due to release from Ag NP-containing products, nanoparticles may enter the soil compartment. Soil properties have a great influence on NP behaviour, and can also have great influence on NP toxicity. This study aimed at assessing the effects of soil properties on the toxicity of Ag NPs and ionic Ag (as AgNO<sub>3</sub>) to isopods, using three natural soils. Moreover, to understand Ag bioaccumulation, toxicokinetic tests with Ag NPs and AgNO<sub>3</sub> were conducted in one soil. Three soils were used in the toxicity tests, with organic matter content ranging from 1.6 to 13% and pH from 5.5 to 6.7. Specimens of the isopod *Porcellionides pruinosus* (>12 mg) were exposed to Ag NPs and AgNO<sub>3</sub> in avoidance behaviour and feeding inhibition tests. For the toxicokinetic study, Lufa 2.2 soil was spiked with Ag NPs and AgNO<sub>3</sub> at nominal concentrations of 30 and 60 mg Ag/kg. Isopods were exposed to an uptake phase for 21 days, followed by an elimination phase for another 21 days. Uptake (k<sub>1</sub>) and elimination (k<sub>2</sub>) rate constants were estimated using a one-compartment model, fitted simultaneously to uptake and elimination data. Total Ag concentrations in isopods from the feeding inhibition and toxicokinetic tests were determined by Atomic Absorption Spectrometry (AAS). The isopods were able to detect and avoid Ag at relatively low soil concentrations, but they were more sensitive to AgNO<sub>3</sub>. AC50 values ranged from 4.2 to 18 mg Ag/kg for Ag NPs, and from 1.4 to 14 mg Ag/kg for AgNO<sub>3</sub>. Soil properties did not have influence on avoidance behavior. Food consumption was dose-related decreased, with higher EC50s found in the soil with higher organic matter content and pH level. It may suggest that dissolved Ag released from NPs played an important role in determining Ag NP toxicity. Effects on biomass were related to Ag body concentration, but this relationship was not significant for Ag NPs and weak but significant for AgNO<sub>3</sub>. Our results show a clear difference in toxicity between Ag NPs and AgNO<sub>3</sub>. We therefore conclude that ionic Ag poses a greater risk to isopods than Ag NPs. On the other hand, Ag uptake from both Ag NPs and AgNO<sub>3</sub> was similar, as shown by the results of the toxicokinetic test. Also, Ag elimination was very slow and did not differ between Ag forms. Isopods have an extremely high Ag accumulation capacity, suggesting the presence of an efficient Ag storage compartment.

#### TU262

##### **Uptake and effects of TiO<sub>2</sub> nanostructures in the soil-plant system**

E. Tassi, ISE-CNR / Institute of Ecosystem Studies; S. Detti, University of Rome Tor Vergata / Department of Business Engineering Mario Lucertini; R. Pini, National Research Council of Italy / Institute of Ecosystem Studies; A. Bianco, University of Rome Tor Vergata / Department of Business Engineering Mario Lucertini

Nanomaterial products become waste and could be accumulated in the environment, being soil one of the final sink at the end of their life cycle. Soil is

susceptible to the accumulation of TiO<sub>2</sub>-NPs directly from fertilizer and/or plant protection products or indirectly from the use of wastewater sewage sludge as manure. Moreover, NPs uptake by agronomic cultures and their translocation to edible plants represent a direct way to transfer them into the food chain. Although several studies investigated the accumulation and effects of TiO<sub>2</sub>-NPs on different plant species, few were conducted in real farm soil and studied in the soil-crop system. It is known that both TiO<sub>2</sub>-NPs and soil OM are ubiquitous for the environment, thus the importance of studying this aspects in real matrices. Soil organic matter present or added to the soil to improve fertility could be an important factor that influence the mobility and transference of NPs into the food chain. This study shows the preliminary results on the uptake and effects of TiO<sub>2</sub>-NPs in crop species growing in agronomic soil with different OM content. Standard germination tests for sorghum and cress were performed in soil matrices containing different amount of pristine TiO<sub>2</sub>-NPs. Moreover, sorghum and pea species grew for 30 days in controlled laboratory conditions in soils with and without organic fertilization and different amount of NPs added (0, 200, 400 and 800 mg/kg soil). In those microcosm growing tests the effect of NPs and OM added to soil were analysed in both plants (Ti accumulation and translocation in plant tissues, biomass, macronutrients content) and soil (bioavailable P and Ti). ICP-OES and UV-Vis techniques were used for the analysis of titanium and phosphorus, respectively. Generally, the germination tests performed in cress showed no significant root inhibition, even though at 800 mg/kg TiO<sub>2</sub>-NPs added to the soil without organic fertilization a low inhibition effect was observed respect to the control soil (no TiO<sub>2</sub>-NPs added). In the soil with higher OM content the concentration of 200 and 400 mg/kg TiO<sub>2</sub>-NPs showed also a slight root inhibition. The roots of both sorghum and pea plantlets showed an increased Ti concentration as a result of increased NPs concentration in soils. A tendency of reduced bioavailable P were found in increased amount of TiO<sub>2</sub>-NPs added to soil without OM fertilization after the growth of sorghum plants.

#### TU263

##### **A floodplain mesocosm system linking fate and effects of engineered nanoparticles at the aquatic-terrestrial interface**

Z. Steinmetz, Universität Koblenz-Landau / Environmental and Soil Chemistry; G. Metreveli, Institute for Environmental Sciences Group of Environmental and Soil Chemistry; H. Vogel, Helmholtz Centre for Environmental Research UFZ / Department of Soil Physics; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; W. Manz, German Federal Institute of Hydrology; T. Baumann, Technische Universität München / Institute of Hydrochemistry; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; F. Lang, Albert-Ludwigs-Universität Freiburg / Institute of Forest Sciences Chair of Soil Ecology; S. Klitzke, Federal Environment Agency; F. Seitz, Inst. for Environmental Sciences / Institute for Environmental Sciences; R.R. Rosenfeldt, University of Koblenz-Landau, Institute for Environmental Sciences / Institute for Environmental Sciences; G.E. Schaumann, University of Koblenz-Landau / Institute of Environmental Sciences

Once released into the environment, engineered nanoparticles (ENPs) will undergo chemical and physical transformation processes. The fate, ecotoxicological potential, and mobility of ENPs in environmental compartments will be influenced predominantly by their aging and current speciation status. In order to understand the aging mechanisms and impact of ENP transformations on their distribution and bioavailability in real environmental systems, mesocosm studies can be helpful. A floodplain mesocosm system was developed to assess the fate and effects of ENPs at aquatic-terrestrial interfaces. It is designed for linking aquatic and terrestrial aging of ENPs with their biological effects in one system under near-natural conditions. The floodplain mesocosm enables us to perform long-term (several months) aging experiments with variable environmental conditions including periodical flooding and drying events. This experimental design offers the advantage of investigating ENP aging and distribution without interrupting the aquatic-terrestrial transition pathway. Thereby the artifacts, which can be generated by separation of these two compartments, can be avoided. The system is run with natural river water, natural repacked soil but with quartz sand as sediment phase. Convective water exchange between soil and aquatic compartments occurs at high water level. On this poster, we will present the design of the mesocosm system together with the first findings on fate and biological effects of silver nanoparticles.

#### TU264

##### **Aquatic and terrestrial toxicity of nickel nanoparticles: ion release but possible nanoparticle related effect**

T. Sovova, Institute of Chemical Technology / Department of Environmental Chemistry; V. Bartunek, Institute of Chemical Technology in Prague / Institute of Inorganic Chemistry; H. Palková, Institute of Chemical Technology Prague / Department of Environmental Chemistry; V. Koci, Prague Inst. of Chemical Technology / Department of Environmental Chemistry

Aquatic ecotoxicity of engineered nanoparticles (NPs) have been extensively studied but terrestrial toxicity as well as behaviour of NPs in soil environment is still not well described. This study evaluated aquatic (*Daphnia magna*, *Desmodesmus subspicatus*) and terrestrial (*Folsomia candida*, *Enchytraeus crypticus*) toxicity of nano and bulk Ni particles, and Ni<sup>2+</sup> as (NiSO<sub>4</sub>). Moreover, the amount of dissolved and bioavailable Ni (through 0.01M CaCl<sub>2</sub> extraction) was

assessed in aquatic and soil test media, respectively. For the aquatic species, the values of toxicity indexes expressed using nominal concentrations showed a significantly higher toxicity of ionic form compared to particulate Ni; and the nano Ni was more toxic than the bulk Ni. When the toxicity was expressed using the dissolved Ni data, for *D. subspicatus*, the three Ni forms were equally toxic suggesting that Ni acts through ion release. For *D. magna*, the toxicity of the particulate Ni became significantly more toxic than the Ni; this suggests that apart from ion release, there might be an additional particle-related effect that depends on particle size. For the soil species, the nominal toxicity data showed significantly higher toxicity of ionic Ni than the particulate forms; no particle size related effect was observed. When expressed using the bioavailable Ni data, the toxicity of the three Ni forms was equal; this shows that the (nano)particulate Ni in soil acts through ion release. More research is necessary to confirm as well as to investigate influence of soil and water properties.

#### TU265

##### **Effect of repeated applications of TiO<sub>2</sub> nanoparticles on their transport and toxicity to the microbial community in soil columns**

A. Richaume-Jolion, M. Simonin, Microbial Ecology Lab UMR; G. Uzu, CNRS Université Grenoble 1 / LTHE UMR; J.M. Martins, LTHE University of Grenoble

The soil is exposed to nanoparticles (NPs) due to their use in many commercial products. Chronic exposures lead to an enhancement of NPs concentrations in the soil rising concern about the environmental risk. The adverse effect of NPs on soil microorganisms has been reported in various ecotoxicological studies mainly based on acute exposures. This lack of ecological relevance for soil exposure requires the set-up of more appropriate systems to study the impact of NPs in conditions closer to the soil exposure mode actually expected. By using soil columns, we assessed the influence of single and repeated applications on the transfer of TiO<sub>2</sub>-NPs through soil and we compared the effect of these applications to TiO<sub>2</sub>-NPs on the abundance and activity of soil nitrifying microbial community. Soil columns consisted in 10 cm height glass tubes filled with 4.5g of a silty-clay soil. TiO<sub>2</sub>-NPs suspensions were prepared in soil solution and injected in soil columns as a single, two and three exposure conditions with 50, 25 and 16.7 mg L<sup>-1</sup> respectively to achieve the same final concentration. The applications were separated by 15 days of incubation at 28°C. After the last application, all soil columns were cut into layers according to the depth. Each slice was incubated for two months at 28°C. TiO<sub>2</sub>-NPs transport was investigated by measuring the Ti content in column leachates. The effect of TiO<sub>2</sub>-NPs on the soil microbial community was assessed by measuring the nitrifying activity (NEA) and microbial abundance of nitrifiers (ammonia-oxidizing archaea, AOA, ammonium oxidizing bacteria, AOB and nitrite oxidizing bacteria, NOB) by qPCR targeting functional genes (*amoA*, *nirA*). After the first application, we observed that TiO<sub>2</sub>-NPs are highly retained in soil columns whatever the concentration of the suspension applied. Nevertheless, TiO<sub>2</sub> mobility is higher for the lowest injection concentrations. Interestingly, repeated applications of the same concentration limited TiO<sub>2</sub>-NPs transport. The number of exposures impacted the microbial community. Triplicated exposure resulted in a significant decrease of NEA and abundances of AOA, AOB and NOB, whereas no effect was observed for the others. By different exposure conditions of soil columns, we showed the influence of repeated exposures on NPs transport. Moreover, we highlighted the more detrimental effect of the chronic contamination on the nitrification process than the acute contamination in this soil.

##### **Impact on Surface Stabilization on the Leaching of Nano-ZnO from Municipal Solid Waste**

T.T. Onay, Bogazici University / Institute of Environmental Sciences; T. Sakalliglu, I. Temizel, C. Uyguner Demirel, Bogazici University; N.K. Coptay, Institute of Environmental Sciences; B. Demirel, Bogazici University; T. Karanfil, Clemson University / Department of Environmental Engineering and Earth Sciences

Nano-scale Zinc Oxide (nano-ZnO) is used in numerous applications ranging from cosmetics, food products, to paints, ceramics and concrete. The widespread synthesis and uses of nano-ZnO means that large volumes nano-ZnO will ultimately end up in landfills after the disposal of these products. Nano-ZnO however is synthesized with various surface stabilizers depending on its intended use. The purpose of this study is to evaluate the impact of surface stabilization on the leaching potential of nano-ZnO within municipal solid waste. Batch experiments were conducted using fresh solid waste samples from a real municipal solid waste (MSW) landfill. The waste samples were spiked with different types of nano-ZnO ranging in concentration between 10 and 100 mg/L. Two different pH values were considered, namely basic 8-9 and acidic 5-6. The effect of ionic strength (IS) on the leaching of nano-ZnO was also evaluated. Leachate samples were regularly collected over a three-day period and analyzed for pH, electrical conductivity, particle size distribution and Zn content. A kinetic model was developed to evaluate the deposition and detachment of nano-ZnO onto the solid surface. The model was used to estimate deposition and detachment coefficients for various nano-ZnO surface stabilizers. Preliminary results suggest that over the duration of the tests large fractions of the nano-ZnO were retained within the solid waste matrix, but that the surface stabilization played an important role on the fate and transport nano-ZnO. Keywords: Nano-ZnO, leaching, landfill leachate

## TU267

### Effect of cerium dioxide, titanium dioxide, silver, and gold nanoparticles on the activity of microbial communities intended in wastewater treatment

A. Sánchez, L. Delgado, Universitat Autònoma de Barcelona; E. Casals, Institut Català de Nanotecnologia; V. Puntès, Institut Català de Nanociència i Nanotecnologia (ICN2); X. Font, Universitat Autònoma de Barcelona; A.A. Markeb, Autonomous University of Barcelona; A. Alonso, Autonomous University of Barcelona / Chemical Engineering; J. Carrera, Universitat Autònoma de Barcelona

Growth in production and use of nanoparticles (NPs) will result increased concentrations of these in industrial and urban wastewaters and, consequently, in wastewater-treatment facilities. Uncertainty about the consequences of the presence of the NPs on the environment has initiated studies on the effects of nanomaterials by some facilities that use microorganisms for environmental restoration [5,6]. Several studies have been reported which aimed to determine the toxicity of NPs on different sentinel organisms such as *Daphnia magna* [8], bioluminescent bacteria, and different plant seeds [9–12]. There have been some studies on the entire lifecycle of NPs including production, use, and release into the environment. It was shown that a portion of the released NPs finally ends up in the wastewater-collection systems and then enters biological wastewater-treatment plants (WWTP) [15,16]. Different treatment operations could help to remove NPs from wastewater [4], but, it has been demonstrated that NPs can also be found in sewage sludge [18]. However, the effect of the NPs on the performance of the wastewater-treatment process has not been studied systematically and including all the microbial communities involved in wastewater treatment. The present work investigates, by using respiration tests and biogas-production analysis, the inhibitory effect of four different commonly used metal oxide ( $\text{CeO}_2$  and  $\text{TiO}_2$ ) and zero-valent metal (Ag and Au) NPs on the activity of the most important microbial communities present in a modern WWTP. Specifically, the actions of ordinary heterotrophic organisms, ammonia oxidizing bacteria, and thermophilic and mesophilic anaerobic bacteria were tested in the presence and absence of the NPs. In general,  $\text{CeO}_2$ -NPs caused the greatest inhibition in biogas production (nearly 100%) and a strong inhibitory action of other biomasses; Ag-NPs caused an intermediate inhibition in biogas production (33–50%) and a slight inhibition in the action of other biomasses, and Au- and  $\text{TiO}_2$ -NPs caused only slight or no inhibition for all tested biomasses. Also, the maximum toxicological effect that NPs can produce in the biological activity of the microbial communities was studied by calculating the  $\text{EC}_{50}$  value. Au-NPs and  $\text{TiO}_2$ -NPs present zero or low toxicity, while Ag-NPs present an intermediate toxicity (inhibition around 33%). Knowledge of the  $\text{EC}_{50}$  value for each NP should enable us to anticipate changes in the performance of practical WWTP.

## TU268

### Emission of metals under colloidal phase in wastes leachates: ICP-AES and SEM-EDX analysis

a. anderson, University of Toulon / var; S. VILLAIN, University of Toulon; P. HENNEBERT, INERIS; P. Merdy, University of Toulon / Chemistry  
European Union is aiming to promote sustainable long-term progressive reduction of contaminant discharges to the environment. Potentially toxic elements and hydrophobic organic contaminants inputs and transfer of metals and organic contaminants to the environment occur from various sources: domestic, industrial and urban runoff. Different types of waste are extensively produced all over the world by industrial and domestic activities, but after disposal, their fate in the environment is poorly known, especially when pollutant release occurs under colloidal form. So, a general recommendation to protect the water and soil environment is that a biodegradability and fate assessment should be required for these various wastes, in order to determine subsequent implications for the environment. The complexity and variability in the composition of these wastes involve to study a large panel of them, since speciation of pollutants considerably depends on chemical composition, pH, Eh, ionic strength. Speciation, mobility and toxicity of these pollutants could be quite predictable in the aqueous or particulate phases, whereas their fate is unsure when they exist under colloidal form. Thus, it is of great interest to evaluate the composition of metals under colloidal form present in waste leachates in order to study the phase they are bound to, and finally predict their behavior and fate. In this context, 5 different wastes were studied: Bauxite residue, coastal marine sediments, sludge of wastewater treatment plant, crushed wastes and ashes from household incineration. After leaching, filtrations and measurement of element concentrations in the microfiltrate and ultrafiltrate fractions by Inductive Coupled Plasma Atomic Emission Spectroscopy (ICP-AES), we used Scanning Electron Microscopy- Energy Dispersive X-ray spectroscopy (SEM-EDX) to specifically detect the phases bound to metals of colloidal size. Some answers dealing with emission of pollutants from wastes were given.

### When organic contaminants interact with particles: consequences on fate, exposure and effects (P)

## TU269

### Sorption behaviour of functionalized carbon nanotubes

M. Kah, University of Vienna / Department of Environmental Geosciences; X. Zhang, University of Vienna; T. Hofmann, University of Vienna / Department of

## Environmental Geosciences

Understanding the interactions between organic contaminants and carbon nanotubes (CNTs) is essential for evaluating the potential environmental impact of CNTs (through, for example, facilitated nanoparticle-bound cotransport of organic contaminants), as well as their potential efficiency as a superior sorbent (e.g., for waste water treatment, or for use in solid phase extraction cartridges). CNTs tend to form large aggregates in water. Many industrial applications, however, require CNTs to be dispersed, which is typically achieved through sonication and surface functionalization. In addition to such intentional modifications, CNT surfaces can also be altered when exposed to oxidative conditions, which is likely to occur during purification treatments and/or after their release into an aquatic environment. The sorption behavior of a series of functionalized CNTs ( $-\text{OH}$ ,  $-\text{COOH}$  and  $-\text{NH}_2$ ) has therefore been systematically evaluated using a passive sampling technique over a wide range of concentrations and dispersion scenarios. Low levels of functionalization significantly affected sorption affinity for pyrene. Sonication greatly increased both the sorption affinity and the maximum capacity of all types of CNTs, to an extent that overwhelmed the differences initially observed (increase of up to 1.5 orders of magnitude lead to log  $K_d$  values close to 9 L/kg). Results demonstrated that a significant proportion of the CNT surface was unavailable to pyrene prior to sonication. The presence of humic acids enhanced dispersion but decreased sorption, especially when combined with sonication. Sorption affinity, however, remained very high in all cases (log  $K_d > 7.5$  L/kg), suggesting that CNTs can act as strong sorbents under a wide range of conditions, and may consequently affect the fate of organic contaminants. Kah et al. (2014) Sci. Total Environ. 497-498, 133-8

## TU270

### Impact of Humic Acid Coating on Sorption of Naphthalene by Biochars

Z. MENG, W. Xilong, S. Liang, G. Xiaoying, S. Xiaofang, Peking University / College of Urban and Environmental Sciences; Y. Yu, University of Nevada / Department of Civil and Environmental Engineering; X. Baoshan, University of Massachusetts / Stockbridge School of Agriculture; T. Shu, Peking University / College of Urban and Environmental Sciences

Biochar usually produced as a soil amendment would be introduced to the environment, which may interact with dissolved organic matter (DOM) like humic acid (HA) upon contact. Their interactions would alter the physicochemical properties (i.e. bulk chemical composition, surface functionalities, SA and porosity) of biochars, thereby affecting their sorption behaviors for hydrophobic organic contaminants (HOCs) as well as the transport and fate of HOCs. Impact of HA coating on biochar properties and the associated influence on naphthalene (Naph) sorption were studied. Coating with HA evidently decreased the sorption capacity and isotherm nonlinearity of Naph by the biochars, resulting from their chemical composition and surface property changes. At low solute concentrations, the suppression of HA coating on Naph sorption was primarily due to micropore blockage. At high solute concentrations, sorption suppression of Naph resulted from surface coverage by the coated HA molecules. The aromatic carbon components in the original and HA-coated biochars served as more important sorption domains for Naph over the alkyl carbon ones. HA coating reduced aromatic carbon content of the biochars, which weakened the  $\pi$ - $\pi$  and hydrophobic interactions between biochars and Naph. Such a process also introduced O-containing polar moieties, especially the O-alkyl and C=O polar components, to the surfaces of biochars, which reduced accessibility of Naph molecules to their hydrophobic carbon domains. Hence, Naph sorption was suppressed. Results of this work are critical for better understanding of the mechanisms controlling influence of DOM loading on sorption of aromatics to biochars, which in turn is helpful for predicting their environmental behaviors in soils after biochar application.

## TU271

### Lake retention of carbon-based nanoparticles and associated organic contaminants

A.A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management Group; I. Velzeboer, Wageningen University  
For twenty-five world lakes and three types of environmental nanoparticles (ENP), lake retention was calculated using a uniformly mixed lake mass balance model concept. This concept follows similar approaches for nutrients and organic pollutants traditionally used in water quality models. Lakes were selected such that lake residence times, depths and areal hydraulic loadings covered the widest possible range among existing lakes. Sedimentation accounted for natural colloid as well as suspended solid settling regimes for three ENP types:  $\text{C}_{60}$ , MWCNTs and nanoplastic (nano-polystyrene; Nano-PS). An ENP specific mixed sedimentation regime is proposed. This regime combines ENP sedimentation through slow settling with natural colloids from the water column, with faster settling with suspended solids from a selected part of the water column. The general ENM retention model was extended with coefficients that quantified the sorption of PCBs to the ENPs, thus allowing for simulation of the effect of the presence of ENPs on total lake retention of PCBs. By comparing the retention caused by the presence of ENPs with that caused by the presence of regular natural suspended solids, the relative importance of carbon based nanoparticles on the overall retention of POPs was assessed.

## TU272

### **Sorption mechanism of carbonaceous materials for naphthalene, lindane and atrazine: Site energy distribution-based analysis**

X. Shen, X. Guo, Peking University / College of urban and environmental science; M. Zhang, X. Wang, Peking University; S. Tao, Peking University / College of Environmental Sciences; B. XING, Department of Plant, Soil and Insect Sciences / University of Massachusetts

Sorption of naphthalene, lindane and atrazine was investigated on ten kinds of carbonaceous materials, including four kinds of graphene, three kinds of graphite, two kinds of carbon nanotubes and one kind of mesoporous carbon, and approximate sorption site energy distributions were calculated based on the Dubinin-Ashtakhov (DA) model. Further more, average sorption site energy and standard deviation of the site energy distribution were deduced and applied to analyze the interaction between the sorbents and compounds, and the sorption site heterogeneity. The introduced oxygen-containing functional groups decreased the average sorption energy of the sorbents for the studied compounds. However, number of sorption sites, indicated by physical properties (i.e. surface area and porosity), still played a more important role in the sorption capacity. Sorption site heterogeneity of the sorbents also decreased as their oxygen contents increased. One reason could be the better dispersion of the oxygen-containing materials as indicated by TEM micrographs. This study put forward a method to quantify the average sorption energy and sorption heterogeneity and made a better understanding of the sorption mechanisms between organic pollutants and carbonaceous materials.

### **TU273**

#### **Interactive effects of n-TiO<sub>2</sub> and 2,3,7,8-TCDD in *Mytilus galloprovincialis*: a transcriptomic and immunohistochemical study**

M. Banni, Laboratory of Biochemical and Environmental Toxicology; S. Sforzini, Università Del Piemonte Orientale Amadeo Avogadro / Department of Sciences and Technological Innovation DiSIT; T. Balbi, University of Genova / DISTAV; A.G. Viarengo, Università del Piemonte Orientale / Department of Sciences and Technological Innovation DiSIT; L. Canesi, university of genoa / DISTAV  
Exposure of marine organisms to nanoparticles (NPs) in the presence of other pollutants may affect the pattern of contaminant uptake/bioaccumulation as well toxicity at different levels of biological organization. We have recently shown that in the marine mussel *Mytilus galloprovincialis* exposure to n-TiO<sub>2</sub>, one of the most widespread type of NPs in use, in combination with 2,3,7,8-TCDD, chosen as model persistent organic xenobiotic, can exert antagonistic or synergistic effects on different biomarkers from the molecular to the tissue level, depending on cell/tissue and type of measured response. In order to better understand the interactive effects of n-TiO<sub>2</sub> and TCDD in mussel digestive gland, a detailed study was carried out using an integrated approach transcriptomics/immunohistochemistry. To this aim, we employed a cDNA microarray with 1673 sequences to measure relative transcript abundances. In animals exposed only to TiO<sub>2</sub>, functional genomics analysis of the microarray data (48 differentially expressed genes- DEGs) highlighted three biological processes, largely dominated by the up-regulation of microtubule-based movement-related genes. Exposure to TCDD yielded 49 DEGs exhibiting distinct patterns in terms of biological processes. Finally, exposure to the mixture rendered 62 DEGs that were characterized by the regulation of response to chemical stimulus, microtubule-based movement and intracellular signal transduction. Immunohistochemical evaluation of cytoskeletal components confirmed the effect of the mixture on tubulin expression. Moreover, n-TiO<sub>2</sub> reduced TCDD accumulation in the tissue, as indicated by immunofluorescence analysis using specific anti-TCDD fluorescent antibodies. The results show that the utilization of the transcriptomic/immunohistochemistry approach can help identifying often unexpected modes of action and sublethal effects of NPs, alone and in combination with other contaminants, on marine organisms.

### **TU274**

#### **Combination effects of nano-TiO<sub>2</sub> and 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) on biotransformation gene expression in the liver of European sea bass (*Dicentrarchus labrax*).**

M. Vannuccini, University of Siena / Physical earth and environmental science; C. Della Torre, University of Siena / Department of Physical Earth and Environmental Sciences; M.J. Leaver, University of Stirling / Institute of Aquaculture; I. Corsi, University of Siena / Physical Earth and Environmental Sciences

The aim of present study was to investigate the influence of titanium dioxide nanoparticles (nano-TiO<sub>2</sub>, Aeroxide®) on 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) dependent biotransformation gene expression in juvenile European sea bass *Dicentrarchus labrax*. An *in vivo* 7 days of aqueous exposure was performed with nano-TiO<sub>2</sub> (1 mg/L), TCDD (46 pg/L), singly and in combination. The mRNA expression of aryl hydrocarbon receptor repressor (*ahrr*), estrogen receptor (*er $\beta$ 2*), ABC transport proteins as *abcb1*, *abcc1-c2-g2*, cytochrome P450 (*cyp1a*), glutathione-S-transferase (*gst*), glutathione reductase (*gr*) and engulfment and motility (ELMO) domain-containing protein 2 (*elmod2*) were investigated in liver tissue. *Ahrr*, *er $\beta$ 2*, *abcb1* and *abcc2* were down-regulated with respect to controls in all experimental groups. Co-exposure to nano-TiO<sub>2</sub> and TCDD caused a further significant down regulation of *ahrr*, *er $\beta$ 2*, *abcb1* and *abcc2* compared to single chemical exposure (nano-TiO<sub>2</sub> or TCDD alone). No effects were observed for TCDD and nano-TiO<sub>2</sub> alone in *abcb1* gene, while *abcc2* was down-regulated by nano-TiO<sub>2</sub> alone. *Cyp1a*, *gst* and *elmod2* genes were up-regulated by TCDD and to

a similar extent after co-exposure to nano-TiO<sub>2</sub> and TCDD. HR-TEM showed nano-TiO<sub>2</sub> (~27nm) which not affected by co-exposure by TCDD. Overall the results indicate that nano-TiO<sub>2</sub> is unlikely to interfere with TCDD-dependent biotransformation gene expression in the liver of European sea bass, although additive effects of co-exposure observed in ABC transport mRNAs might suggest effects on xenobiotic metabolite transport in liver.

## **Adverse outcome pathway concept in research and risk assessment (P)**

### **TU275**

#### **Development of Adverse Outcome Pathways for *Lemna minor* in response to single and multiple stressors**

L. Xie, Norwegian Institute for Water Research; T. Gomes, Norwegian Institute for Water Research (NIVA); Y. Song, Norwegian Institute for Water Research (NIVA) / Ecotoxicology and Risk Management; T. Christensen, Norwegian Radiation Protection Authority; K. Solhaug, Norwegian University of Life Sciences; B. Salbu, Norwegian University of Life Sciences UMB / Department of Plant and Environmental Sciences; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment  
Standard toxicity testing performed in multi-trophic bioassays (e.g. aquatic plants, algae, crustaceans and fish) is applied extensively to predict the effects of chemicals in ecosystems and subsequent risk assessment. Although being highly useful for regulatory purposes focusing on traditional adverse endpoints, these methods provide limited information about the toxic mechanism or mode of action (MoA) of chemicals and rarely address complex environmental issues such as exposure to combinations of stressors (multiple stressors). This applies especially to aquatic plants, which has not received the same attention as algae, crustaceans and fish within scientific and regulatory research. *Lemna minor* is a freshwater aquatic plant routinely used for assessing chronic toxicity of chemicals using standardized methods (OECD Growth Inhibition Test 221), mainly due to its high sensitivity to toxicants, rapid reproduction capacity, resource-effective exposure format and central function in the aquatic ecosystem. The present study aims to develop an effect toolbox focusing on genomic (e.g. transcriptomics), functional (e.g. Photosystem II inhibition, ROS formation) and adverse (e.g. growth) toxicity endpoints using *L. minor* as a model organism. Several key stressors will be assessed, namely conventional contaminants as metals and organics, ionizing radiation, UV radiation (UVA and UVB) and environmental conditions relevant under climate change scenarios, tested singly and in combination, and their single/combined effects characterized with the suite of methods developed. Successful development of such toolbox is envisioned to facilitate linking MoA information to adverse and regulatory-relevant endpoints, potentially through supporting concepts such as Adverse Outcome Pathways (AOP) that may be used to characterize impact of these stressors on the individual and population level. The objectives and results obtained will be presented to illustrate how the present concept may enhance the knowledge about single and multiple environmental stressors in this aquatic plant species.

### **TU276**

#### **Development of Adverse Outcome Pathways for molting-related developmental effects of emamectin on *Daphnia magna***

Y. Song, Norwegian Institute for Water Research (NIVA) / Ecotoxicology and Risk Management; T. Gomes, Norwegian Institute for Water Research (NIVA); L. Xie, Norwegian Institute for Water Research; D. Eidsvoll, Norwegian Institute for Water Research NIVA; T. Rundberget, Norwegian Institute for Water Research; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment

A number of exogenous compounds have the potential to interfere with the endocrine system of animals and may perturb vital endocrine processes to a degree causing an adverse effect (outcome) on ecologically relevant endpoints such as growth, development and reproduction. These endocrine disrupting (ED) effects have been well characterized in aquatic vertebrates and mammals due to a well-defined endocrine system and substantial research effort in the last decades, but knowledge on ED effects in a larger range of species are still poorly characterized. Lack of knowledge on ED effects in invertebrates is currently a major limiting factor to properly perform risk assessment of endocrine disrupting chemicals (EDCs) across taxa. The present project aims to develop and evaluate adverse outcome pathways (AOPs) for ED in the freshwater crustacean *Daphnia magna* by linking responses at the molecular level with adverse outcomes (AOs) relevant for regulatory processes. A literature survey was performed first to collect existing knowledge of ED effects on *D. magna* or closely related crustaceans. Putative AOPs were assembled to identify knowledge gaps prior to experimental studies. Computational and experimental methods were additionally used to identify possible ED targets in *D. magna* and discover novel EDCs in crustaceans for subsequent verification of potential mode of action (MoA). *In vivo* exposure studies were then conducted with the endogenous hormone 20-hydroxy ecdysone and the insecticide emamectin-benzoate using standardized test protocols and determination of effects on transcriptional, functional and apical toxicity endpoints to identify perturbations of key molecular initiating events (MiEs), key events (KEs) and AOs of regulatory relevance.

### **TU277**

#### Use of Chemical-Gene and Gene-gene interaction databases to assemble putative AOPs

P. Antczak, University of Liverpool / Institute of Integrative Biology; T. Williams, University of Birmingham / School of Biosciences; F. Falciani, University of Liverpool / Functional Genomics; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment

Transcriptomics measures alterations in gene activity, by finding differences in the abundance of different messenger RNAs between different biological samples. Traditionally ecotoxicology has assessed biological effect through a number of acute or chronic toxicity endpoints and a small number of endocrine disruptor biomarkers. While these have shown to be informative, they suffer from several limitations. They do not for example allow for identification of potential adverse outcome pathways (AOPs) and they do not provide quantitative assessment of risk nor do they allow prediction of exposure effects. Transcriptomics coupled with a battery of computational modelling tools and the wide-ranging variety of chemical and biological measurements has the potential to link chemical exposure with a physiological outcome. We propose, in the first instance, using a computational biology approach to integrate available transcriptomic information from online databases such as the comparative toxicogenomics database (CTD) and Stitch 4.0 to develop putative adverse outcome pathways. Initially the data is screened for highly confident gene-chemical interactions which allows cross chemical identification of mechanisms of action. In addition, each gene is interrogated for its suitability as a putative molecular initiating event (pMIE). These can include biological targets (e.g. receptors, enzymes and proteins) associated with specific cellular compartments such as the cell membrane, cytosol, mitochondria, the nucleus or even extracellular proteins. By ranking genes on their association with specific cellular compartment we can then define novel pMIEs and putative Key events (pKE) that are associated with a given adverse outcome and thus form the basis for proposing novel AOPs. Finally by integrating this data with experimentally derived data from high-throughput screening approaches such as Toxcast/Tox21, we can associate additional gene-chemical information to strengthen the evidence for KE and KE relationships in our putative AOPs. Adverse outcomes can then be assigned via already available and/or expert knowledge, or by assigning chemical-disease associations such as are available in the CTD. *Acknowledgement* - The SOLUTIONS Project is supported by the Seventh Framework Programme (FP7-ENV-2013) of the European Union under grant agreement no. 603437.

#### TU278

##### Linking metabolic fingerprints to ecotoxicological effect assessment: the Metabolic Effect Level Index

J. Riedl, Safety in the Food Chain; R. Schreiber, Helmholtz Centre for Environmental Research UFZ / Bioanalytical Ecotoxicology; M. Otto, TU Bergakademie Freiberg / Analytical Chemistry; H. Heilmeyer, TU Bergakademie Freiberg / Working group Biology/Ecology; R. Altenburger, UFC Centre for Environmental Research / Department of Bioanalytical Ecotoxicology; M. Schmitt-Jansen, UFZ - Helmholtz Ctr Environm. Research / Department of Bioanalytical Ecotoxicology

A major goal of ecotoxicology is the prediction of adverse outcomes of populations from early and sensitive physiological or cellular responses. A snapshot of the physiological state of an organism can be provided by metabolic fingerprints. However, to inform risk assessment multivariate metabolic fingerprints need to be converted to readable endpoints suitable for effect estimation and extrapolation. The responsiveness of metabolic fingerprints to the PS-II inhibitor isoproturon was investigated using a *Myriophyllum spicatum* bioassay. Hydrophilic and lipophilic leaf extracts were analyzed with GC-MS and preprocessed with XCMS. Metabolic changes were integrated in the quantitative Metabolic Effect Level Index (MELI), allowing effect estimation from Hill-based concentration-response models. Hereby, the most sensitive response was revealed by the hydrophilic MELI, followed by the inhibition of photosynthetic efficiency and one order of magnitude higher, by the lipophilic MELI and shoot length change. 50% of the hydrophilic MELI compares to 30% inhibition of photosynthetic efficiency and 10% inhibition of dry weight change, indicating effect progression between different response levels. In conclusion, the Metabolic Effect Level Index enables linkage to mode-of-action specific information on physiological responses and integrates metabolic responses in the adverse outcome pathway of chemicals, potentially valuable for the risk assessment process.

#### TU279

##### The SEURAT-1 ab initio case studies: a proof of concept from theory to application

A. White, Unilever; G. Ouedraogo, L. OREAL; A. Lostia, European Commission DG Joint Research Centre; A. Richarz, Liverpool John Moores University; B. Hardy, Douglas Connect; E. Heinze, Saarland University; E. Benfenati; F. Bois, INERIS; J. Hengstler, IfADO; L. van Grunsven, Vrije universiteit Brussel; R. Judson, US Environmental Protection Agency / Office of Research and Development; S. Escher, Fraunhofer Institute of Toxicology and Experimental Medicine (ITEM) / Chemical Risk Assessment; E. Berggren, European Commission Joint Research Centre (JRC) / Institute for Health and Consumer Protection IHCP and EU Reference Laboratory for Alternatives to Animal Testing EURL ECVAM; T. Gocht, University of Tuebingen / Institute for Experimental and Clinical Pharmacology and Toxicology; C. Mahony, Procter Gamble

SEURAT1 is a research initiative aiming at developing knowledge and technology building blocks required for the development of solutions for the replacement of current repeated dose systemic toxicity testing *in vivo* used for the assessment of human safety. Within the project a proof of concept study integrating the building blocks is currently ongoing to demonstrate the possibility of addressing the safety assessment of chemicals for systemic toxicity using *in silico* and *in vitro* tools. The approach is driven by the needs of the risk assessor to determine a quantitative point of departure for critical decision points and assess this in relation to the applicable exposure scenario for the use case. The quantitative risk assessment or ab initio case study is based on a proof of concept at multiple levels: theoretical, methodological as applied within a toxicological MoA framework. In the scope of SEURAT1, the quantitative assessment of repeated dose toxicity is specifically related to liver hepatotoxicity. Several tools and assays developed within SEURAT1 will be used to qualitatively and quantitatively address 1) the initial critical pathway determination and 2) assess the adverse outcome pathways (AOPs) described on liver (Vinken, M. *Toxicology*. 2013 Oct 4; 312:158-65). Dose response data on applicable *in vitro* concentrations will be utilised across key *in vitro* models to determine a relevant biological point of departure for the AOPs and relate this through *in vitro* to *in vivo* extrapolation (IVIVE) using derived ADME (administration, distribution, metabolism and excretion) and PBPK models to define a pertinent exposure metric. The approach will be benchmarked with gold compounds that have dose dependent defined toxicities i.e. low well tolerated dose – and at higher doses increasing incidence of hepatotoxicity. The purpose is to provide an exemplar case study of how to quantitatively translate findings from *in vitro* and *in silico* approaches to a chronic systemic exposure relevant for human safety and to identify gaps. The ability to address the uncertainty of adverse risk to consumers under different consumer populations & exposure scenarios and for chronic repeat dose systemic endpoints will also be considered in the ab initio case studies. Work is currently ongoing on three gold compounds: methotrexate, valproic acid and doxorubicin. Preliminary results on these compounds will be discussed.

#### TU280

##### Using AOPs to Support Read-Across Predictions - 'testing the hypothesis in Seurat-1'

T.W. Schultz; C. Mahony, Procter Gamble; A. Lostia, European Commission DG Joint Research Centre; A. Richarz, Liverpool John Moores University; B. Hardy, Douglas Connect; E. Heinze, Saarland University; E. Benfenati; J. Hengstler, IfADO; L. van Grunsven, Vrije universiteit Brussel; R. Judson, US Environmental Protection Agency / Office of Research and Development; S. Escher, Fraunhofer Institute of Toxicology and Experimental Medicine (ITEM) / Chemical Risk Assessment; T. Gocht, University of Tuebingen / Institute for Experimental and Clinical Pharmacology and Toxicology; E. Berggren, European Commission Joint Research Centre (JRC) / Institute for Health and Consumer Protection IHCP and EU Reference Laboratory for Alternatives to Animal Testing EURL ECVAM. Read-across is an analogue or chemical category-based alternative method used for hazard identification (potential), hazard characterisation (potency) and/or safety assessment (potential/potency and exposure). Read-across strategically integrates and weights all relevant data to inform marketing decisions and/or regulatory applications. The challenges facing the use of read-across largely pertain to deriving a sufficiently robust rationale for prediction acceptance. Purposes of read-across include: 1) Prioritization and screening, 2) Hazard identification, 3) Hazard characterization and 4) Safety assessment and Regulatory acceptance. Describing the context of a read-across includes noting the purpose to be addressed. There are three basic types of similarity: 1) Chemistry, 2) Absorption, distribution, metabolism, excretion (ADME), and 3) Toxicology, which includes using AOPs. The purpose often determines the type of similarity required. For example, safety assessments often need toxicokinetic similarity to assess exposure as well toxicological similarity, especially in the form of mode of action/mechanistic similarity. Mechanistic uncertainty is best assessed within the context of an AOP. It is recognized that knowledge of an AOP evolves and, as such, AOP development represents a continuum, with increasing quality, quantification and strength of the key events (KEs) and key event relationships (KERs). A KER is scientifically-based and connects one KE, to another KE, inferring or extrapolating the state of the up-stream KE from the knowledge of the down-stream KE. The confidence in an AOP is based on considerations which determine its applicability for the various purposes. Confidence in using an AOP is typically informed by: 1) the extent of support for the biological plausibility of KEs and KERs relative to the *in vivo* apical outcome (AO) under consideration, 2) the extent of support for the essentiality of the Molecular Initiating Event (MIE) and other KEs, and 3) the extent of empirical data quantifying the KEs and support for the KERs. In SEURAT-1, the largest ever EU research initiative on alternative testing, co-funded by the European Commission and Cosmetics Europe we are developing category formation/refinement approaches for testing the read-across hypothesis using Seurat-1 approaches and methods in the context of liver AOPs (based on repeated oral exposure); for  $\beta$ -unsaturated alcohols relating to liver fibrosis.

##### Adverse Outcome Pathway (AOP) of silver nanoparticles in nematode *Caenorhabditis elegans*

J. Jeong, H. Kim, J. Yang, N. Chatterjee, University of Seoul; H. Eom; J. Choi,

School of Environmental Engineering Graduate School of Energy and Environmental system Engineering

Adverse Outcome Pathway (AOP) is a framework to link direct molecular initiating event (MIE) to adverse outcome (AO) at higher level of organization, developed by OECD to increase the confidence of molecular data in risk assessment. With this framework, we can predict apical endpoints (e.g. mortality, reproduction) of the chemicals with *in vitro* or *in vivo* tests in model systems. Toxicity of silver nanoparticles (AgNPs) has been intensively studied, as they are one of the most widely used and applied nanomaterials. We previously reported AgNPs induced oxidative stress and reproductive toxicity in the nematode *Caenorhabditis elegans*. In this study, we build AOP of AgNPs in *C. elegans*. We first built a draft AOP of AgNPs from our previous studies, which constitutes the molecular initiating event, as ROS formation, and adverse outcome, as developmental/reproductive toxicity. DNA damage and oxidative stress responsive signaling pathways seem to constitute as key events between them. To confirm this AOP, we conducted *C. elegans* developmental test covering whole developmental stage using COPAS Select. Synchronized L1 stage worms were exposed to three different concentrations of AgNPs for 24, 48 and 72h, and their developmental kinetics was investigated by examining exposure time- and concentration dependent changes of EXT and TOF values. We found AgNPs caused delayed development and at the highest exposure concentration, significant reproduction failure was observed. To experimentally elucidate linkage between MIE and AO, developmental test is on-going using *C. elegans* functional mutants involved in MIE. Acknowledgement : This work was supported by the grant from the Korea Ministry of Environment as "Environmental Health R&D Program"(2012001370009).

### In silico Modeling of Aryl Hydrocarbon Receptor (AhR) Activation

M.S. Lawless, J. Ghosh, Simulations Plus Inc; A.C. Lee, Simulations Plus, Inc. / Life Sciences; R.D. Clark, CalScience Environmental & Marine Chemistry Laboratories

Activation of the aryl hydrocarbon receptor AhR is the molecular initiating event in several adverse outcome pathways (AOPs). It is linked to embryolethality in fish and birds, to uroporphyrin in birds, and liver tumors in rodents. AhR is a cytosolic transcription factor protein that is translocated into the nucleus after activation by ligand binding. A quantitative high-throughput screening assay (qHTS) to detect AhR activators was performed as part of the U.S. Tox21 program. The assay (PubChem AID 743122) used firefly luciferase expression in the HG2L7.5c1 cell line to identify AhR activators. A few of the most potent activators were 2,3,7,8-tetrachlorodibenzodioxin, C.I. Solvent Yellow 14, and diflubenzuron (an insecticide). Using the ADMET Modeler™ module within ADMET Predictor™, we developed an artificial neural network ensemble classification (ANNEC) model for AhR activation as part of the Tox21 2014 Data Challenge. Compounds with AC50 < 100 μM were categorized as activators. The data were curated by removing organometallic compounds, ionic liquids, and mixtures. This was followed by removing spectator ions and molecules, such as Na<sup>+</sup>, HCl, water, and sulfate, from multicomponent compounds. Next, duplicate structures from different vendors were grouped together into classes in order to investigate the reproducibility of the assay. The "percent positive ratio" was calculated by taking the ratio of positives to the positives and negatives from classes with at least one positive assay result. The "percent positive ratio" was 85%, implying that the assay has fairly good reproducibility. One structure from each replicate class was retained. The curated data set is highly skewed towards non-AhR activators (89%). All curated data were divided into a training pool (5442) and external test set (605). The final ANNEC model used 50 descriptors and 9 neurons and the ensemble consisted of 33 separately trained neural networks. The descriptors included 13 electrotopological-state indices, 9 Fukui indices for various atom/group types, the medium topological moment of inertia, lipophilicity, and fraction of anionic or cationic species. The Fukui indices reflect atomic reactivity and are derived from our EEM-Hückel model that was parameterized to reproduce partial atomic charges from high-level density functional theory calculations. The AhR model yielded a concordance of 90%, specificity of 91%, and sensitivity of 77% on the external test set.

## TU283

### PAHs Do Not Have Dioxin-Like Activity

B.H. Magee, ARCADIS; N. Forsberg, ARCADIS US Inc / IEST

It is well known that 2,3,7,8-TCDD (TCDD) and other 2,3,7,8-substituted dioxin and furan congeners bind to and activate the aryl hydrocarbon receptor (Ah receptor). The Ah receptor is a cytosolic protein that translocates into the cell nucleus and regulates gene expression when ligands like TCDD bind to it. One of the responses to that ligand binding is the induction of xenobiotic metabolizing enzymes. This has led some to develop *in vitro* screening assays for Ah binding affinity and xenobiotic enzyme induction and labeling chemicals that are positive in these assays as having dioxin-like activity, with the inference that they have similar toxicity as TCDD. Many PAHs bind to and activate the Ah receptor and will induce xenobiotic metabolizing activity, but PAHs do not have dioxin-like activity and are far less potent than TCDD in causing cancer in rodents. Okey (2007) reminds us in his Deichmann Lecture that the Ah receptor is "not just a 'dioxin receptor' or 'TCDD receptor'" and that "high affinity AHR ligands are not necessarily toxic." Thus, one should not use the above *in vitro* assay results to assign Dioxin Toxic

Equivalency Factors to PAHs and assess the risks of PAHs using cancer slope factors and reference doses for TCDD, nor should one use such *in vitro* results to assign Benzo(a)pyrene (BaP) Relative Potency Factors to other PAHs. This paper presents a validation comparison of the published TCDD Toxic Equivalency Factors and BaP Relative Potency Factors from various studies, including Machala et al. (2001), Villeneuve et al. (2002), Masunaga et al. (2004), and Pieterse et al. (2013) to published animal carcinogenicity data to demonstrate that there is no correlation between results in Ah receptor binding or enzyme induction assays and carcinogenic potential in animals. USEPA agrees with this conclusion. Windal et al. (2005) stated that PAHs are "not considered dioxin-like compounds, since they ...do not produce AhR-dependent toxic effects." In addition, EPA (2009) agrees that Ah receptor binding affinity does not correlate with carcinogenicity and cannot be used to derive PAH Relative Potency Factors: "some PAHs that strongly activate the AhR, such as benzo[k]fluoranthene (Machala et al., 2001), are only weakly carcinogenic."

## TU284

### Chemical characterization and toxicological effects of atmospheric fine particulate matter on human bronchial epithelial cells

M. Borgie; Z. Dagher, Université Libanaise; F. Ledoux, Université du Littoral Côte d'Opale; A. Verdin, Université du Littoral Côte d'Opale / Unité de Chimie Environnementale et Interactions sur le Vivant UCEIV EA; F. Cazier, Université du Littoral Côte d'Opale; H. Greige, Université Libanaise; P. Shirali, D. Courcot, Université du Littoral Côte d'Opale

In October 2013, the International Agency for Research on Cancer (IARC) classified outdoor air pollution and fine particulate matter (PM<sub>2.5</sub>) as carcinogenic to human (Group 1). Despite the clearly relationship established by epidemiological studies between PM exposure and the onset of respiratory and cardiovascular diseases, uncertainties remain about the physiopathological mechanisms responsible for these diseases. The aim of this work was to determine the composition of two samples of atmospheric PM<sub>2.5</sub> collected at urban and rural sites and to evaluate their toxicological effects on human bronchial epithelial cells, BEAS-2B, especially to investigate the metabolic activation of organic compounds, the alteration of epigenetic mechanisms (*i.e.* microRNAs genes expression), the phosphorylation of H2AX and the telomerase activity. Our results showed a significant increase in *CYP1A1*, *CYP1B1* and AhRR genes expression, miR-21 gene expression, H2AX phosphorylation and telomerase activity in BEAS-2B cells after their exposure to PM<sub>2.5</sub>, both in a dose and site dependent manner. These results showed that PM<sub>2.5</sub>, especially urban PM, are able to induce the expression of metabolizing enzymes which can provide metabolic biotransformation of organic compounds into more toxic and carcinogenic metabolites, and to induce the expression of the oncomiR miR-21 which promotes cell growth and enhances tumor invasion and metastasis in lung cancer. In addition, our results have highlighted the role of PM<sub>2.5</sub> in the activation of telomerase, which can maintain the telomeres length and subsequently preventing cell death, and have also demonstrated the ability of PM<sub>2.5</sub> to induce DNA breaks and thus to increase the risk of mutations or chromosomal translocations that lead to genomic instability. All these factors may contribute to cell abnormalities, and thus the development of cancer.

## TU285

### Toxicokinetic modeling of selected POPs in human breast milk biomonitoring study

J. Václavíková, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; O. Mikes, Masaryk University; M. Černá, National Institute of Public Health; P. Čupr, Masaryk University, Faculty of Science, RECETOX / RECETOX Research centre for toxic compounds in the environment

Persistent organic pollutants (POPs) are known for their harmful effects on the environment, where they can accumulate and pass through food-chains into humans. This study is focused on the risks assessment of the human health outcomes for pregnant women in the Czech Republic (1994-2009; more than 4750 samples) connected to the exposure of POPs. Samples of breast milk were collected and measured (selected POPs: PCBs, HCB, HCHs, DDT, DDE and DDD) in the biomonitoring of National Institute of Public Health in the Czech Republic. The calculations of health risks were carried out using modified PBPK model developed by Trapp et al. The primary route for exposure in PBPK model was assumed to be through the dietary intake. Model was reversed to predict chronic daily doses from the biological data. The final predicted doses from breast milk, in the form of chronic daily intakes (CDI<sub>milk</sub>), were compared with the intakes from Czech Dietary Exposure Monitoring (CDI<sub>food</sub>). The highest risks were estimated for PCBs. Predicted CDI<sub>milk</sub> were generally higher than predicted doses from the food consumption. These facts might indicate new, unknown exposure, which will be discussed.

## Delving into the planetary boundary concept and issues related to biodiversity and natural resources use in LCA (P)

## TU286

### Analysis of endpoint-oriented LCIA methods assessing impacts of water use

#### on ecosystem quality

C. Bouchard, Université Laval; M. Núñez, UR Laboratoire de Biotechnologie de l'Environnement; M. Margni, École Polytechnique de Montréal / Mathematical and Industrial engineering; A. Boulay, CIRAIQ - École Polytechnique de Montréal / Chemical engineering department; C. Bulle, CIRAIQ - ESG - UQAM / Strategy corporate social responsibility

Assessment of ecosystem damages due to water use is making large progress. Many methods addressing a multiplicity of impact pathways dealing both with water consumption, water pollution and water infrastructure exist today. The structure of the characterisation models and indicators of these methods is diverse: some models include a fate sub-model and an effect sub-model whilst others are composed of an indivisible characterisation factor (CF). Some measure damage to aquatic biodiversity whereas some others measure damage to terrestrial biodiversity. Impact units (e.g., PDF, species\*year) among models also differ. Given the variety of modelling choices, before ecosystem quality indicators are used all together and combined in a single metric, a detailed analysis of the coherence, complementarity and compatibility of existing characterisation models should be performed. This was the objective of this study. The methods review was based on the analysis of good practice rules for characterization model development in relation to the following four issues: 1) covered impact pathway (e.g., connection between the inventory flow and the CF); 2) structure of the characterisation model and factor (e.g., one CF vs CF made of fate and effect factors); 3) fate factor modelling (e.g., good use of steady-state models and data in the modelling of pulse interventions); 4) effect factor modelling (e.g., taxonomic and geographic coverage). Results show that, in their present form, methods cannot be integrated into a joint indicator. The adoption of guidelines with general recommendations for water use impact assessment modelling may help in enhancing actual problems of incompatibility among existing methods as well as future new developments.

#### TU287

##### Land use impact assessment of live swine: A case study of US live swine production comparing three impact assessment methodologies

B. Putman, Biological Engineering; G. Thoma, University of Arkansas / Department of Chemical Engineering; J. Burek, University of Arkansas / Chemical Engineering

Global growth and development place high demand on arable land in an attempt to feed an expanding population that now totals over 7 billion people. The impact of these forces on the capacity of land to provide ecosystem services and support natural assets, like biodiversity, are not well understood. Quantifying the human influence on terrestrial resources is critical to guarantee the longevity of our food systems. The National Pork Board (NPB) commissioned the Center for Agricultural and Rural Sustainability (CARS) at the University of Arkansas to perform a life cycle assessment (LCA) of United States pork production in order to quantify land use throughout the supply chain. The functional unit is one kg of live swine at the farm gate. The supply chain is divided into two stages: production of swine rations and animal rearing on the swine farm (with three sub-stages for sow, nursery, and finishing barns). This case study applies three preeminent biodiversity impact assessment methodologies on the inventory flows identified by the NPB LCA. The methodologies chosen were developed, in part, by members of UNEP/SETAC's Life Cycle Initiative for land use impacts on biodiversity. The methodologies were chosen in order to help the initiative and the LCA community move toward consensus in assessing land use impacts on biodiversity. In this presentation a direct comparison of three of the leading methodologies for assessing land use impacts on biodiversity is made. The case study highlights the potential strengths and weaknesses of each approach, as well as the relative difficulty of collect information and carrying out the methodological requirements. The resulting impacts on biodiversity calculated by each impact assessment method are presented graphically to illustrate similarities and differences in results. Preliminary results show that methods requiring species richness are easier to acquire input data. The amount of land occupation is shown to have the greatest impact of biodiversity, which is demonstrated by each of the methodologies. The type of species-area relationship used shows a considerable effect on biodiversity impact.

#### TU288

##### Land use biodiversity impact assessment of the Finnish economy

A. Holma; L. Saikku, Finnish Environment Institute

Land use change as well as land occupation for anthropogenic use are among of the most important threats to biodiversity. Regardless of the importance of the issue, methods for the assessment of land use-related impacts on biodiversity in Life cycle assessment (LCA) are not yet fully established. Biodiversity can be assessed at different spatial scales of loss (e.g., local, regional, or global loss). Also, the indicators should be applicable in the impact assessment of national level economy, which is done with environmentally extended input-output (EEIO) models that combine consumption, production and environmental impacts. A reliable method to link Finnish biodiversity effects to products and services is still lacking. The aim of this study is to explore what are the biodiversity impacts of land-use from the life-cycle perspective in Finland. First, the usability of some of the most relevant biodiversity indicators will be tested with regular LCA calculations. Second, detailed characterization factors (CF) are developed in particular for Finnish land use and tested at the national level. Indicators used in this study are biodiversity damage potential (BDP) and potentially lost nonendemic species (PLNS), which

include the rates of actual extinctions. We study the variation in the results of these indicators with the indicators that take into account the change in the quality of land. To estimate the difference, application of the Hemeroby concept is also applied and the results are compared to the results gained with indicators based on species diversity. Detailed CF's are developed in particular for Finnish land use and tested at the national level. National boreal data is used to improve the characterization factors. To test the existing and developed indicators and characterization factors, we use forest products as an example, and use LCA to measure biodiversity impacts directly related to the product, as well as EE-I-O modelling to measure direct and indirect impact related to wood products industries of Finland including impacts abroad. As a result, life cycle indicators that are applicable to be used at a local level, but also to account for impacts abroad, are developed for Finland. The biodiversity impacts of products and services, as well as impacts of industries of the Finnish economy can be assessed. With the results we aim to discuss if the indicators measure ecologically relevant issues in terms of ecosystem quality.

#### TU289

##### Life Cycle Sustainability Assessment of the Production and Supply of Raw Materials and Primary Energy Carriers: integrating existing frameworks

J. Dewulf, EC JRC - IES / Sustainability Assessment unit; L. Mancini, European Commission Joint Research Centre / Sustainability Assessment Unit Institute of Environment and Sustainability; G. Blengine, EC-JRC; S. Sala, European Commission DG Joint Research Centre / Institute for Environment and Sustainability Sustainability Assessment Unit; C.E. Latunussa, Joint Research Centre - European Commission - Institute for Environment and Sustainability / Sustainability Assessment Unit Institute of Environment and Sustainability; D. Pennington, European Commission

The sustainable production and supply of raw materials ('non-energy raw materials') and primary energy carriers ('energy raw materials') is at stake in many policies: their natural resource base for their production and supply, and the access to are limited; moreover, it is high on environmental and social impact agendas as well. A broad-in scope and quantitative framework that supports decision makers is recommended to make use of raw materials and primary energy carriers more sustainably. The contribution proposes a holistic classification of the full set of raw materials and primary energy carriers our society relies on; this is an essential prerequisite when one aims at developing an Integrated Sustainability Assessment Framework that is to be applicable generically. Overall 85 raw materials and 30 primary energy carriers are identified, grouped respectively into seven and five subgroups. Seeking for comprehensiveness, the proposed framework integrates sustainability issues that have been covered and modeled in quite different quantitative frameworks: ecosystem services, environmental life cycle assessment, social life cycle assessment, resource criticality assessment, and particular international concerns (conflict minerals assessment). The resulting four areas of concerns, i.e. environmental, technical, economic and social/societal, have been detailed into 10 specific sustainability concerns. Finally, these concerns have been given shape through 15 indicators enabling the quantitative sustainability assessment of the production and supply of raw materials and primary energy carriers. For the implementation of the framework, expertise and data from quite different fields will be essential: economic, environmental and social impact expertise, including associated models, software and data will be indispensable. Nevertheless, if society and its policy makers strive for sustainability, this challenge is to be taken as it may result in a compass for meeting their objective.

#### TU290

##### Life Cycle Analyses of local and imported foods in the United Arab Emirates (UAE)

F.A. AlKadhim, S.L. Knuteson, F. Samara, American University of Sharjah / Biology Chemistry and Environmental Sciences

The UAE relies to a great extent on the import of fruits and vegetables from other countries. Intense pesticide usage, soil and water pollution and industrial emissions raise a question on the food security of these products. Markets for locally grown and organically cultivated fruits and vegetables have been on the rise in the UAE, however, as a desert region, locally grown foods have their own environmental impacts. This study developed comparative Life Cycle Analyses (LCA) on several food choices involving both literature research on areas such as production and transport and laboratory analyses of heavy metals (HMs) such as mercury (Hg), cadmium (Cd), lead (Pb), chromium (Cr) and arsenic (As) and organic pollutants such as polychlorobiphenyls (PCBs), polychlorinated dibenzo-p-dioxins (PCDDs) and dibenzofurans (PCDFs) in locally grown and imported foods. Orange, mango, cucumber, tomato and radish were tested using ICP-OES, GC-MS and IDXX. On average, heavy metals and organic pollutants in imported crops exceed locally grown crops. Values of certain heavy metals including Lead were higher than the Maximum Daily Intake. As an example, imported cucumber had an average of 0.013 mg/kg of arsenic, but mercury was below the detection limit. Domestic tomatoes and cucumbers had high threshold values but did not exceed the safe level. Similar results were observed for organic compounds. Results on bacterial content of domestic crops and imported crops did not show a significant difference. The emirates of Ras Al Khaimah, Sharjah (Al Dhaid) and Abu Dhabi (Al Ain) have proved to have fertile soil suitable for growing better quality crops; however other areas have poorer arid sandy soils, less suitable for crop production. With minimal

organic matter in the local soils, fertilizer use increases, leading to possible contamination of groundwater. Many areas in the UAE are dependent on either brackish ground water, leading to salinization of the soils, or desalinated water, with climate change impacts and brine impacts to local aquatic ecosystems. The results of the study show that both imported foods and locally grown foods have large environmental and climate change impacts. A combination of imported and locally grown foods should be used in the UAE, with a focus on advanced sustainable and high yield farming technologies such as hydroponics to produce high quality crops and meet with the demands of a fast growing population.

#### TU291

##### **The Switch from Coffee to Cocoa: Is it sustainable?**

L. Laurin, Earthshift; V. Prado, Arizona State University

The United States (US) Department of State is currently funding four projects in Latin America with the goals of modernizing workforce skills, improving trade and competitiveness and fostering sustainable business practices. These projects include an online tool that allows small and medium sized enterprises (SMEs) to calculate energy consumption and GHG emissions and provides tools for continuous improvement in Peru and Chile, a company that provides high tunnels for reduced pesticide use and higher yields of tomatoes and other crops in Guatemala, a consultancy that works within companies on change management and continuous improvement in Mexico, and an education system to improve cocoa yields for small farmers in Nicaragua. For the first time, the department has asked to understand the return on their investment from a sustainability perspective in a way that takes into account the economic, social and environmental opportunities and risks of each stakeholder involved. Sustainability Return on Investment (S-ROI) is being applied to each of these four projects to understand the effect of the US State Department grants and improve their efficacy in the future. S-ROI starts by engaging with the corresponding stakeholders, decision makers and local groups to capture the most significant social, environmental and economic opportunities and risks of the project according to different perspectives. This methodology combines traditional return on investment, environmental life cycle assessment, social impacts and risk assessment via a monetization approach that allows for high uncertainty in estimates. The results show both, the best case and worse case scenario for the return to the investor in monetary terms and the effect on each stakeholder, in and out of the value chain.

#### TU292

##### **The need for an established allocation method when assessing absolute sustainability on a product level**

M. Ryberg, Technical University of Denmark / Quantitative Sustainability Assessment Department of Management Engineering; M. Owsianiak; M. Hauschild, DTU Management Engineering  
Assessment of absolute sustainability within life cycle assessment (LCA) framework is operational on the country scale. However, it is difficult to apply the existing approaches to products, which are typically the scope of LCAs. How should we assess whether a chair is (absolutely) sustainable? If we assess the life cycle and relate the impact scores to the remaining capacity available for impacts, there is a risk that all products are seen absolutely sustainable. In addition, how should we decide on who can use the remaining capacity? To address these issues an allocation method is proposed for dividing the remaining capacity between and within product groups. The method is a two-step method developed based on the annual consumption pattern of an average person in the country and share of product sub-groups in the group. For example, in the first allocation step, the remaining capacity share allocated to furniture should correspond to the share of an average person's income that is spent on furniture. In this way the impact of the chair is related to the remaining capacity allocated to this particular product group. In the second step, allocation is done between product sub-groups using allocation keys specific to each product group, e.g. mass for furniture, or economic revenue for IT. The proposed method facilitates assessment of absolute sustainability of products within the LCA framework.

#### TU293

##### **Role of biodiversity in life cycle impact assessment through ecosystem services evaluation: a case study on crops pollination and carbon sequestration**

B. Othoniel, CRP Henri Tudor / Centre de Ressources des Technologies pour l'Environnement; B. Rugani, Centre de Recherche Public Henri Tudor (CRP Henri Tudor) / Centre de Ressources des Technologies pour l'Environnement CRTE; R. Heijungs, Leiden University / Faculty of Economics and Business Administration Department of Econometrics and Operations Research; U. Leopold, Public Research Centre Henri Tudor / Resource Centre for Environmental Technologies (CRTE); C. Withagen, Vrije Universiteit Amsterdam / Faculty of Economics and Business Administration Department of Spatial Economics; C. Braun, Public Research Centre Henri Tudor / Resource Centre for Environmental Technologies CRTE; E. Benetto, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE

Current Life Cycle Impact Assessment (LCIA) methodologies for biodiversity evaluation (i.e. based on species richness and functional diversity indicators) do not account for the role of biodiversity in sustaining human well-being. In effect, while representing the roles of biodiversity in regulating ecosystems' quality and resilience, they do not consider the benefits to society provided by various

biodiversity components. To help fill this gap and thus emphasize the multiple roles of biodiversity in LCA, we present here a complementary approach to current LCIA practices. This is based on the impact characterization of ecosystem services (ES) in relation to the ecosystems' elements that support their provision. By modelling the supply chain of these services from the multi-functional ecosystems and their composing biodiversity elements to the benefiting society, we are able to retrieve space-dependant characterization factors for the impact assessment of land use changes (used as inventory flows) on biodiversity and ES. To this end, the Multi-scale Integrated Model of Ecosystem Services (MIMES) is used, harmonizing different ecosystems functional models. The impacts of rapeseed production on crop pollination and carbon sequestration services in Luxembourg are assessed to illustrate our approach. After tuning MIMES with data from life cycle inventory and other site-specific parameters, ES flows are characterized in order to assess their monetary value with a marginal pricing approach. As a result, the generated regionalized characterization factors relate land use changes occurring in a certain location to changes in biodiversity composition and ES values in other locations. We obtain three main findings. First, our approach encompasses the joint role of biodiversity within ecosystems to supply different benefits to society. This information, so far lacking in LCA, may be useful to incentivize the conservation and management of biodiversity. Second, the model allows the evaluation of trade-offs and synergies between ES and biodiversity, supporting the identification of multi-functional biodiversity and ES hotspots. Finally, it considers spatially heterogeneous relationships between biodiversity, ecosystems and society. Although not free from shortcomings (modelling improvements are on-going), the proposed approach is a first step of a research project we are pursuing on the implementation of integrated ecological-economic dynamics in LCIA of ES.

#### TU294

##### **Biodiversity characterization factors development for a run-of-river hydropower in Life Cycle Assessment**

J. Cettier, J. Payet, Cycleco

**Keywords:** Biodiversity, run-of-river hydropower, Life Cycle Assessment  
Run-of-river (ROR) hydropower runs without water storage and uses the river flow. This kind of plant has several physical impacts on the river. First, a portion of the water could be diverted upstream thanks to weirs in the river channel. Secondly, water upstream the weirs has a lower velocity and induces a deposition of the finest particles. These physical impacts result in a lower biodiversity and change the population of macroinvertebrates and fishes. In this context, the aim is to develop a new characterization factor (CF) for biodiversity in Life Cycle Assessment (LCA) of ROR hydropower. The methodology is based on two databases: one with 473 invertebrates (Tachet's database) and another one with 26 fishes (curve preference by IRSTEA). From these two databases, a new database of 499 species was created with their preference score for five classes of water velocity from 0 (no affinity) to 3 (very strong affinity). The type of river and the geographic affinity are also available in the database. For a diminution of speed class (hypothesis between before and after ROR hydropower installation), if the score is better passing through a lower class, the species is considered non-affected (NA), if the score is worse passing through a lower class other than 0, the species is considered affected (A), otherwise the species is considered disappeared (D). At the end, the percentage of population NA, A and D is known for each speed class diminution. These percentages are also attributed to a flow diminution by converting velocity using the relation:  $Q$  (flow in  $m^3/s$ ) =  $v$  (speed in  $m/s$ )  $\times$   $S_m$  (Cross section in  $m^2$ ). Percentage are modified to obtain fraction disappeared (PDF) and fraction disappeared + affected (PAF) for one  $m/s$  or  $m^3/s$  lost. Then, PDF and PAF are integrated over time and space to create biodiversity impacts of a ROR hydropower in  $PDF/m^2/year$  and  $PAF/m^2/year$ . Biodiversity CF calculation for a ROR hydropower is ongoing and results will be presented and discussed at the SETAC 2015 Meeting. Taking into account biodiversity impacts is new in LCA. The method based on species traits allows a consideration of the species preferences under physical changes created by ROR hydropower. Implementation of this new biodiversity CF will allow to consider this environmental impact of ROR hydropower in LCA compared to other impacts categories already implemented.

#### TU295

##### **Hemeroby as an impact category indicator for the integration of land use and biodiversity into the Life Cycle (Impact) Assessment**

H. Fehrenbach, IFEU-Institute for Energy and Environmental Research; B. Grahl, Fa. Integrail; M. Busch, IFEU Institute for Energy and Environmental Research  
Traditionally, LCAs carried out by the German Federal Environment Agency (UBA) include the impact category land use based on the metric 'Degree of naturalness of areas'. Despite the recent developments on land use in LCAs, the authors find the fundamental idea to characterise 'naturalness' as an overarching conservation goal (desired state) forming the basic concept to address selected conservation assets still highly appropriate. The idea central to the concept follows the logic that intact ecosystems are not prone to higher levels of disturbance and negative impacts. Recently the authors have developed the so called hemeroby concept in order to provide an applicable and meaningful impact category indicator for the integration of land use and biodiversity into the Life Cycle (Impact) Assessment. This approach is operationalized by a multi-criteria assessment linking the use of land to different subjects of protection: Structure and functionality of ecosystems, biological diversity and different ecosystem services contributing to human

wellbeing. In this sense hemeroby is understood as a mid-point indicator giving explicite information on naturalness and providing implicite information, at least partly, on biodiversity (number of species, number of rare or threatened species, diversity of structures), and soil quality (low impact.) The hemeroby approach provides a methodology to include the quality of land-use systems focussed on naturalness as conservation goal. Further end-point indicators like biological diversity and ecosystem services are implicitly enclosed. The approach is directly applicable but is currently under development in terms of widening the scope.

#### TU296

##### **How to link biodiversity evaluation and LCA within the AgBalance evaluation method**

P. Saling, BASF SE / Sustainability Strategy; J. Schoeneboom; C. Kuenast, e-syncon; M. Gipmans, BASF SE; M. Frank, BASF SE Agrarzentrum Limburgerhof; A. Ufer, BASF SE / Ecotoxicology

The sustainability evaluation method for agriculture and food supply chains "AgBalanceTM" is based on the principles of life cycle assessments which evaluate impacts which may contain conflicting objectives. For example, a definite farming activity may be positively rated for productivity, but it may be negatively rated for biodiversity development. The intention of AgBalance is to specify alternatives which allow decision makers to prioritize farm management strategies and to specify the respective strengths and weaknesses. Herewith, AgBalance follows the principles of the multi-attribute value theory (MAVT) which allows assessments on the basis of conflicting objectives (v. Witzke 2011). The need to describe quantitatively sustainability (or elements of sustainability which includes biodiversity) has led to develop AgBalance which is based on precursor systems. In building on the environmental impacts and economic costs assessed in the Eco-Efficiency Analysis (Saling 2005) and the additionally integrated social impact indicators in SEEBALANCE® (Schmidt 2004) (Kölsch 2008), AgBalanceTM was designed as a specific type of a new LCA system to assess the sustainability performance of the production of agricultural goods. Therefore, AgBalance in addition to SEEBALANCE contains a range of new agriculture-specific indicators, namely biodiversity, soil health and land use which were identified and developed in a dialogue with various stakeholders. This holistic system allows assessing parameters which contribute to the development of sustainability in agriculture at several user categories: (1) for the farmers, by assessing current practices and developing scenarios for improved processes, (2) for the agri-food value chain, by assessing agriculture's contribution over the complete product life cycle and developing options for improvement, and (3) for policy makers, by assessing the impact of legal bodies and regulations on products and farming practices. Depending on the level of assessment of a study, a "balance" between unequally or even controversially directed factors can be evaluated and assessed by the indicator system.

#### TU297

##### **Ecocentric implementation of the economic dimension into LC + DEA studies** D. Iribarren, Instituto IMDEA Energía / Systems Analysis Unit; M.M. Gamboa, Instituto IMDEA Energía; J. Dufour, Instituto IMDEA Energía / Systems Analysis Unit

Current methodologies for sustainability assessment usually cope with environmental, economic and social aspects of human-dominated activities following an anthropocentric perspective. However, this perspective is insufficient when it comes to assessing the contribution of natural resources to production processes. In this respect, emergy analysis (Em) arose from the need for developing a link between economic and ecological systems. This work shows different pathways to implement the economic dimension into the LC + DEA concept, emphasising its capability for taking into account ecosystem services. The LC + DEA concept refers to the combination of life-cycle (LC) approaches with Data Envelopment Analysis (DEA) for the sustainability assessment and benchmarking of multiple similar entities. In particular, the Em + DEA method has the potential to translate emergy benchmarks into market-driven indicators for the valuation of ecosystem services. Solutions to enhance the economic dimension of LC + DEA studies have recently been proposed in order to deal with environmental, economic and social aspects in balance. Two different perspectives are distinguished. On the one hand, the traditional anthropocentric perspective focusses on the estimation of the economic savings directly linked to the calculated operational benchmarks. On the other hand, the novel ecocentric perspective quantifies external cost savings as well as emergy savings, relying on the previous calculation of environmental and emergy benchmarks. The application of this methodological framework is illustrated with a case study of 25 wind farms located in Spain. Overall, significant direct economic savings and emergy savings are estimated for the inefficient wind farms, while low external cost savings are found due to the good environmental performance of wind power in terms of air pollution. It is concluded that the economic dimension of LC + DEA studies can be feasibly enhanced by calculating not only direct economic savings linked to operational benchmarks, but also external cost and emergy savings linked to environmental and emergy benchmarks. In this sense, anthropocentric and ecocentric perspectives are found to complement one another, providing decision makers with a valuable set of economic indicators. This enhanced LC + DEA methodological framework enriches sustainability assessment and strengthens the analysis of the interactions between ecosystem elements and human-driven processes.

#### TU298

##### **Assessing sand and gravel use in LCIA: state of the art and perspectives**

E. Loiseau, UMR ITAP; P. Loubet, Veolia Eau d'Île-de-France / UMR ITAP ELSA; A. Helias, INRA; P.C. Roux, Irstea / UMR ITAP ELSA

Sand and gravel are the third most consumed resource in the world after air and water. These resources are mainly extracted from land quarries and riverbeds, which are sources almost unlimited at a global scale. Nonetheless, human users may face local or regional depletions, and other sources of sand and gravel are thus being sought. Among them, marine aggregate extraction is getting more and more important. This intensive extraction of resources could have significant impacts on the environment, sometimes resulting in harmful socio-economic and political effects. The most striking example is the disappearance of sand islands in Indonesia. In light of these findings, it seems paramount to account for the impacts of sand and gravel extraction in Life Cycle Impact Assessment (LCIA). However, little attention was paid on these issues in LCIA methods. This paper aims at establishing a preliminary LCIA framework to address sand and gravel use impacts in a comprehensive way. To this end, a review was performed on the effects of sand and gravel extraction both as (i) a resource used for different human activities (e.g. construction) leading to abiotic depletion and (ii) as a contributor to impacts on different land categories (e.g. mineral extraction sites, coastal regions or seabeds). The different LCIA methods were assessed in order to determine how sand and gravel are currently taken into account. Only certain LCIA methods account for sand and gravel depletion at a global scale. In addition, except for land occupation and transformation incurred by land quarries, no LCIA method consider the effects due to sand and gravel extractions on natural ecosystems (e.g., coastal land or water bodies). Yet, many environmental mechanisms have been inventoried such as land destruction, erosion, seafloor destruction, inland salt water intrusion or water table lowering. From the existing frameworks designed for assessing the impacts of land use, water use and sea use in LCIA methods, we identified the possible impact pathways linking sand and gravel extractions to impact categories at midpoint and endpoint levels. Moreover, we emphasized the fact that human users can potentially develop compensations scenarios to adapt to a resource deprivation and that the indirect impacts due to these scenarios should also be quantified. The resulting preliminary framework paves the way for the future developments required to quantify all the impacts of sand and gravel extraction.

#### TU299

##### **Towards operationalizing the Planetary Boundaries concept in LCA for products**

R. MURPHY, University of Surrey / Centre for Environmental Strategy; H. King, Unilever; S. Sim, Unilever RD Colworth / Safety and Environmental Assurance Centre SEAC; J. Chenoweth, I. Christie, University of Surrey / Centre for Environmental Strategy; J. Clavreul, Unilever R&D Colworth / SEAC; J. Lee, University of Surrey / Centre for Environmental Strategy; R. Clift, University of Surrey

The Planetary Boundaries (PB) concept of Rockström et al (2009) has attracted significant international attention as an approach to defining an 'absolute sustainability' space within which mankind needs to remain. This recognition of a safe operating space has clear relevance to LCA work and is potentially a novel perspective on a 'distance to/from target' approach. We have been working with a group of international experts to explore the science underpinning the PBs approach and to explore aspects of operationalising the PB concept in the fast moving consumer goods sector. Traditional LCA approaches are already used in the sector and we are currently researching the potential for adaptation of LCA methods as a potential tool to enable operationalization of absolute sustainability metrics based around PBs. In this presentation we examine the opportunities and limitations for operationalising the PBs concept in LCA with particular regard to the Biodiversity, Chemicals and Water boundaries.

#### TU300

##### **Towards a common understanding of the Area of Protection 'Natural Resources' in Life Cycle Assessment**

J. Dewulf, EC JRC - IES / Sustainability Assessment unit; L. Benini, JRC Institute for Environment and Sustainability - European Commission / Sustainability Assessment unit; L. Mancini, European Commission Joint Research Centre / Sustainability Assessment Unit - Institute of Environment and Sustainability; S. Sala, European Commission DG Joint Research Centre / Institute for Environment and Sustainability - Sustainability Assessment Unit; G. Blengini, European Commission DG Joint Research Centre; F. Ardente, Joint Research Centre / Sustainability Assessment Unit - Institute of Environment and Sustainability; M. Recchioni, EC JRC - IES; J. Maes, EC-JRC; R. Pant, European Commission DG Joint Research Centre / Institute for Environment and Sustainability - Sustainability Assessment Unit; D. Pennington, European Commission Life Cycle Impact Assessment (LCIA) in classical Life Cycle Assessment (LCA) aims at analyzing potential impacts of products and services typically on three so-called Areas of Protection (AoPs): natural environment, human health and natural resources. This contribution proposes an elaboration of the AoP Natural Resources. It starts with analyzing different perspectives on Natural Resources as they are somehow sandwiched in between the Natural Environment (their cradle) and the human-industrial environment (their application). Reflecting different

viewpoints, five perspectives are developed with the suggestion to select three in function of classical LCA. They result in three safeguard objects: the Asset of Natural Resources, the Provisioning Capacity of Natural Resources, and the Global Functions of Natural Resources. Whereas the Provisioning capacity is fully in function of humans, the global functions go beyond provisioning as they include non-provisioning functions for humans and regulating and maintenance services for the globe as a whole, following the ecosystem services framework. A fourth and fifth safeguard object has been identified: recognizing the role Natural Resources for human welfare, either specifically in their role in supply of products and services and also more in general. But as these are far broader as they in principle should include characterization of mechanisms within the human industrial society, they are considered as objects for an integrated sustainability assessment (LCSA: Life Cycle Sustainability Assessment), i.e. incorporating social, economic and environmental issues.

## Midpoint or single score for decision making? (P)

### TU301

#### Screening of sustainability indicators for bioenergy systems: Are they suitable for single-score aggregation?

M. Martín-Gamboa, Instituto IMDEA Energía / esLCA Network Systems Analysis Unit; D. Iribarren, Instituto IMDEA Energía / Systems Analysis Unit; M. Fuss, Karlsruhe Institute of Technology / Institute for Technology Assessment and Systems Analysis ITAS; D. Garrain, CIEMAT / Energy Energy Systems Analysis Unit; Y. Lechon, CIEMAT / Energy Dpt Energy Systems Analysis Unit; W.R. Poganietz, Karlsruhe Institute of Technology / Institute for Technology Assessment and Systems Analysis ITAS; J. Dufour, Instituto IMDEA Energía / Systems Analysis Unit

Governments and decision makers are increasingly aware of the need for assessing sustainability, which is especially relevant to the energy sector. In this respect, Life Cycle Sustainability Assessment is considered to be a promising methodology for the evaluation of energy systems. However, a careful identification of performance indicators is required. Within the framework of the EERA JP e3s (www.eera-set.eu), a review of more than 100 articles and reports on the evaluation of energy systems is carried out. In order to facilitate the identification of appropriate sustainability indicators, an analysis at the sub-sector level is proposed. In particular, this study shows a thorough selection of sustainability indicators for bioenergy systems. The recommendation of indicators for the sustainability assessment of bioenergy systems is based on the screening of more than 600 indicators reported in the literature. A pre-screening of indicators reduces this number to approximately 150 by removing recurrent indicators. A final screening results in less than 30 indicators to provide a complete picture of the sustainability performance of bioenergy systems. This final screening is carried out according to a set of defined criteria including life-cycle perspective, practicality (linked to availability and reliability) and specificity for the assessed sub-sector (relevance). The set of recommended indicators covers the three common sustainability dimensions (environmental, economic and social) while also including multi-dimensional indicators such as cumulative energy demand (technical and environmental dimensions), external cost (economic and environmental dimensions) and labour (socio-economic indicator). Both general (e.g., global warming, eutrophication, net present value and job creation) and bioenergy-specific (e.g., direct/indirect land use change, deforestation and food security) indicators are included in this selected set. The suitability of the selected indicators for aggregation when it comes to further interpreting and reporting the sustainability of bioenergy systems is discussed. Two levels of aggregation are explored: intra-dimensional aggregation (one single score per sustainability dimension) and multi-dimensional aggregation (one single score for sustainability). Overall, despite the ease with which results are reported using a single score, aggregation is not seen as a robust approach to support sensible decision making in terms of sustainability.

### TU302

#### Midpoint vs single score in multi-criteria optimization under LCA constraints: the case of potable water treatment chains

F. Capitanescu, CRTE; E. Igos, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; A. Marvuglia, Luxembourg Institute of Science and Technology (LIST) / Resource Centre for Environmental Technologies CRTE; Resource Centre for Environmental Technologies CRTE; E. Benetto, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE. In order to offer decision makers efficient solutions for reducing the environmental impact of a process, Life Cycle Assessment (LCA) needs to be complemented by multi-goal optimization tools. The paper reports the successful coupling between a multi-goal optimization tool and EVALEAU, which is a state-of-the-art flowsheet-based process modelling - LCA tool for prospective and retrospective simulation of potable water treatment chains. The EVALEAU simulator was developed in Umberto®, relies on the software PHREEQC® for water chemistry calculation, and its modules are linked to the Ecoinvent® database for the LCI of background processes. Since EVALEAU simulator involves a such deep level of software embedding the use of mature derivative-based mathematical programming methods is unreasonable. Consequently, key design operational parameters of the potable water plant treatment chain were optimized by resorting to a metaheuristic

global optimization algorithm, called Strength Pareto Evolutionary Algorithm (SPEA2), which is a natural candidate for black-box multi-objective optimization. The work also assesses the pros and cons of using midpoint versus single score as environmental goal metrics in a decision making process based on very challenging multi-goal optimization of water treatment chains. The problem computational challenges stems from the facts that EVALEAU is a time consuming simulator and the computational complexity (i.e. approximation of Pareto front and running time) of a multi-objective optimization problem grows dramatically with the number of conflicting objectives and may be unmanageable. The results show that solving such optimization problems under both approaches is technically feasible provided that, for midpoint approach, a small number of key conflicting environmental impact metrics are carefully chosen by the decision maker. Other midpoint impact categories can be straightforwardly incorporated into the optimization problem as constraints but the optimization results may depend on their apriorily expert-based limits.

### TU303

#### LCA in multicriteria optimization tools for process design: sewage sludge-based biodiesel production

C.M. Torres, Departament dEnginyeria Química; M. Olkiewicz, Universitat Tòrrida i Virgili / Chemical engineering department; F. Castells, Universitat Rovira i Virgili / Chemical engineering department; C. Bengoa, L. Jiménez, Universitat Rovira i Virgili / Chemical Engineering

Decision-making tools for process design must combine both economic feasibility and environmental impacts evaluation in order to meet the stakeholders' interests. It is the aim of the ongoing researches in alternative raw materials and processing technologies to produce biodiesel. This study analyses from a realistic point of view the biodiesel production from primary sewage sludge by a simulation-based automated evaluation tool. This computational procedure allows automating the calculation of both mid-point and aggregated multicriteria indicators, the identification of the key variables and process hot spots through sensitivity analysis, and the implementation of uncertainty analysis under several scenarios and process assumptions. The automated characterization approach is based on the plant simulation in AspenHysys v8 and the automated iterative process programmed in Matlab to establish the pattern given by the optimization algorithm, uncertainty model or sensitivity analysis procedure to be followed. Three process alternatives were selected to find the best technological solution: a novel wet extraction procedure (Wet route alternative) developed at laboratory scale versus traditionally alternatives from dry sludge, using conventional dry extraction with hexane (DryA alternative) and in situ transesterification route (DryB alternative). The alternatives comparison in the base case scenario is complemented by a sensitivity analysis to check the importance of the assumptions made during the inventory phase. Additionally, Monte Carlo analysis was performed over the correspondent distribution functions defined for the key operational variables, the predefined economic parameters and the characterization factors of the LCA. The resulting simulation gives no significant difference between the LCA of the Wet and DryA routes, while the better economic results points out the Wet alternative as the preferable option with 98% of confidence. The available computational tools allow us to better estimate, analyse and draw conclusions about the environmental evaluation through LCA, taking into account multiple scenarios, assumptions and design choices, without having to assume certain parameters and keeping a detailed perspective in each step of the analysis. The use of appropriate techniques can give a broader view of the process performance avoiding to face tiresome calculations and a vast number of scores.

### TU304

#### Agricultural efficiency as a trigger to slow down global warming: the CF + DEA method of Ecuadorian bananas

L. Roibás; I. Vázquez-Rowe, CRP Henri Tudor / Resource Centre for Environmental Technologies CRTE; A. Elbehri, Food and Agriculture Organization of the United Nations; A. Hospido, Almudena Hospido / Dept of Chemical Engineering

The carbon footprint of Ecuadorian banana production was calculated based on the inventory data gathered in 17 farms. The resembling agricultural practices throughout the production units lead to the combined application of Data Envelopment Analysis (DEA), a method that computes efficient and inefficient units based on their operational parameters, seeking an improvement of inefficient systems. Moreover, it is expected that the optimization of these farms would bring along a reduction in the average carbon footprint of the fruit. Four inputs were chosen, together with banana output, as operational parameters to apply the DEA model: diesel use, nitrogen fertilizers consumption, the consumption of other fertilizers and agricultural oil use. This choice was based on the significant contribution of those items to the whole banana footprint, but also taking into account model requirements and limitations. After a sensitivity analysis, one of the farms was left out of the study, since its characteristics were not comparable to the remaining ones. Seven of the sixteen farms were found to be inefficient, and no relation was found between farm sizes and the resulting efficiency scores. The chosen DEA model provides target values for the inputs under study that can be applied to optimize the inefficient farms without reducing their banana production. By using those targeted values, the carbon footprint can be recalculated in order to compare the results of the optimized farms to those of the original ones. Therefore,

the average carbon footprint of banana farming was reduced by 15% when applying these optimization measures. The application of the CF+DEA method was found to be a valuable tool for farming optimization, allowing an easy estimation of the environmental improvements that would result of the application of given target values to inefficient units. DEA constitutes, however, a complex model, leading to the conclusion that results should be carefully analyzed to ensure target viability before implementing any optimization measure.

Rieradevall, Institute of Environmental Science and Technology ICTA Universitat Autònoma de Barcelona / sostenipra; M. Termes-Rifé, University of Barcelona / Department of Economic Policy Faculty of Economics and Business; F. Hernandez-Sancho, University of Valencia

The recently released standard for eco-efficiency assessment (ISO 14045:2012) is proposed to support decision-making when dealing with urban water cycle management. The lack of such an integrated assessment may lead to non-eco-efficient performances both from the economic and the environmental point of view. The most appropriate environmental, economic and eco-efficiency indicators were selected after the application of both LCA and LCC to the urban water cycle activities of two small-medium cities in Spain. Nevertheless, with respect to LCA results, midpoint and endpoint indicators have been compared in order to select which were the most understandable ones for end-users. The midpoint indicators selected were Global Warming (GWP), Ozone Layer Depletion (ODP), Eutrophication (EU) and Cumulative Energy Demand (CED) as those were the common relevant indicators in the four stages of urban water cycle (drinking water treatment, supply network, sewer network and wastewater treatment and discharge). Both construction and operation and maintenance impacts were included as for treatment plants the most important stage is Operation and for networks it is more relevant the construction stage. Regarding the economic assessment, besides LCC, cost functions were developed in order to estimate costs for water facility and monetisation of externalities was also carried out in order to have a single economic indicator including, costs, monetised environmental impacts and monetised environmental benefits that can be understood by itself. With respect to the eco-efficiency assessment, many previous works from academia and companies showed that there are many different ways to assess the "value" of a product or activity while the standard clearly identifies LCA results as the most appropriate indicators for the environmental assessment. In the case of urban water activities, LCA midpoint and endpoint indicators have been used to correlate them with economic indicators (CAPEX, OPEX and externalities) and also with quality indicators (e.g. BOD reduction or GHG emissions). The most preferred results were the ones that have a graphical interpretation that best supports decision-making. A user friendly web tool for eco-efficiency assessment in the urban water cycle devoted to non-lifecycle experts has been developed gathering all this knowledge and as a collaborative work within academics, water utilities and public institutions.

### TU307

#### **Carbon footprint of plant derived surfactant use in leather industry**

E. Kilic, LEscuela dEnginyeria dIgualada / Textile and Leather Fashion Design Department; R. Puig, A. Navarro, Universitat Politècnica de Catalunya / GIR Escola dEnginyeria dIgualada EEI

In leather production degreasing is an important processing step where the excess of natural fat substances are removed from animal skin. The conventional degreasing methods used for degreasing of skins generally involve using polluting products such as organic solvents and/or synthetic surfactants, or their mixture in the form of aqueous emulsions. The industrial application of these methods has been questioned and raises the question of sustainability because of non-biodegradable structure of synthetic chemicals. Surfactants are shown to be toxic to aquatic organism and their presence generate severe environmental burdens due to use of large amounts of water and cause significant problems in the conventional wastewater treatment processes. The possibility of using plant derived biosurfactant in the degreasing of sheep skins have been investigated and biosurfactant based

degreasing process has been described as a viable and promising ecological degreasing option for leather industry. This study analyzes the environmental performance of the biosurfactant based degreasing process in leather industry in comparison to conventional process where synthetic surfactants are used. Life Cycle Assessment (LCA) methodology is applied and biosurfactant use was evaluated by analyzing the global warming potential impact category defined by CML 2001 (measured in kg of CO<sub>2</sub> equivalent emissions), water and energy consumptions.

### TU308

#### **Benchmarking carbon footprint of wine industry: comparing data from 20 wineries in Spain and France.**

A.N. Diarte; R. Puig i Vidal, Universitat Politècnica de Catalunya / GIR Escola dEnginyeria dIgualada; E. Kilic, LEscuela dEnginyeria dIgualada / Textile and Leather Fashion Design Department; P. Fullana i Palmer, Universitat Pompeu Fabra / UNESCO Chair in Life Cycle and Climate Change

Inventory data were obtained from 20 wineries with varying production volumes participating in two projects coordinated by Cyclus: 8 within the *CO<sub>2</sub> Vino* project (financed by the *European Social Fund through the Program empleaverde from Biodiversity Foundation*) and 12 within the *VINECO* project (financed by the *Euroregion Pyrenees-Mediterranean*). The wineries were distributed in 12 designations of origin from 5 regions in Spain (Galicia, Castilla La Mancha, Murcia, Catalonia and Balearic Islands) and 2 in France (Midi Pyrenees and Languedoc-Roussillon). Both projects had as a goal the fight against climate change, together with increasing competitiveness by delivering environmental information to sensitized markets. In addition to CO<sub>2</sub> emissions, the VINECO project aimed at evaluating and reducing water and energy consumption as well. A comparative analysis of the inventory data collected to calculate the carbon footprint of the 20 mentioned wineries is presented. Specifically, a comparative statistical study of consumptions of chemicals and energy per hectare of vineyards, per kg of grapes and per liter of wine produced has been performed. Different variables have been identified as relevant to the results, such as fuel consumption, use of phytosanitary products and weight and type of packaging. The comparative results obtained in this study can be used by wineries as a benchmark to compare their impacts to the average and identify what variables are causing their deviation from the average. This may help and encourage wineries to adopt measures to reduce their carbon footprint.

#### **Assessment of risks posed by systemic insecticides to hymenopteran pollinators: from lab via (semi-)field to landscape scale testing (P)**

### TU309

#### **Spatial representativeness of field studies on neonicotinoids used for the EU risk assessment to bees**

A. Ippolito, EFSA - European Food Safety Authority / Institute for Environment and Sustainability IES; M. Arena, EFSA - European Food Safety Authority / Pesticides; D. Auteri, Auteri / Pesticides Unit; T. Molnar, R. Sharp, EFSA - European Food Safety Authority / Pesticides Unit; F. Streissl, EFSA / Pesticides Unit; C. Szentes, Pesticides Unit

In view of the various studies and research activities carried out in recent years, in 2012 the EU Commission requested EFSA to revise the risk to bees of neonicotinoid active substances by focussing on clothianidin, imidacloprid, and thiamethoxam applied as seed treatments and granules. In particular EFSA was tasked to consider the acute and chronic effects on colony survival and development, effects on bee larvae and bee behaviour, including effects of sublethal doses. The mandate recommended to perform the risk assessment on the basis of the EFSA PR Panel Opinion, 2012. The risk assessment for honey bees concentrated on three main routes of exposure: via intake of residues in nectar and pollen collected in the flowers of treated plants; from dust produced during the sowing or the application of the granules and drifting on to nearby vegetation; via intake of residues in guttation fluid produced by the treated plants. To this purpose, a number of semi-field and field studies were submitted for the approval of the active substance at EU level and in support of the product authorisations at Member State level. These studies were conducted under certain environmental conditions (e.g. specific crop, landscape, and climate) and therefore their representativeness for different regions and environmental conditions in Europe was questionable. In the present work, the aforementioned studies will be geographically characterised using maps. Their spatial relationship with the distribution of bee-attractive crops and biogeographic regions across Europe will be shown. Uncertainties in extrapolating results from field studies to a pan-European scale will also be discussed. To enhance the interpretation of the results, a short meta-analysis will briefly highlight the main issues undermining the reliability of some studies.

### TU310

#### **Calculators developed for the EFSA Guidance Document on Risk Assessment of Plant protection products on bees (*Apis mellifera*, *Bombus* spp. and solitary bees)**

C. Szentes, Pesticides Unit; G. Zancanaro, European Food Safety Authority / AMU; F. Streissl, EFSA / Pesticides Unit

New perspectives on the risk assessment of PPPs to bees were provided by EFSA new guidance document. This guidance suggests the implementation of tiered risk assessment schemes (screening, first tier, second tier, highest tier). The guidance document was heavily criticised by different stakeholders as being too complex at lower tiers and difficult to apply refined risk assessments at higher tiers. The high number of risk quotients, which need to be calculated for the lower tiers, originates from the complexity of the different exposure routes in agricultural landscapes. This complexity is addressed by using different combinations of default factors for the exposure estimations of the different situations. In order to ease the required calculations, a user friendly calculator based on MS-Excel<sup>®</sup>, named 'Bee-Tool', had been developed by a small working group of EFSA. The Bee-Tool is able to quickly perform all the necessary calculations for the screening step and for the first tier. The calculator underwent a verification process. The most complex factors used in the exposure estimation are the 'Shortcut values'. The default shortcut values (90<sup>th</sup> percentile 'worst case') were derived by Monte-Carlo simulations considering a set of default residue levels in pollen and nectar and information on feed consumption of bees. Among others, these shortcut values can be refined at second tier of the risk assessments if compound or crop specific data are available (i.e., residue levels in pollen and nectar of the pesticide under evaluation, crop specific sugar content of the nectar, crop specific pollen consumption). In order to ease the calculations of crop or compound specific shortcut values, the so called 'SHVAL' tools were developed by EFSA. SHVAL tools are small applications developed for 'R' statistical software. The SHVAL tools allow for inputting raw data sets as well as reference values (central tendency measurements / ranges). First, where possible, they fit theoretical distributions to the input data and then they run a Monte-Carlo simulation. The simulations result in an estimate of the 90<sup>th</sup> percentile shortcut value and its 95% confidence interval. Graphical presentations of the fitted distributions and for the simulated shortcut values are also available. The presentation will give an overview of these calculator tools. Also, with some examples, it will be demonstrated how these calculators work in practice.

### TU311

#### Dilution at the hive - a Dutch field study

L. Roessink, Alterra; D. Belgers, Alterra Wageningen UR; J. Van der Steen, Wageningen UR; A. Focks, Alterra Wageningen University and Research Centre / Ecotoxicology Environmental Risk Assessment Team; h. baveco, Environmental Risk Assessment Team; J. Boesten, Alterra / ERA team

This study was performed to assess potential dilution of pesticide concentrations entering the beehive. For this purpose two flowering fields of oilseed rape (*Brassica napus*) (A and B), situated 650m apart, were sprayed with a separate tracer each. Tracers comprised boscalid and metconazole, both non-toxic for bees. After application, bees were collected every hour simultaneously in the sprayed field and at the entrance of the beehive. In addition, foraging bumblebees were collected in the field as well. On the boscalid treated oilseed rape field, concentrations in nectar collected from field-bees approximated 300 ng/g immediately after application, resulting in an Residues per Unit Dose (RUD value) of about 3 mg/kg. However, concentrations in nectar collected from returning bees in front of the hive situated next to the Boscalid treated field were much lower (approximating 50 ng/g). Interestingly, no metconazole was measured in these samples as well. This indicates that even with an attractive crop such as oilseed rape at close distance, bees may still use a significant other part of the landscape to forage, leading to dilution of initial nectar concentrations as observed in the field.

### TU312

#### Appropriate use of available evidence - an example of exposure of bees to in-field weeds

S.K. Maynard, Syngenta / Environmental Safety; P.C. Campbell, Syngenta / INRS-ETE

In recent years the European Food Safety Authority (EFSA) has increased its programme of preparing guidance and opinions in the field of environmental risk assessment. Many of the current and proposed risk assessment scenarios are worst case and are based on theoretical assumptions that certain scenarios could constitute a risk rather than based on evidence of actual risk. In July 2013 the European Food Safety Authority (EFSA) released its final guidance on the risk assessment of plant protection products (PPPs) to bees (EFSA, 2013). This scheme requires a first tier assessment through various exposure scenarios, one of which is exposure to bees through foraging on attractive weeds within the treated field. The guidance suggests, as a refinement option, that if < 10% of the area of use is covered in attractive weeds then the exposure route is not relevant in the 90<sup>th</sup> percentile case. Efficacy trials for herbicides follow common practices throughout Europe, are designed to measure weed coverage in-field, and are of a standard suitable for regulatory submissions. This project aims to, using this empirical evidence, answer the question posed by the EFSA bee guidance document regarding the relevance of the weeds in the treated field scenario: "Is a significant fraction of the surface area of treated fields covered by attractive weeds for >10% of the area of use?" Using a database of around 11500 efficacy trials (containing approximately 67000 individual weeds recordings) across 9 separate crop groups, data was extracted on weed species, growth stage and ground cover. Initial analyses demonstrate that of all weeds recorded < 2% were at a flowering growth stage. For permanent crops this value was higher (36%) due to differences in agricultural practices. However, future analyses considering the attractiveness of flowering weeds to bees and the

actual ground coverage of weeds is considered these values will significantly reduce these figures and more robustly quantify the exposure to weeds. This large data analysis has demonstrated that the scenario of weeds in the treated field is not applicable for the crops assessed here (wheat, oilseed rape, sugar beet, sunflower, potatoes, maize, peas, beans and permanent crops (orchards and vines)). This work also demonstrates that the currently available regulatory data submitted to member states and EFSA during submissions could be used more effectively when preparing opinions and guidance documents.

### TU313

#### A pragmatic approach to assess the exposure of the honey bee (*Apis mellifera*) when subjected to pesticide spray

Y. Poquet, INRA; L. Bodin, ANSES; M. Tchiamitchian, INRA; M. Fusellier, National Veterinary School (Oniris); B. Giroud, Institut des Sciences Analytiques UMR TRACES Team; F. Lafay, CNRS Université Lyon; A. Bulete, Institut des Sciences Analytiques UMR TRACES Team / Service Central d'Analyse; S. Tchamitchian, M. Cousin, M. Pelissier, J. Brunet, INRA; L. Belzunces, INRA / Umr Abeilles Environnement

Plant protection spray treatments may expose non-target organisms to pesticides. In the pesticide registration procedure, the honey bee represents one of the non-target model species for which the risk posed by pesticides must be assessed on the basis of the hazard quotient (HQ). The HQ is defined as the ratio between environmental exposure and toxicity. For the honey bee, the HQ calculation is not consistent because it corresponds to the ratio between the pesticide field rate (in mass of pesticide/ha) and LD<sub>50</sub> (in mass of pesticide/bee). Thus, in contrast to all other species, the HQ can only be interpreted empirically because it corresponds to a number of bees/ha. This type of HQ calculation is due to the difficulty in transforming pesticide field rates into doses to which bees are exposed. In this study, we used a pragmatic approach to determine the apparent exposure surface area of honey bees submitted to pesticide treatments by spraying with a Potter-type tower. The doses received by the bees were quantified by very efficient chemical analyses, which enabled us to determine an apparent surface area of 1.05 cm<sup>2</sup>/bee. The apparent surface area was used to calculate the exposure levels of bees submitted to pesticide sprays and then to revisit the HQ ratios with a calculation mode similar to that used for all other living species. X-tomography was used to assess the physical surface area of a bee, which was 3.27 cm<sup>2</sup>/bee, and showed that the apparent exposure surface was not overestimated. The control experiments showed that the toxicity induced by doses calculated with the exposure surface area was similar to that induced by treatments according to the European testing procedure. This new approach to measure risk is more accurate and could become a tool to aid the decision-making process in the risk assessment of pesticides.

### TU314

#### Assessing the potential effects and risk of chronic thiamethoxam exposure to honey bees: results of a hive feeding study conducted in North Carolina, USA

J. Overmyer, Syngenta Crop Protection, LLC. / Environmental Safety; F. Rice, Syngenta Crop Protection LLC; S. Bocksch, Eurofins Agrosience Services GmbH; M. Hill, Eurofins Agrosience

Thiamethoxam is a systemic, neonicotinoid insecticide used to control chewing and sucking insect pests on various crops. As bees can potentially be exposed to thiamethoxam via residues in nectar and pollen, a colony feeding field study was conducted to evaluate the potential effects of chronic dietary exposure to honey bees (*Apis mellifera*). Honey bee colonies were exposed to thiamethoxam for six weeks via sucrose solution (1:1 sugar:water) using in-hive feeders. Exposure occurred during the summer in which a dearth of floral resources was expected in order to increase consumption of treated solution. Five concentrations of thiamethoxam were tested ranging from 12.5 to 100 ppb; control colonies received untreated sucrose. Colonies were placed in one of twelve separate apiaries in a randomized block design. Honey bees were allowed to forage freely throughout the duration of the study. Colony condition was assessed at eight time points starting in May 2014 prior to exposure, during the exposure, and after exposure until the end of October 2014. Additional colony assessments will be conducted in March and April 2015 to determine overwintering success and spring population build-up. Data will be analyzed to determine any significant effects of thiamethoxam exposure on the number of adult bees, eggs, larvae, pupae, amount of stored pollen and honey, hive weight and hive mortality compared to controls. For risk assessment purposes, effects data obtained from this study will be compared to measured residues of thiamethoxam in pollen and nectar from various crops.

### TU315

#### Diversity and abundance of pollinators in chlorpyrifos-treated cider apple orchards in Herefordshire UK

C. Garrido, BeeSafe; U. Zumkier, Tier3Solutions; C. Wolf, Tier3 Solutions GmbH; S. Norman, RidgewayEco; G. Weyman, Makhteshim-Agan; N. Poletika, Dow Agrosciences / RSGAACES

Though special attention is given to the protection of pollinators in agricultural crops, only little is known about effects of specific PPP applications on the non-managed pollinator communities. The aim of the study was to monitor the diversity and abundance of the pollinator populations on cider apple orchards in Herefordshire, UK, treated with chlorpyrifos. Risk to pollinators is managed by never applying during blossom-time. Ten conventionally-managed orchards were

chosen in Herefordshire, UK. Chlorpyrifos is usually applied on these orchards once before flowering and once after flowering for control of apple blossom weevil and sawfly – which impact apple yield. Pollinator populations were assessed by transect walks and the observation of defined patches. All orchards were assessed once before first application of chlorpyrifos, once after first application, during apple bloom and after the second application. A total of 22 pollinator (morpho-)species was observed during the transect walks, 17 of these being bee species. The most frequent bees were three mining bee species (*Andrena haemorrhoa*, *A. nitida* and *A. cineraria*). Highest diversity and abundance of pollinators was observed during apple flowering. The species spectrum changed after the time of the 2<sup>nd</sup> application. At this time dipteran flower visitors became more frequent while bee species were observed less. Diversity and abundance differed on the different study orchards at any time and was not dependent from chlorpyrifos application but on the presence of flowering weeds and the heterogeneity of the orchard. The same species spectrum as in the transect walks was observed in the observation patches; mining bees being the most abundant also in this case. The differences between the orchards were bigger than those between different areas in the single orchards. The abundance of pollinators depended on the presence of flowering plants and the life cycle of the observed species and could not be attributed to the chlorpyrifos applications. Diversity and abundance of pollinators at the study orchards were not influenced by the chlorpyrifos applications at population level. Differences between the orchards in the species spectrum and frequency of pollinators was dependent of the presence flowering plants and heterogeneity of the orchards.

### TU316

#### Assessment of the imidacloprid insecticide effects in the intestine and Malpighian tubules of *Melipona scutellaris* bees.

T.C. Grella; R.C. Nocelli, Ciências Biológicas / Departamento de Ciências da Natureza Matemática e Educação; O. Malaspina, Universidade Estadual Paulista UNESP; H.M. Soares, Departamento De Biologia

In Brazil there are 192 species of stingless bees responsible for pollinating 30% to 90% of the native species of the Caatinga, Atlantic Forest and Pantanal. Among these species there is *Melipona scutellaris*, endemic in the northeast and able to perform vibration pollination. Like others, this species is endangered by incorrect application of pesticides, because the new generation of insecticides, such as imidacloprid, is able to translocate by the plant, so even when they are applied in the seed the molecule arrive at the nectar and pollen. When the contact is oral, the first affected organs are the ventricle and Malpighian tubule, responsible for absorption and excretion, respectively. So, the aim of this study was to assess the damages caused by sublethal doses of imidacloprid on the mentioned organs. For this, foragers bees were collected packed in pots of 250 mL and feeding with a solution of 50% water and 50% granulated sugar. In the laboratory the sucrose solution were replaced by other that contained sublethal doses of  $LC_{50} = 0.81 \text{ ng a.i./diet}$ ,  $LC_{50/10} = 0.081 \text{ ng a.i./diet}$  and  $LC_{50/100} = 0.0081 \text{ ng a.i./diet}$  diluted in food. After 24 and 48 hours individuals were anesthetized with CO<sub>2</sub>, the intestine and Malpighian tubule were collected, sectioned at 5 µm thickness, stained with hematoxylin and eosin, were dried, stick with ethellan and observed employing light microscopy. In ventricle treated with lower doses, we observed an increase of apocrine secretion, loss of cytoplasmic material and increase of cells eliminated to the lumen. Already in the higher doses were identified regenerative cells with spaces among them, disorganized nuclei and cells with irregular shapes, when compared with the control. Malpighian tubules showed even in the lower doses loss of cytoplasmic material and apocrine secretion, whereas at higher, we observed an irregular shape of the tubule, cellular swelling, loss of brush border, more intense apocrine secretion and cellular disorganization. In both organs the results can be indications of cell death and tissue regeneration failure due to the action of the insecticide. Thus we conclude that sublethal doses of imidacloprid cause changes in the digestive and excretory bees organs, which can compromise digestion, nutrient absorption, regeneration of cells excretion of toxic waste.

### TU317

#### Cyantraniliprole: Low risk for bees resulting from seed treatment use in oilseed rape

A. Dinter, DuPont de Nemours (Deutschland) GmbH / Crop Protection; A. Samel, DuPont Crop Protection / Ecotoxicology

Cyantraniliprole (DPX-HGW86, DuPont<sup>TM</sup> Cyazapypyr<sup>®</sup>) is the second active ingredient in the anthranilic diamide insecticide class (IRAC Group 28; next to chlorantraniliprole (DuPont<sup>TM</sup> Rynaxypyr<sup>®</sup>)) and the first to control a cross-spectrum of chewing and sucking pests. Cyantraniliprole is a systemic insecticide and mobile via xylem. Oilseed rape seed treatment with Cyantraniliprole 625 g/L FS (DuPont<sup>TM</sup> Lumiposa<sup>®</sup>) at 50 µg a.s./seed provides excellent control of pests like flea beetles in young emerging rape. The DuPont<sup>TM</sup> Lumiposa<sup>®</sup> seed treatment product is registered for use in rape in USA and Canada. Cyantraniliprole is characterized by low water solubility (about 0.01 g/L). No increased honeybee mortality was determined in the oral acute toxicity test at maximum water solubility level of cyantraniliprole indicating a low risk potential for bees via systemic plant exposure routes. Also, cyantraniliprole shows rapid decline in soil with DT50soil values ranging between 13-87 days with no potential for accumulation in soil from repeated uses according to cyantraniliprole labels. Cyantraniliprole residue can be found in guttation droplets of young emerging rape

plants, but the cyantraniliprole concentrations in guttation droplets show a rapid decline. No residues of cyantraniliprole metabolites were detected in any rape guttation liquid samples. Worst-case oral risk assessments indicate low risk for bees resulting from the potential cyantraniliprole uptake via guttation liquid.

Cyantraniliprole residues or residues of plant metabolites were not detected in pollen or nectar of flowering summer or winter rape or in bee matrices like honey or wax. Honeybee colonies exposed next to flowering winter oilseed rape seed-treated with DuPont<sup>TM</sup> Lumiposa<sup>®</sup> and honeybee colonies exposed to control field in Germany and France confirmed the safe use of DuPont<sup>TM</sup> Lumiposa<sup>®</sup> and lack of any effects on honeybee colonies. Based on the available data for cyantraniliprole and its metabolites it is unlikely that the intended use of DuPont<sup>TM</sup> Lumiposa<sup>®</sup> as oilseed rape seed treatment will have any unacceptable in- and off-crop effects on bees resulting from systemic exposure (guttation droplets, nectar or pollen) or from dust drift during drilling.

### TU318

#### Detection of morphological alterations caused by pesticides in bees collected on field

R.C. Nocelli, Ciências Biológicas / Departamento de Ciências da Natureza Matemática e Educação; A.d. Fidalgo, Instituto de Botânica / Núcleo de Pesquisas em Sementes; R.A. Barbosa, Universidade Estadual Paulista UNESP / Centro de Estudos de Insetos Sociais Departamento de Biologia; T. Roat, Biology; P. Cintra Socolowski, Universidade Estadual Paulista UNESP / Centro de Estudos de Insetos Sociais Departamento de Biologia; O. Malaspina, Universidade Estadual Paulista UNESP

Bees are the most important pollinators of native and cultivated areas. In their activities to collect pollen and nectar they can be exposed to pesticides. Many laboratory studies have shown that different molecules causes impairment in target and non target organs, but there are no data about what can happen in these organs in bees on field. To understanding, this study aimed evaluate brain, gut and malpighian tubule from bees collected in native and cultivated areas. Bees were collected on flowers of the orange orchards surrounding the Mogi Guaçu Biological Reserve and on native species. Their organs were removed, fixed in and processed to histology. The positive control were treated with Dimethoate LD50 to africanized *Apis mellifera*. The gut from treated and collected bees showed an increase of cells in the lumen. Epithelial cells showed increase in the secretory granules, nuclear alterations with condensed chromatin and nucleolar irregularities. There were differences in regenerative cells as disorganization and spaces between them. Were observed Malpighian tubules cells with an increase in the cellular volume, losses in the basal and apical region of the cells, and decrease of lumen diameter. In the brain no alterations were detected. The alterations observed can compromising individual capacity to intake food and process toxic substances, leading to death. These results indicate that bees can suffer effects of pesticides even in preservation areas, because the areas are small and they need to forager in crops to get food. This is a problem not just for foragers, but to all the colony that depends of them to collect pollen and nectar and can receive less and contaminated food.

### TU319

#### Large-scale field study of seasonal effects of Clothianidin dressed oilseed rape on pollinating insects in northern Germany: Residues in nectar and pollen collected by honey bees in tunnel tents

M. Persigehl, Tier3 Solutions GmbH

In order to investigate possible long-term side effects of Elado<sup>®</sup> (10 g Clothianidin & 2 g Beta-Cyfluthrin /kg seed) dressed Oilseed Rape (OSR) on different pollinating insects, a large-scale monitoring project was initiated in 2014 in Mecklenburg-West Pomerania, Germany. In this region, OSR is usually cultivated at 25 - 33 % of the arable land. Within this project the present residue study provided reliable data of Clothianidin residues in nectar and pollen of Elado treated and untreated OSR collected by honey bees (*Apis mellifera*). The study was conducted on 35 study fields of a control and a treatment site of approx. 65 km<sup>2</sup> each. During OSR blossom 73 pollen and 73 nectar samples of 18 Elado treated study fields and 17 control fields were sampled and analysed for residues of Clothianidin and its metabolites TZNG and TZMU. Between 21 April and 16 May 2014 meshed tunnel tents of about 50 m<sup>2</sup> in size were erected at the study fields and small honey bee colonies enclosed to expose the honey bees exclusively to OSR. A minimum of 100 mg of OSR pollen was sampled via pollen traps attached to the honey bee hive. About 200 returning honey bees were sampled before entering the hive to collect nectar and their honey stomach dissected. Analyses of samples were conducted by Eurofins Agrosience Services Chem GmbH, Hamburg, Germany. Neither Clothianidin or its metabolites were present at 34 samples of nectar and pollen from the control site: residue concentrations of Clothianidin in pollen and nectar were below the Limit of Detection (LOD = 0.3 µg/kg), except of three pollen samples with Clothianidin residues of below the Limit of Quantification (LOQ = 1.0 µg/kg). In mean the metabolites TZNG and TZMU were analysed as < LOD in all pollen and nectar samples. At the treatment site, Clothianidin was detected in pollen and nectar of all study fields. In 34 out of 39 pollen samples and 22 out of 39 nectar samples of the treatment site residue concentrations were slightly higher than the LOQ. Residues of TZNG in pollen and nectar were lower than the LOQ or even lower than the LOD, whereas residues of TZMU were below the LOD in all samples. Maximum analysed concentrations of Clothianidin were 3.6 µg/kg in

nectar and 3.5 µg/kg in pollen and on mean average 1.3 µg/kg in nectar and 1.7 µg/kg in pollen. In summary, this study constitutes a worst case scenario of honey bee exposure since honey bees collected pollen and nectar only from the target plant OSR in tunnel tents.

#### TU320

##### **Sampling Methods of Nectar and Pollen of *Brassica napus* (oilseed rape) and *Phacelia tanacetifolia* (Lacy Phacelia)**

S. Knaebe, EAS EcoChem GmbH / Ecotox Field; P. Mack, EAS EcoChem GmbH; S. Bocksch, Eurofins Agrosience Services GmbH

The new EFSA guidance document on the risk assessment of plant protection products on pollinators includes not only the honey bees but also bumble bees and solitary bees. Additional assessment factors were introduced for bumble bees and solitary bees to account for their potential greater sensitivity, since there are no standard test protocols available for testing. For a risk assessment refinements a more precise estimate of the possible exposure via the expected residue values in nectar and pollen is possible. With regards to the specific morphology and various yield of pollen and nectar of the different plant species it is necessary to adapt the sampling methodology accordingly since it is important to get enough material for the subsequent residue analysis. Over the last years we have conducted several studies with sampling of nectar and pollen and will present our experience with manual methods as well as with the use of honey, bumble and solitary bees exemplary for *Brassica napus* and *Phacelia tanacetifolia*. Results from an evaluation of forager bee samples for the amount of nectar and pollen load will be presented and different sampling methods will be discussed.

#### TU321

##### **In vitro honey bee larvae testing: lessons learned and improving the way forward**

S. Kimmel, Innovative Environmental Services (IES) Ltd. / Ecotoxicology; R. Odemer, Innovative Environmental Services IES Ltd / Ecotoxicology; V.J. Kramer, Dow AgroSciences LLC / Analytical Chemistry and Environmental Sciences; G. Meregalli, Dow AgroSciences Italia srl / Regulatory Scies & Government Aff. With the recently adopted OECD guideline 237 for in vitro bee larvae acute testing in the laboratory, a new step towards assessment of effects on honey bee brood was implemented. Having now performed several dozens of these new studies under GLP, a second thought on current shortcomings and possible modifications of the test design is useful. Even though this new in vitro larval test may be useful for preliminary screenings on possible hazardous substances for the bee brood, from the stakeholders' point of view, the test design is questionable and several improvements may need to be considered to increase the robustness and reliability of the derived results. Results for controls and reference item treatments from several data sets are presented. Recommendations on possible modification of the test design are discussed.

#### TU322

##### **Variability of brood termination rates in bee brood studies according to Oomen and OECD GD 75\***

J. Lueckmann, Rifcon GmbH; R. Becker, BASF Aktiengesellschaft; S. Schmitzer, IBACON GmbH

\*on behalf of the bee brood working group of the German AG Bienenschutz and the ICP-PR Bee Brood Working Group Based on EU Regulation 1107/2009/EC the current regulatory risk assessment on bees has to address the risk on honeybee larvae or brood. According to the new "EFSA Guidance Document on the risk assessment of plant protection products on bees" (EFSA 2014), both, the Oomen bee brood feeding test (Oomen *et al.*, 1992) as well as the OECD Guidance Document 75 (2007; OECD GD 75) are given as the two higher tier options to refine the risk on honeybee brood if concern is raised in tier 1. Concerning the Oomen method the EFSA GD recommends extending the feeding period of a contaminated feeding solution from one to nine days to ensure a chronic exposure to the larval stages. Hence, a suitable test design for the chronic Oomen feeding test was developed and subsequently ring-tested in 2013 and 2014 by members of the aforementioned working of the German AG Bienenschutz. Additionally results of acute Oomen feeding studies with the aim to compare the results of brood termination rates (hereafter BTR) as one of the main endpoints were compiled and assessed (Lückmann & Schmitzer 2014) [1]. Furthermore, BTRs in OECD GD 75 bee brood studies displayed a certain degree of variability. Therefore Pistorius *et al.* (2011) [2] proposed several modifications to improve the method and their success were evaluated verified by Becker *et al.* (2014) [3]. The current presentation gives the updated findings on BTRs, presents the analysis of BTRs in acute and chronic Oomen and OECD GD 75 testing and finally shows the possibilities and limitations of these three methods. For this purpose data of more than 20 acute plus 7 chronic Oomen feeding studies and more than 60 OECD GD 75 studies from Germany and Switzerland were assessed. ----- [1] Lückmann J & Schmitzer S (2014): The effects of fenoxycarb in a chronic Oomen feeding test – Results of a ring-test. 12<sup>th</sup> Internat Symp ICP-PR, Ghent, Belgium, 2014. #### TU323

##### **New methods to assess forager losses in honeybees**

M. Wang, WSC Scientific GmbH / Dept Efate Modelling

In the context of colony collapse disorder (CCD) forager losses by pesticide use has been widely discussed. Currently, the fate of foragers exposed to toxicants is based on manual marking of individual honeybees, which are observed when they leave a hive, when they subsequently reach a foraging station and when they return to the hive. Since this method is rather labor intensive, we explored methods using video analysis in order to measure the number of foragers leaving the hive and return from foraging trips. With this method large numbers of foragers can be analyzed automatically and also diurnal patterns of activity can be studied.

#### TU324

##### **Reducing sampling bias in honeybee monitoring studies**

M. Wang, WSC Scientific GmbH / Dept Efate Modelling

In recent years, a number of new methods have been tested to obtain large amounts of reliable, quantitative data for risk assessment of honeybees. Especially the use of digital photography has become a wide spread method to evaluate either the brood development or the development of entire colonies under field conditions. Without efficient computer methods, the analysis of large data bases of images is not practical. Therefore, only single combs are usually evaluated manually. However, while computer methods do make it possible to analyze large quantities of data, they also include a small measurement error. Using power analysis, we compare conventional and computer methods in order to reveal which test is more accurate and how to obtain the most reliable results from monitoring studies.

#### TU325

##### **How to assess the reproductive toxicity of pesticides to the honey bee, *Apis mellifera*. L. ?**

G. Kairo, INRA (Institut National de la Recherche Agronomique); F. Ben-Abdelkader, H. Haji, M. Cousin, Y. Poquet, S. Tchamitchian, M. Bonnet, J. Sénéchal, M. Pellissier, A. Kretschmar, INRA; L. Belzunces, INRA / Umr Abeilles Environnement; J. Brunet, INRA

By its pollinating activity, the honey bees are of high agro-environmental importance. However, this activity exposes them to myriads of environmental pollutants including pesticides. Pesticides and especially insecticides have been recently identified as a putative cause of honey bee colony losses. It has been shown that insecticides not only elicit lethal effects but also have adverse sublethal effects. They could be more insidious inducing physiological and behavioural disturbances leading to colonies weakening and eventually to death. One of known sublethal effects of pesticides in animal kingdom is a reduced fertility. Concerning bees, few studies were conducted to determine the reproductive toxicity of pesticides. In this study, we investigated the impacts of pesticides on honey bee drone fertility. Two methods have been developed to rear drones and expose them to a phenylpyrazole pesticide from emergence to sexual maturity in laboratory and semi-field conditions. To test and compare each method, drones were chronically exposed to fipronil through the food at an environmental concentration in both laboratory and in semi-field conditions. These two methods have been developed and compared to each other to assess the potential reproductive toxicity of pesticides. In both cases, Fipronil has no effect on the survival and sexual maturity rates of drones but induces an alteration of sperm quality. Fipronil reproductive toxicity was reflected in a decrease in the sperm concentration of spermatozoa associated to an increase of their mortality. The results highlight the reproductive properties of Fipronil for the honey bee. Nevertheless, it is probably not the only pesticide able to disrupt the fertility in bees. Thus, we propose that such tools could be used in the future for assessment procedure to determine the reproductive toxicity of plant protection products to honey bee before their registration.

#### TU326

##### **Higher tier testing for non-Apis bees : current state of play**

S. Kimmel, Innovative Environmental Services (IES) Ltd. / Ecotoxicology; C. Sandrock, Innovative Environmental Services IES Ltd / Ecotoxicology

The recently published EFSA guidance document on risk assessment of plant protection products on pollinators had a significant impact on current procedures for not only risk assessors, but also testing laboratories in charge of conducting the requested and often uncertain higher tier studies. Especially for non-*Apis* bees, such as bumble bees and solitary bees, there is still considerable uncertainty: either regarding extrapolating from honey bees that are routinely tested but still exhibit largely different life-cycle habits, or facing the challenge to conduct newly requested laboratory or higher tier studies in a GLP-compliant manner despite the general lack of standardisation and validation. Aside the theoretical approach of modelling the effects for non-*Apis* bees based on actual effects on honey bees, the setup of standardized and validated methods for higher tier non-*Apis* studies is of great value and will gain even more importance in the near future. Furthermore, the aspect of gathering realistic exposure residue analysis data in higher tier terrestrial studies increases in importance as well. The here presented data provides some examples conducted under GLP, the combined approach of effect testing and residue analysis and the proposal of some technical solutions as well as their advantages and limitations.

### TU327

#### Short-term acute and extended chronic toxicity of six selected chemicals and a reference toxicant to solitary bees, honeybee and bumblebees

H. Hesketh, Centre for Ecology and Hydrology; E. Lahive, Centre for Ecology & Hydrology (NERC); M. Heard, Centre for Ecology and Hydrology; C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology; J. baas, Centre for Ecology Hydrology; A. Robinson, A.A. Horton, Centre for Ecology and Hydrology; D. Spurgeon, Centre for Ecology & Hydrology

The toxicity of a range of insecticides, other pesticides and contaminants to three bee species: *Apis mellifera*, *Bombus terrestris audax* and *Osmia bicornis* has been assessed in chronic feeding tests. These tests used individual worker bees for the colonial species male and female solitary bees. The time series effects on mortality obtained from these tests was used to parameterise dynamic energy budget toxicity (DEBtox) analysis tools for calculating toxicokinetic and toxicodynamic and the full time-course of effect. Chronic feeding results highlighted different pattern of effects both in the control and exposed bees. Among species there were variations in the rates of background mortality. These differences influenced the assessment of toxicity using classic concentration response models, but they can easily be accounted for within DEBtox. Between chemical contrasting patterns in the time dependence of observed effects were found. For some chemicals a rapid progression of toxicity in time was seen, such that there was only a relatively small variation between effect concentrations concentrated calculated for the short and long-term exposures. DEBtox analysis suggested that for these chemical internal concentrations reached equilibrium within a few hours of exposure. Comparing species, only relative small variations in calculated effect concentrations and DEBtox parameters were found in the majority of cases. Only for selected chemicals were large inter-species differences in toxicity suggested. These differences could be related to the toxicokinetics and toxicodynamics of the particular chemicals. The study first suggests that tests with the three bee species are feasible. Second inter-species differences may be limited only to special cases. Finally, the use of a processed based model such as DEBtox can help link the results from short-term tests to long-term effects in individuals. Acknowledgement: These results were obtained in work funded by EFSA contract OC/EFSA/SCER/2013/02.

### TU328

#### First results of a method proposal for a Bumblebee (*Bombus* spp.) first tier acute contact and oral laboratory test

N. Hanewald, BASF SE / Ecotoxicology; I. Roessink, Alterra; M. Sergey, Independent Consultant; K. Amsel, BioChemagrar GmbH; L. Bortolotti, CRA-API; M. Colli, Biotecnologie BT Srl; D. Gladbach, BayerCropScience; S. Kimmel, Innovative Environmental Services (IES) Ltd. / Ecotoxicology; C. Molitor, Testapi; E. Noel, SynTech Research; H.P. Schmitt, Eurofins Agrosience Services EcoChem GmbH / Terrestrial Ecotoxicology Laboratory; S. Haupt, IBACON GmbH; S. Wilkens, FERA; L. Jeker, DR. KNOELL CONSULT Schweiz GmbH; S. van der Steen, WUR

The European Food Safety Authority (EFSA) has evaluated the current risk assessment for honeybees and Plant Protection Products (PPPs) and issued an EFSA Scientific Opinion and Guidance Document. Relevant gaps in the current testing systems, especially concerning non-*Apis* bees, were identified. For bumblebees (*Bombus* spp) several methods for toxicity testing of PPPs have been published over the last years (e.g. van der Steen 1994 and 1996). The methodologies developed for bumblebee workers in the laboratory are based on the established methods for honey bee (*Apis* spp.) toxicity testing and allow a determination of an acute oral and/or contact LD<sub>50</sub>. Since then the test methods have been adopted and modified several times but so far no agreed testing protocol exists. Beginning of 2014 the ICPPR Non-*Apis* working group, representing 13 laboratories from academia, contract research institutes and chemical industry, agreed on two draft protocols for contact (group and single housing) and one draft protocol for oral laboratory (single housing) tests with bumblebees. During 2014 tests according to these protocols were performed by several laboratories. Experimental results from 11 single contact tests, 14 group contact tests and 13 single oral tests were collected. First data show that reproducible results were obtained with the single housing methods (contact and oral) with control mortalities usually not exceeding 10%. There was a tendency for a decline of the LD<sub>50</sub> estimates over time, which would typically slow down after 48 h. The results indicate that the test produces reliable results within 48 to 96 h. The variability in the data (LD<sub>50</sub> values) of the different laboratories was highest for the oral exposure and the group contact exposure tests. The endpoints obtained in the single contact tests were more consistent among laboratories. The study shows that the new protocols for acute bumble bee testing are promising but additional work is needed for a validated and workable test guideline.

### TU329

#### Experiences with bumble bee semi-field and field studies for ecotoxicological risk assessment

O. Klein; T. Juette, G. Bosse, Eurofins Agrosience Services EcoChem GmbH / Ecotoxicology Field

Since many years, semi-field greenhouse studies are performed with bumble bees (*Bombus terrestris*) to assess eventual impacts on pollination efficiency. The new proposed EFSA risk assessment of plant protection products for pollinators

includes for the first time not only honey bees but also non-*Apis* pollinators. However, no official guideline for the testing of non-*Apis* pollinators in semi-field and field trials exists so far. To overcome this lack of guidance suitable semi-field and field test designs have to be developed. Experiences on different designs for greenhouse, semi-field and field studies are presented. Possible endpoints and techniques to assess these are discussed focusing on different attractive crops like phacelia and oil seed rape and less attractive crops like tomato, potato and cucurbitaceous plants. Endpoints including adult and larval mortality, flight and foraging activity, hive weight development, food consumption and reproduction (worker, queen and drone production) are considered. The aim of this presentation is to give an overview on possible test designs, their chances and limitations.

### TU330

#### A Field Study Monitoring Effects of Thiamethoxam Applied as a Seed Treatment to Winter Oilseed Rape on Development of Bumble Bee (*Bombus terrestris*) Colonies

N. Ruddle, m. coulson, Syngenta; H. Thompson, Syngenta Ltd / Environmental Safety; S. Wilkins, Food and Environment Research Agency / Centre for Chemical Safety and Stewardship

The study was designed to determine the effects on the development of colonies of bumble bees (*Bombus terrestris*) of foraging on flowering winter oilseed rape that had been grown from seed treated with thiamethoxam. The exposure phase was carried out for the five weeks when the crop was flowering with 25 bumble bee colonies per field. The test design included one field (2ha) planted with thiamethoxam treated seed and two control fields (each 2ha) planted with untreated seed and these were located in Lincolnshire, UK. All field sites were separated by at least 2km and were chosen so as not to be close to bee attractive crops flowering at the this time. Once flowering was over the colonies were moved to a monitoring site with untreated forage for a further four weeks. Colony development was evaluated by monitoring the colony mass and forager activity both at the hive and within the crop. Pollen and nectar samples were taken from the treated and untreated crop for residue analysis and pollen stored within the colonies was identified to determine the presence of winter oilseed rape pollen. Pollen collected from the treated crop contained residues of 1.0 µg thiamethoxam/kg and 3.0 µg CGA322704 (metabolite)/kg and nectar contained residues of 1.8 µg thiamethoxam/kg. No residues of thiamethoxam or CGA322704 were detected in samples from the control fields. Pollen identification showed that between 45%-93% of pollen sampled from within the colonies originated from winter oilseed rape and *Bombus terrestris* were observed actively foraging on all the fields. Colonies on all three fields showed similar rates of mass gain during the exposure phase and comparable production of gynes and drones.

### TU331

#### Chlorantraniliprole: Lack of effects on bumblebee reproduction (*Bombus terrestris*) under semi-field conditions in *Phacelia tanacetifolia*

A. Dinter, DuPont de Nemours (Deutschland) GmbH / Crop Protection; K. Brugger, DuPont Crop Protection

A semi-field study was conducted to determine the effects of the insecticide Chlorantraniliprole 20SC (Coragen®) on the bumblebee *Bombus terrestris* L. (Hymenoptera, Apidae) applied as spray solution on *Phacelia tanacetifolia* in Germany based on general SETAC/ESCORT recommendations (BARRETT *et al.* 1994) and EPPO Guideline No. 170 (4), (2010). Additionally, nectar and pollen from forager honeybees and from honeybee combs and nectar from bumblebee colonies were taken for residue analysis. Coragen® was applied twice at 60 g chlorantraniliprole/ha. No residues above the limit of quantification (LOQ) 0.001 mg/kg were found in any of the control samples. Residues of chlorantraniliprole above the LOQ level were found for all matrices after application in the Coragen® treatment. Residues in pollen samples were generally higher compared to the nectar samples. Coragen® applied twice via spray application on flowering *Phacelia* with a 9-day interval during daily bumblebee flight did not have any pertinent effects regarding all parameters assessed, i.e. mortality, flight activity, consumption of sugar solution, hive weight, condition of colonies, development of bumblebee brood, production of young queen offspring and vigor relative to the water treated control. Similar numbers of young queens and drones were determined in the Coragen® and control treatments. These results show that Coragen® – applied at highest registered use rate – is not suppressing reproduction in *Bombus terrestris*, as postulated by Smaghe *et al.* (2013) (Pest Manag Sci 69: 787-791) based on an unrealistically dosed laboratory feeding study. Overall, and on the basis of DuPont data (Dinter *et al.* (2009), Julius-Kühn-Archiv 423: 84-96), independent research (e.g. Gradish *et al.* (2009), Pest Manag Sci 66: 142-146) and practical experiences made since the commercial use of chlorantraniliprole products, Coragen® and Altacor® provide excellent tools for integrated pest management (IPM) programs to conserve pollinating honeybees and bumblebees.

### TU332

#### First results of a method proposal for a solitary bee (*Osmia* spp.) first tier acute contact laboratory test

I. Roessink, Alterra; N. Hanewald, BASF SE / Ecotoxicology; C.W. Schneider, BASF SE; P. Mrdzycki, CRA-API; J. Bosch, University of Barcelona; S. Hinarejos, Sumitomo Chemical Agro Europe SAS / Registration Regulatory Affairs; D. Gladbach, BayerCropScience; L. Stanisavljević, University of Belgrad;

A. Schnurr, BioChemagrar GmbH; H.P. Schmitt, Eurofins Agrosience Services EcoChem GmbH / Terrestrial Ecotoxicology Laboratory; L. Jeker, DR. KNOELL CONSULT Schweiz GmbH; E. Noel, SynTech Research; C.A. Bruehl, University of Landau, Institute for Environmental Sciences / Institute for Environmental Sciences; J. Van der Steen, Wageningen UR

The recently updated EFSA draft honeybee Guidance document also specifies other hymenopteran pollinators, like solitary bees and bumblebees, as groups to take into consideration when assessing the risk of plant protection products to pollinators. However no validated test protocol and consequently no extensive data set is available to compare sensitivities of other relevant pollinators to those of honeybees. Within the current project of the ICPPR Non-Apis working group a start was made to develop a first-tier acute contact test for *Osmia* spp. bees. Based on the honeybee OECD213 and Ladurner et al. (2005) a test was designed using dimethoate as test substance, *Osmia bicornis* (separate tests with males and females), *Osmia cornuta* (separate tests with males and females) housed in groups or individually were performed. First results indicate that reproducible results were obtained using the group housing, which resulted in better control survival than individual housing. Furthermore, sensitivities of *O. cornuta* and *O. bicornis* appeared to be rather similar with LD<sub>50</sub>-96h values of 2.3 (±0.3) and 3.2 (±1.3) µg a.s./bee, respectively. Interestingly, the response of the smaller males of *O. cornuta* and *O. bicornis* was rather similar to that of their larger female counterparts with LD<sub>50</sub>-96h values of 3.2 (±1.0) and 2.0 µg a.s./bee, respectively. The study shows that the new protocols for acute *Osmia* spp. testing are promising but additional work is needed for a validated and workable test guideline.

### TU333

#### Development of suitable experimental designs for field and semi-field trials with the solitary bee *Osmia bicornis*

T. Juette, Eurofins Agrosience Services EcoChem GmbH / Ecotoxicology Field; O. Klein; G. Bosse, Eurofins Agrosience Services EcoChem GmbH / Ecotoxicology Field

The new proposed EFSA risk assessment of plant protection products for pollinators includes for the first time not only honey bees but also non-Apis pollinators. However, no official guideline for the testing of non-Apis pollinators in semi-field and field trials exists so far. To overcome this lack of guidance a suitable field test design has to be developed and ring tested. Also there is more basic knowledge needed as a foundation for field testing. Semi field and field studies were performed this year to increase the knowledge about suitable test designs and the handling of the test organisms. The aim of our studies was the development of a test system for trials under field and semi-field conditions with solitary wild bees. The species chosen for the test was *Osmia bicornis* as proposed in the SETAC / ICPPR meeting 2013 and 2014. Semi-field and field trials with *Osmia bicornis* were conducted in two different crops. For this purpose winter oil seed rape and *Phacelia* were chosen. Different nesting materials, set-ups and release techniques were tested. First results on the hatching success, dispersal rates, acceptance of different nesting materials, the nest occupation by female individuals, the reproduction capacity by means of produced cells and cocoon will be presented and discussed. Recommendations are given on possible test designs.

## From ecosystem services to risk assessment for aquatic and terrestrial plants (P)

### TU334

#### Sensitive response of sediment-grown *Myriophyllum spicatum* exposed to carbon limitation and environmentally relevant arsenate pollution

E.M. Gross, University of Lorraine / Laboratoire Interdisciplinaire des Ecosystemes Continentaux; D. Paroshin, University of Lorraine / LIEC CNRS UMR; A. Hussner, Heinrich-Heine University Düsseldorf  
*Myriophyllum spicatum* has recently been included as new test system for rooted aquatic plants (OECD239). This submerged macrophyte is found in diverse aquatic systems, exhibiting a broad environmental tolerance e.g. to pH, nutrient and carbon availability. The plant can use both CO<sub>2</sub> and bicarbonate for photosynthesis, the latter being the dominant carbon source at alkaline pH. We hypothesized that arsenate toxicity toward *M. spicatum* would be stronger when the plant has to rely on bicarbonate, as plants in unpolluted conditions grow better with CO<sub>2</sub>. In a 2 x 4 factorial design we exposed *M. spicatum* to either CO<sub>2</sub> (high carbon or HC) or bicarbonate (low carbon or LC; pH 6.8 and 8.1, respectively) and 0 – 1.44 – 7.2 and 36 ppm As(V) in the sediment. Plants were grown for 2 weeks in a set-up adapted from the new OECD239 guideline. We measured different endpoints based on growth (length, fresh and dry mass, relative growth rates / RGR), biomass allocation (leaf mass fraction / LMF, root/shoot ratio / R/S-r) and physiological parameters (CNP stoichiometry, pigments, phenolic compounds). Most endpoints showed significant effects starting at 7.2 ppm As(V), with mostly no difference between 0 and 1.44 ppm or 7.2 and 36 ppm As(V). Growth based on RGR-L and dm, and R/S-r declined with higher As(V) concentrations, but carbon source affected only RGR but not R/S-r. LMF declined already at the lowest As(V) concentration, and was less affected at LC. Nutrient (N, P) content was affected by As both in the whole plant and in leaves, but little affected by carbon source. Variable effects of As(V) and carbon source on nutrient stoichiometry, pigments and phenolic compounds were observed, often showing the interaction of both

factors for a given endpoint. We conclude that the new test guideline for *M. spicatum* can be used in modified set-up to evaluate the role of resource availability (CNP) on pollution effects. Such modifications are useful to estimate variable effects due to environmental heterogeneity, i.e. based on nutrient availability or carbon source such as observed in our study.

### TU335

#### Use of sanitized sewage sludge as agricultural input: Assessment of biochemical, morphological, anatomical and cytogenetic effects in *Carica papaya* L. and *Allium cepa* L.

M.M. Marques Bonomo, Federal University of Sao Carlos / Department of Physiological Sciences; M. Morozesk, UFSCar / Departamento de Ciências Fisiológicas; L.d. Souza, Federal University of Sao Carlos / Department of Physiological Sciences; L. Rocha, I. Duarte, Universidade Federal do Espírito Santo / Departamento de Ciências Biológicas; A.d. Costa, Federal University of Espírito Santo / INCAPER; M.N. Fernandes, Universidade Federal de Sao Carlos / Ciencias Fisiologicas; S. Matsumoto, Universidade Federal do Espírito Santo  
Sewage sludge is a biosolid residue which final destination represents an environmental concern. Its growing use as agricultural input is an effective measure, contributing in biogeochemical nutrient cycle and acting as an additional source of organic matter, micro and macro nutrients thus stimulating plant growth. Thereby, plant growth assessments allow in monitoring individual development and the effects in each organ, representing a very useful tool to compare distinct situations. In addition, evaluations of biotransformation and antioxidant enzymes associated to cytotoxic analysis are broadly applied in monitoring of compound effects. Therefore, the aim of this study was to evaluate the effects of sewage sludge application in initial growth of *Carica papaya* and its cytotoxic influences in *Allium cepa*, integrating chemical characterization and biological responses to elucidate potential risks of this residue utilization. Nutritional levels in chemical analysis of substrates corroborates the potential of sanitized sewage sludge use as soil conditioner and additional nutrient input, as well as the low levels of analyzed contaminants make the residue within established by Brazilian legislation. High enzymatic activity in substrate without sewage sludge addition, after 60 and 90 days, confirmed the nutritional deficit promoted by the lack of soil supplementation which may lead to a high metabolic cost to plants. Furthermore, sanitized sewage sludge addition stimulated plant development which was evidenced by the higher growth in plants with higher residue doses applied. Moreover, biochemical and cytogenetic assessments also complements results observed in growth evaluation of *C. papaya* in order to help the determination of ideal application rate, where genotoxic and mutagenic effects were detected in higher doses, along with first biochemical results. Thus, findings of this study indicates that an excessive addition of sanitized sewage sludge may demand responses of plants in order to adapt to these stress conditions, which can lead to damage generation, where balancing costs and benefits of this residue application are essential to assure a high crop quality and help in environmental management.

### TU336

#### Toxicity tests with 3,5-dichlorophenol on six aquatic plant species in water-sediment system

H. Rzodeczko, Institute of Industrial Organic Chemistry Branch Pszczyna / Dpt of Ecotoxicology; K. Brzozowska, Institute of Industrial Organic Chemistry Branch Pszczyna; A. Swierkot, Institute of Industrial Organic Chem. Branch Pszczyna; P. Fochtman, IPO Pszczyna

Aquatic plants toxicity testing plays a role in risk assessment of various compounds. Water-sediment system, considered as ecologically relevant model of toxicity testing, was used in studies conducted with the reference substance recommended in standard tests (OECD TG 201, 221, 239). 3,5-dichlorophenol (3,5-DCP) interferes with oxidative phosphorylation process and algae, duckweed and aquatic macrophytes are sensitive to its mode of action. Results of the toxicity tests performed with six species of freshwater plants were compiled. These were with - dicotyledonous rooted species: eurasian watermilfoil (*Myriophyllum aquaticum*) and parrot's feather watermilfoil (*Myriophyllum spicatum*), - monocotyledonous rooted species: canadian waterweed (*Elodea canadensis*), curly waterweed (*Legarosiphon major*) and dense waterweed (*Egeria densa*), - monocotyledonous floating species: duckweed (*Lemna gibba*).

### TU337

#### Plant density and growing conditions in NTTP studies - influence on data validity

H. Teresiak, C. Stroemel, Agro-Check

For testing phytotoxicity to non-target terrestrial plants (NTTP) in the context of plant protection products (PPP) registration processes in Europe two study guidelines are currently in use: Seedling and early growth test (OECD 208) and vegetative vigor test (OECD 227) Plant biomass - the key evaluated endpoint- is dependent on equal seedling emergence and evenness during the following growth process. Therefore the validity criterion for NTTP studies, an emergence rate of ≥ 70%, was set. Within both OECD guidelines in addition seed densities of 3 - 10 seeds per 100cm<sup>2</sup>, dependent upon the species, pot size and test duration, are recommended, to secure adequate growth conditions and to avoid any overcrowding during the study conduct. This is a main factor to determine significant differences. There have been concerns raised about the value of NTTP

studies, some focusing on potential overcrowding in the test pots. From the perspective of a testing facility, we want to present information demonstrating the influence of plant densities on emergence and plant growth. Seed viability of test species used in NTTP studies varies due to inherent species characteristics, dormancy pattern and also with the degree of breeding progress. Improved seed viability is one advantage of using crop species. Cereals, maize and tomato normally reach always about 95% emergence rate, other crop species like carrot or onion have generally lower viability (75-80%), although only high quality seed batches are used. We also give information how an equal emergence will influence the further growing process and therefore the significance of the test results. We will discuss how seed viability may influence plant density in the pots. We present some generic data from our lab to compare effects of different plant densities and will discuss a range of parameter influencing plant growth and how these parameters can be controlled to prevent effects that could be linked to potential overcrowding. Further we will also discuss pragmatic options for the implementation of recommendations laid out in the OECD Guidelines 208/227 used for phytotoxicity testing.

### TU338

#### **Prioritizing Ecosystem Services for Risk Assessment: Whose Values Count?**

Y. Pan, University of Sheffield / Animal and Plant Sciences; L. Maltby, The University of Sheffield / Dpt of Animal Plant Sciences

It is impossible to protect everything in the environment and a key question for decision makers is what do we want to protect? One approach is to base protection goals on the values of society. Identifying ecosystem services (i.e. benefits that we receive from ecosystems) that are important to society can help decision makers to prioritize specific services for protection. The specific protection goals prioritized can then be used to guide environmental risk assessments. Understanding which ecosystem services are valued by different sections of society is crucial to establishing effective specific protection goals. For example, do rural and urban communities prioritize the same ecosystem services? If not, what are the consequences for decision making and risk assessment? The value of freshwater ecosystem services in different communities in China was investigated by conducting face-to-face interviews with 30 rural and 30 urban respondents in the same region. There were clear differences between the ecosystem services directly used by rural and urban communities and their perceived values. The rural community uses more ecosystem services than the urban community. Nevertheless, for both communities the most common activity was walking by the river banks (recreational use). Riparian vegetation is essential to the maintenance of river banks by preventing erosion. The rural community values ecosystem services more highly than the urban community as they interact more frequently with freshwater ecosystems. In particular, the rural community valued the fauna and flora in the river more than the urban community. This study sets out a framework for investigating the ecosystem values of different communities. In addition, it raises the question of whether there should be different protection goals for rural and urban regions where ecosystem values can be considerably different.

### TU339

#### **Evaluation of non-crop wild species with respect to their suitability in regulatory testing of PPP**

H. Teresiak, Agro-Check; C. Mayer, BASF SE / Ecotoxicology; M. Geiger, BASF SE / Crop Protection

**Introduction and Method** The use of wild species as test species is currently discussed for NTTP-risk assessment purposes. Guidelines (OECD 208/227 – Seedling emergence/Vegetative Vigor) include a list of non-crop wild species (NCWS), which were considered suitable in meeting the validity criteria for testing in the scope of these guidelines. However, suitability of these species has not been subject to systematic scrutiny. The above mentioned validity criteria include  $\geq 70\%$  emergence rate and low variation in growth and morphology. Further criteria for selection of test species include constant availability of uniform high quality seeds, displaying reliable and even germination among different seed batches, further species must be compatible with growth conditions of the test method. NCWS seeds can be obtained commercially including information on their viability; Latter however is often based on different methods, some including the use of germination promoting growth modulators, which are not allowed to be used in OECD studies. Seed batches of nine selected NCWS (8 families) from different sources were tested on their germination and growth behavior to evaluate their suitability in phytotoxicity studies according to OECD 208/227. Bioassays comprise parallel sets of germination tests on filter paper and emergence/growth tests in soil. Each set of bioassay was conducted at three different periods within one year (Jan/Feb, Mar/Apr, Sep/Oct) to evaluate potential seasonal effects. **Results** The Emergence rates were less than germination rates and seed viability information did not match the experimentally determined germination rates. Only few species reached 70% emergence in the tested batches and many species show seasonal influence on germination and emergence rate. A high variability in emergence and seedling vigor increases variance of endpoint biomass which impedes a robust statistical analysis. **Conclusions** Most of the tested NCWS do not meet the required quality criteria with respect to emergence rate, seedling vigor and equal plant development. Only one species showed reliable germination rates independent of batch and season, however, failed concerning the parameter 'growth characteristics'. Three further species meet the emergence rate criteria in a limited amount of seed batches.

Although a range of NCWS are listed as potential test species in respective OECD guidelines, they may not be suitable due to low quality seed material.

### TU340

#### **Primary producers in pesticide risk assessment: endpoints and level of protection**

K. Swarowsky, German Federal Environment Agency (UBA) / Dept IV; S. Duquesne, UBA, Federal Environment agency; L. Hönemann, Umweltbundesamt Federal Agency of Environment; S. Matezki, Plant Protection Products; U. Kühnen, Federal Environment Agency Germany; A. Aldrich, Research Station Agroscope ACW / Ecotoxicology; J. Berchtold, Austrian Agency for Health and Food Safety / Institute of Plant Protection Products Department for Ecotoxicology Efficacy and Integrative Pest Management; V. Poulsen, ANSES / French Agency for Food Environmental and Occupational Health Safety; P. van Vliet; J. Wogram, German Federal Environment Agency UBA / Section Plant Protection Products

As part of the current risk assessment of plant protection products towards aquatic organisms, the risk for primary producers is assessed using  $EC_{50s}$  (growth inhibition) as endpoint.  $EC_{50s}$  can be expressed as inhibition of the average specific growth rate ( $E_rC_{50}$ ) or as reduction biomass, calculated from final biomass ( $E_yC_{50}$ ) or as the integral under the growth curve ( $E_iC_{50}$ ). Current PPP data requirements (Annex III to Regulation (EU) No 544/2011) do not specify which  $EC_{50s}$  should be used. Hence, according to the precautionary principle, for past regulatory decisions, the lowest available figure (usually  $E_yC_{50}$ ) was used to derive safe concentrations of pesticides in surface water bodies. The new aquatic guidance document (EFSA, 2013), now recommends to use  $E_rC_{50s}$  in priority, due to various reasons (e.g. conceptual criticism and lower robustness of the  $E_yC_{50}$  endpoint). Here, we present the results of a comparison of growth rate and biomass endpoints by the German Federal Environment Agency (UBA) based on an extensive dataset for Algae (687 cases) and *Lemna* (41 cases). This analysis performed previously (Martin and Kühnen, SETAC Europe 14<sup>th</sup> Annual Meeting, 2004) provides a good estimate of the impact on the level of protection when shifting from a biomass to a growth rate endpoint. These data indicate that using growth rate endpoints systematically lowers considerably the level of protection of current risk assessment, i.e. by a factor 4.5 and 9.5 (90<sup>th</sup> percentile) for Algae and *Lemna*, respectively. According to the EFSA Opinion on the development of specific protection goal options for pesticide risk assessment (EFSA, 2010), new risk assessment methods according to regulation 1107(2009) should be calibrated to meet specific protection goals, which was not done yet for aquatic primary producers. As a conclusion, we strongly recommend to calibrate the current PPP risk assessment for primary producers to ensure that lowering the level of protection will however meet the intended level of protection.

### TU341

#### **Effect response of *Myriophyllum spicatum* - Extrapolating chemical induced effects from the lab to the field**

S. Heine, Bayer CropScience / Environmental Modelling; G. Goerlitz, Bayer CropScience AG / Environmental Safety; E. Bruns, Bayer CropScience AG / BCS D ETX Ecotoxicology; M. Dollinger, Bayer CropScience; T.G. Preuss, Bayer CropScience / Environmental Modelling; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences

The prediction of environmental concentrations (PEC) of chemicals, such as plant protection products occurring in edge-of-field water bodies, is a basic principle of the risk assessment. Therefore, long-term exposure patterns of specific chemicals are generated within the exposure assessment. Unfortunately, the risk quantification of these exposure patterns, especially strongly varying ones, is hardly possible on an experimental basis because of the time and labour such experiments demand and because of difficulties to exactly mimic exposure patterns. In this area, toxicokinetic and toxicodynamic model approaches offer a promising tool to realistically address the risks posed by time-variable concentrations of toxicants by extrapolating effects from standard laboratory conditions to field conditions. However, experimental data to illustrate the predictive power of such model approaches are rare. In this contribution, field data from a flow-through system, describing the growth response of *M. spicatum*, are used to test the predictive power of a TK/TD model of the same species. The experimental data consisted of length measurements during a period of 42 days in a flow-through system where in the first 24 hours a Sulfonylurea herbicide was applied. The experimental flow-through approach represents an environment that typically occurs in edge-of-field water bodies. By comparing model predictions with experimental data, we show that the TK/TD model is able to predict the effects caused by the Sulfonylurea in the outdoor flow-through system, realistically. Model predictions were in good agreement with the experimental data for the three tested concentrations 1, 3, 10 and 30  $\mu\text{g/L}$ . The presented approach is a method to increase the realism in the aquatic risk assessment.

### TU342

#### **The Minimum Detectable Difference (1): Appropriate experimental design and endpoint selection for macrophytes in mesocosm studies**

A. Arenas-Sanchez, Cambridge Environmental Assessments; S. Taylor; F. Pickering, S. Priestly, Cambridge Environmental Assessments

Recent guidance on the conduct and interpretation of mesocosm tests highlights the importance of using the most appropriate aquatic communities for the chemical

being investigated. In addition, it is equally important that for robust effects assessments, the selection of appropriate measurement endpoints and ecological evaluations, is critical to the derivation of powerful statistical results with reasonable Minimum Detectable Difference (MDD) values. Furthermore, selecting an experimental design aligned with the endpoints of interest has been identified as a factor that might significantly increase the statistical power of experimental studies for risk assessment. Here we will show the evolution of study design and endpoint selection for macrophytes using examples drawn from recent state of the art regulatory tests with herbicides. Earlier studies were conducted using flat bottomed mesocosms that included deep water macrophytes planted into the sediment whereas shallow water and marginal plants were potted and suspended at varying depths within the water column. More recently, we have conducted mesocosm studies with herbicides using sloped mesocosms that enable macrophytes to be planted at water depths that most accurately reflect natural edge of field water-bodies allowing for true community effects to be evaluated. We will provide an analysis of the available data for macrophytes comparing the respective reliability of the data generated at each stage of development (mesocosm design and effects measurement parameters) for both mesocosm designs. Additionally, we will also provide recommendations for further work in order to still improve the robustness of the endpoints for use in regulatory risk assessment.

#### TU343

##### **Glyceria maxima, Ceratophyllum demersum, Cabomba caroliniana Water/Sediment Tests**

G. Gonsior,

Some plant protection products and industrial chemicals show an unavoidable high risk for aquatic plants. Due to the fact that *Lemna* only reflects the risk assessment of free-floating aquatic plants there was a need for the establishment of other aquatic macrophyte systems. Up to now further studies could be conducted based on the OECD 238: Sediment-free *Myriophyllum spicatum* Toxicity Test or OECD 239: Water-sediment *Myriophyllum spicatum* Toxicity Test. However, it is still under discussion if *Myriophyllum* and *Lemna* species could cover all questions for doing refined risk assessment on macrophytes. Tests with *Glyceria maxima* are under discussion and could be performed in addition to reduce uncertainties. Further water-sediment tests with *Cabomba caroliniana* and *Ceratophyllum demersum* based on OECD 239 and OECD 221 were developed and will be presented.

#### TU344

##### **Myriophyllum recovery and pulsed exposure tests**

G. Gonsior,

Up to now, tests with *Myriophyllum spicatum* were performed in an unsterile water-sediment or axenic sediment-free system. Both test designs were submitted for OECD evaluation and resulted in the OECD 238: Sediment-free *Myriophyllum spicatum* Toxicity Test and OECD 239: Water-sediment *Myriophyllum spicatum* Toxicity Test. However, when standard laboratory tests are resulting in an unavoidable high environmental risk, aquatic higher tier tests are needed to reduce uncertainties. Tests like monospecies plant tests with a toxicity phase followed by a recovery phase are a tool for demonstrating more realistic exposure scenarios and for doing refined risk assessment. The contribution will present data of a water-sediment *Myriophyllum spicatum* toxicity test followed by a recovery phase and a water-sediment *Myriophyllum spicatum* pulsed exposure test.

## **Improving approaches for difficult non-standard risk assessment of chemicals (P)**

#### TU345

##### **Risk assessment of difficult substances under the REACH Substance evaluation process**

J. Caley, European Chemicals Agency - ECHA / Evaluation; C. Carlon, European Chemicals Agency - ECHA; M. Sobanska, European Chemical Agency; F. Pellizzato, European Chemicals Agency; L.A. Walker, Centre for Ecology & Hydrology; L. Wollenberger, European Chemicals Agency  
Under REACH, the responsibility for the generation of data and the chemical safety assessment of industrial chemicals lies with the manufacturers or importers of the substance (Registrants). Amongst the 6,600 unique substances registered so far, some substances are prioritised based on risk concerns. These substances are evaluated by Member States under the substance evaluation process. Further information from Registrants may be requested under this process to clarify risk concerns. The list of substances to be evaluated by Member States is called the Community Rolling Action Plan (CoRAP), and includes mono- or multi-constituent substances and the so called UVCBs (substances of Unknown or Variable composition, Complex reaction products or Biological materials). By autumn 2014, 201 substances had been included in the CoRAP for evaluation between 2012 and 2016 and a significant proportion of those are UVCBs or substances that form transformation products. These substances pose particular challenges in the assessment. The prioritisation for CoRAP combines hazard criteria (e.g. known or suspected PBT, vPvB and PBT like substances, suspected endocrine disruptors, known or suspected CMRs, known or suspected sensitizers) together with exposure criteria (e.g. wide dispersive use, consumer use and

exposure of sensitive populations such as children, aggregated tonnage from the registrations submitted by several registrants). Substances with a Risk Characterisation Ratio >1 are also prioritized but cumulative exposure from structurally related substances with critical hazardous properties (e.g. similar endocrine disrupting properties like anti-androgenic or estrogenic-like effects) also play a role, where identifiable. The scope of the substance evaluation does not normally include the effects of coincidental mixtures of various substances in the environment. However, it considers the aggregated emissions of a substance from different sources, and the human and environmental combined exposure to the substance via various routes. The process of the substance evaluation will be described as well as the type of substances that are evaluated, and the main challenges in dealing with the assessment of UVCB substances or substances that form transformation products. This poster is linked to and provides the background information for another poster submitted for this session entitled "REACH substance evaluation of a UVCB: assessment of PBT properties".

#### TU346

##### **REACH Substance evaluation of a UVCB: assessment of PBT properties**

F. Pellizzato, European Chemicals Agency; M. Løfstedt, The Danish Environmental Protection Agency; J. Caley, European Chemicals Agency - ECHA / Evaluation; J.R. Peltola-Thies, ECHA-European Chemicals Agency; K. Tyle, DK EPA / Chemicals

Testing of UVCB Substances for potential PBT or vPvB properties poses particular challenges due to the many different constituents they are composed of. In addition, each constituent could potentially degrade into other substances which could also turn out to be PBT or vPvB. Therefore, one of the main challenges is to decide what to use as the test item. The approach taken will depend, e.g., on the type of UVCB being investigated. The PBT testing usually starts with the investigation of the P criterion. Once this is confirmed, the testing strategy moves to the investigation of the B criterion, and, if this is also confirmed, of the T criterion. In this poster, the main challenges of the assessment of UVCB substances will be highlighted by providing an example of an approved PBT testing strategy under the substance evaluation process (background information for this process will be provided in the poster entitled "Risk assessment of difficult substances under REACH substance evaluation process" also submitted to this session) evaluated by the Danish Competent Authority. The substance is a UVCB with 5 major groups of constituents. The available information on PBT properties for each major fraction of the UVCB was assessed. Representative structures of each major fraction were used to conduct QSAR predictions for the following endpoints: water solubility, vapour pressure, Log Kow, photo transformation in air, ready biodegradability, Log Koc, Henry's Law constant, fish BCF (bioconcentration factor) and short- and long-term aquatic toxicity. A tiered testing approach has been developed in order to derive adequate information to conclude on the PBT properties. The tiered strategy developed for this substance unusually consists in the assessment of the B criterion first for four fractions. Constituents that are concluded to not meet the criteria for B- or vB- based on the results from this study do not need to be investigated for their persistency potential (for the purpose of PBT assessment). Due to the expected difficulties in the analytical detection of representative constituents of the substance in the test medium in a biodegradation simulation study, it was considered that a dietary bioaccumulation study is more likely to provide useful results. Hence, it may be possible to reduce or totally eliminate the number of constituents to be assessed at tier two in the testing strategy which would involve biodegradation simulation testing.

#### TU347

##### **Assessing the bioaccumulation potential of Gas to Liquid (GTL) Fuel**

G.F. Whale, Shell Health / Shell Health; J. Dawick, Shell Health / Shell Health Risk Science Team; C.V. Eadsforth, Shell International

GTL Fuel ("Distillates (Fischer-Tropsch), C8-C26 branched and linear") is considered to be a UVCB (Unknown, of Variable Composition, or of Biological Origin) substance under the EU REACH definitions. This has a significant impact on how bioaccumulation potential can be assessed. In the initial testing proposals to assess bioaccumulation potential under REACH notification requirements a standard OECD 305 fish bioconcentration test on specific C13 or C14 radio labelled hydrocarbon constituents was proposed. The justification being that this would provide data to strengthen the Quantitative Structure Activity Relationship (QSAR) models used to predict the BCFs (bioconcentration factors) of constituents of the GTL Fuel. This was rejected by the European Chemicals Agency (ECHA) who recommended that the constituents to be used in the bioaccumulation testing should be based on the outcome of soil biodegradation testing. The latter studies raised some questions because of analytical constraints, notably the sensitivity of the analytical methods. Although no quantifiable persistent constituents could be determined in soil, it could not be verified whether some constituents remained in the soil at concentrations > 0.1% w/w of the GTL Fuel<sup>[1]</sup>. As it was not possible to provide ECHA with the information requested additional studies have been undertaken and these provide weight of evidence that GTL Fuel does not have significant potential to bioaccumulate. Furthermore, the justification for not undertaking any further bioaccumulation assessments of GTL Fuel is also presented and discussed.

#### TU348

#### Assessing Complex Substances: What we need and what we get

E. Burkhardt, Federal Environment Agency (UBA); D. Einhenkel-Arle, D. Claßen, German Federal Environment Agency UBA

Under the REACH Regulation substances of very high concern (SVHC), like e.g. persistent, bioaccumulating and toxic (PBT) substances, very persistent and very bioaccumulating (vPvB) substances, and substances of equivalent concern are to be identified, included in the candidate list and phased out to minimize the risks posed by these substances. Many substances registered under REACH are substances of Unknown or Variable composition, Complex reaction products or Biological materials (UVCBs), which cannot be sufficiently described by their chemical composition. One example for UVCB substances are substances originating from the petroleum chemistry. The German Federal Environment Agency (Umweltbundesamt UBA) is working on the assessment and regulation of certain UVCB substances. The strategy of the German Federal Environment Agency for the SVHC-assessment of UVCB substances is presented by two examples. To assess the hazard associated with an UVCB substance at first each constituent of the substance with at least 0.1 mass % is screened. The constituent(s) with the most severe properties with regard to SVHC is chosen for the SVHC-assessment of the substance. A substance that contains a SVHC with a fraction of at least 0.1 mass % is regarded as a SVHC itself and can be identified as such. Thus, the knowledge of the identity of the components of an UVCB substance is a prerequisite for any subsequent hazard and risk assessment. In practice several challenges are associated with this work. What we would need would be: i) proper identification of all constituents of the substance with a fraction of at least 0.1 mass%, i.e. at least its name, CAS number and typical concentration, ii) hazard data to assess the SVHC-properties of the substance based on the most critical constituents, and iii) a comprehensible presentation of the data in the registration dossiers with regard to substance constituents including sound justification for QSAR or read across. In contrast to this, what we find is usually: i) that the constituents of the UVCB substances are not properly identified, ii) hazard data is not completely available for the critical constituents, and iii) hazard data for certain constituents or substances is used for groups of constituents or substances without sound justification for read across.

#### TU349

##### Integrated testing strategy for aquatic PNEC derivation under REACH

M. Sobanska, European Chemical Agency; F. Pellizzato, R. Cesnaitis, European Chemicals Agency; B.J. Versnoren, European Chemicals Agency - ECHA / Evaluation; A. Karjalainen, ECHA-European Chemicals Agency; V. Bonnomet, European Chemicals Agency; A. RODRIGUEZ-RUIZ, ECHA European Chemicals Agency; A. Nyman, University of Eastern Finland  
REACH, the European Regulation on Registration, Evaluation, Authorisation and Restriction of Chemicals requires so-called 'standard information requirements' to be provided by manufacturers and importers of chemicals in the EU. These include a set of ecotoxicological hazard endpoints, depending on the produced/imported tonnage. These information requirement are then used in a risk assessment, the 'chemical safety assessment'. The information requirements on aquatic toxicity under REACH are specified in REACH Annexes VII – X and further interpreted in the ECHA Guidance document R.7.b[1]. The guidance explains also the recommended integrated testing strategy for aquatic toxicity endpoints. According to REACH standard information requirements, long-term aquatic toxicity testing on invertebrates (preferably *Daphnia*) and fish is required for substances manufactured or imported in quantities of 100 tonnes or more. Long-term studies may be needed at lower tonnages, for instance when the substance is poorly water soluble. As explained in ECHA Guidance R.7.b aquatic long-term testing on only the most sensitive trophic level may be possible if there is compelling evidence suggesting that one trophic level (fish or *Daphnia*) is significantly more sensitive than the other. Furthermore, if the results of the available short-term toxicity data (acceptable experimental, QSAR or read-across data) for algae, *Daphnia* and fish indicate that no one species is substantially more sensitive than the other, aquatic invertebrates are to be tested first. This allows the avoidance of long-term vertebrate testing (fish) in a number of cases, if the resulting risk is adequately controlled (RCR is < 1) with an assessment factor (AF) of 50 (assuming that data on algae are available). The application of this integrated testing strategy may encounter a number of diverse scenarios that will be illustrated with examples. <br clear="all" /> [1]Guidance on information requirements and chemical safety assessment, Chapter R.7b: Endpoint specific guidance

#### TU350

##### Transformation/dissolution testing used in a grouping and read across approach to determine the environmental classification of alloy brazing pastes.

N. Dom, N. Moelants, S. Verberckmoes, Umicore / group RD; A. Schwender, M. Schimperfmann, D. Schnee, Umicore AG & Co KG / Technical materials  
Umicore Technical Materials has a brazing paste and flux portfolio of +30 products. These products are mixtures of metallic alloy powder(s) (containing e.g. Ag, Cu, Zn, Ni ...), a binder and a solvent, of which the metallic powders form the basis of potential environmental concern. For the purpose of aquatic hazard classification under the Globally Harmonized System of Classification (GHS), an integrated testing strategy (ITS) including grouping and read across based on ionic release using the Transformation/Dissolution protocol (TDp) was developed. Since alloys

are considered to be "special mixtures" of which the functional and hazardous properties are different from those of the individual metals, grouping purely based on composition would not be valid. The multi-dimensionality of the issue was addressed by accounting for product specific properties such as type of alloy and its metal content, additional metal powder(s), and type of binder. Our general hypothesis is that "*Grouping and read across can be applied for products with the same alloy type in different binders*". The hypothesis will be assessed in a stepwise and tiered approach on a group of 7 products (Ag-Cu alloys). In a first step, TD tests are being conducted on two brazing products with the same alloy type and identical metal concentrations (Ag 72%-Cu 28%) but with a varying binder. Reason for testing is two-fold: 1) assess the behavior of the individual metal compounds in the alloy and 2) assess the hypothesis that a similar degree of hazard can be expected for the same alloy in different binders. Regarding the behavior of the individual metal compounds, the preliminary results illustrate that there is no need for a worst case environmental classification as acute 1 / chronic 1 by applying the classification rules for mixtures based on composition. Indeed, although the high Ag content (72% vs. 28% Cu) was expected to be the driver for classification, surprisingly it was release of Cu ions that triggered the less stringent aquatic acute category 3 classification. Already these first results confirm that alloys should be considered as "special mixtures" that require a dedicated approach to avoid overly conservative classification. In a next step, the impact of varying binders will be assessed. This binder assessment will be the critical step in determining the validity of this first grouping and read across exercise.

#### TU351

##### Environmental classification of coal and its implications with regard to transport regulation

D. Heijerick, ARCHE; A. Tomczak, World Coal Association; S. Hubbart, Rio Tinto; M. van Gheluwe, ARCHE

Transport of coal in bulk has been regulated in the past under the International Maritime Solid Bulk Cargo Code (IMSBC Code) which classifies coal as a Group B Substance. However, newly introduced regulations (MARPOL, revised IMSBC Code), require the assessment of overseas transported substances against environmental and human health criteria that were not taken into account under IMSBC, and a classification resulting from this assessment may have significant impact on the transport and loading/unloading of the substance in question. According to the International Convention for the Prevention of Pollution from Ships (MARPOL, Annex V), one of the criteria to consider a substance as Harmful to the Marine Environment (SMHE) when it is classified as Aq.Acute Toxic 1 and/or Aq.Chronic Toxic 1,2 (environmental endpoints). Endpoint evaluation should be conducted according to the Guidance given in the Globally Harmonized System of Classification and Labelling of Chemicals (GHS). The same endpoints are considered in the revised IMSBC code which determines whether a substance is a Hazardous Material only in Bulk. Coal is a complex mixture of ubiquitous organic and inorganic compounds, each with their own environmental classification. This degree of complexity makes it virtually impossible to derive a meaningful classification that is based on classification mixture rules as outlined under GHS. The most relevant coal components that could trigger an environmental classification are trace metals and polycyclic aromatic hydrocarbons. A review of available coal composition data resulted in a relevant min/max range of the most relevant trace metals in coal. This information formed the basis for a set of critical limit concentrations: a coal sample that does not exceed any of these limit values, will not be classified as Aq.Chronic 2 (or more severe) for the environment, even under the worst-case assumption that all trace elements in coal are soluble and present under their most toxic form. Analysis of available data on PAH-content of coal samples showed that concentration levels are several orders of magnitude below the concentration limits that would trigger an environmental classification. Both conclusions on PAHs and trace elements are confirmed by the absence of any ecotoxicological effects in tests that used unburnt coal as test substance.

#### TU352

##### The Globally (Un)Harmonised System for Classification and Labelling of Chemicals (GHS)

J. Zhang, Gradient Corp; A.S. Lewis, Gradient Corporation; K. Reid, T. Lewandowski, T.A. Verslycke, Gradient

In 2003, the United Nations (UN) published the Globally Harmonised System for Classification and Labelling of Chemicals (GHS), incorporating "harmonised criteria" for identifying chemical hazards and requirements for labeling and safety data sheets (SDS). In its current revision, GHS incorporates 16 physical, 10 health, and two environmental hazard categories. Various jurisdictions around the world have chosen to adopt this UN framework. Jurisdictions such as the European Union, Australia, China, and Brazil have fully implemented the GHS, while the United States and Canada are currently in the midst of implementation. To further complicate this process, the GHS model has been interpreted in several different ways: some countries have adopted the GHS "as is", some have incorporated the criteria approach into existing legislative frameworks, and others have altered the GHS criteria to fit their existing legislative framework. This has resulted in a rapidly changing global landscape of environmental regulations and chemical compliance, presenting a major challenge for chemical manufacturers and importers. For example, selective adoption of the GHS framework can lead to a difference in hazard classifications for the same chemical or product, confidential

business information (CBI) requirements, and legal recourse. In addition, GHS hazard classification is complex and calls for a level of expertise in (eco)toxicology and chemistry that was not previously needed to communicate chemical safety, particularly for UVCBs (Substances of Unknown or Variable composition, Complex reaction products or Biological materials). This presentation highlights some of the technical and business challenges associated with the ongoing implementation of GHS. Specifically, using several examples, we illustrate key factors that can result in different hazard classifications for the same chemical or product, such as differences in jurisdictional GHS adoption, variable supplier information, reliance on different sources, use of surrogate data, presence of impurities, and different approaches to evaluating the weight-of-the-evidence.

### TU353

#### **Key variables for dynamic modelling of persistent PBT and vPvB substances in the environment: Application in socio-economic analysis (SEA) under the REACH Regulation.**

O. Warwick, Peter Fisk Associates Limited; S. Gabbert, Wageningen University / Social Sciences; P.R. Fisk, Saxon House; I. Hilber, Agroscope ART; D. Disley, C. Gibson, Peter Fisk Associates Limited

Substances that are persistent, bioaccumulative and toxic (PBT) and very persistent and very bioaccumulative (vPvB) attract special consideration under REACH, because no safe threshold for environmental risk assessment can be established. For PBT and vPvB substances, for which continued use depends upon the granting of an authorisation application, a socio-economic analysis (SEA) must be presented as part of that application. The SEA needs to compare two scenarios: the 'applied for use' (AFU) in which the application is granted for a specific use or uses and the 'non-use' (NU) in which the authorisation is refused. The SEA must consider the *net* impacts between these two scenarios in order to decide if the benefits outweigh the risks. For the consideration of environmental impacts in the SEA, it is essential to understand how much of the substance and at what concentrations it will be in the environment in both scenarios, so that the impacts can be compared. This must include consideration of the changes in the amount and concentration of the substance over time (i.e. the *dynamics of the stock pollutant*) since that affects the period over which impacts are relevant. In this poster we apply (a previously described) simple dynamic model for predicting the behaviour of PBT/vPvB substances to explore the *variability* and *sensitivities* of estimates of concentration and environmental load of a PBT and vPvB substance. This is combined with consideration of how those outputs can be transformed into values for decision-making in the context of environmental impact/cost assessment for a REACH authorisation SEA. Key variables that determine the sensitivity of the model are the substance half-life in the environmental compartment of interest, the amount already in the environment and the release rate of the substance. The influence of these variables on *stock dynamics* is considered using two separate example PBT and vPvB substances. In addition, we illustrate how the variability of parameters, even the absence of any reliable information, can affect the outcome and decision-making in the SEA. The conclusions indicate a strong need for clear guidance on understanding and presenting environmental concentrations and impacts in terms of the differences in environmental burden of the PBT/vPvB substances between the AFU and the NU scenarios. Such guidance should include a framework for assessment and presentation of PBT/vPvB residence time and stock dynamics.

### TU354

#### **The role of nutrition as a confounder for human cumulative risk assessment** M.C. Petriello, University of Kentucky / Toxicology; B.J. Newsome, University of Kentucky / Chemistry; B. Hennig, University of Kentucky / Superfund Research Center

Cumulative risk assessment is complex and may be influenced by chemical as well as non-chemical stressors or buffers. An emerging body of evidence correlates persistent environmental toxicants, such as dioxins and complex PCB mixtures, with human diseases like atherosclerosis. Many communities that reside around hazardous waste sites face daily pollutant exposure risks in addition to the impact of a multitude of other physiological and social stressors. One such confounding stress is sub-optimal nutrition, which has now been shown to exacerbate toxicant-induced disease. Toxicants and poor nutrition can both act as stressors, promote chronic inflammation and oxidative stress and thus work synergistically to promote a more profound disease phenotype. In contrast to sub-optimal nutrition, evidence now shows that diets focused on healthful nutrition (e.g., diets centered on fruits, vegetables and healthier fats) may act as buffers and thus be able to counteract the detrimental effects of POPs such as PCB mixtures. We have shown that mice supplemented with the tea catechin EGCG are protected against PCB-induced inflammation and oxidative stress by exhibiting a more efficient antioxidant response. Although complete remediation of persistent environmental pollutants may be necessary to eliminate their contribution to disease pathologies, this process is extremely time-consuming and cost-prohibitive. Therefore, it is necessary to identify easily available modulators of toxicant-induced disease. Bioactive food components with antioxidant and/or anti-inflammatory properties, such as polyphenols and omega-3 polyunsaturated fatty acids, may act as a sensible means to provide physiological buffers against toxicant-related diseases. This new paradigm that the nutritional status of an individual can impact the toxicity of pollutants has important ramifications for cumulative risk assessment.

Understanding the nutritional makeup and tendencies of a community will allow scientists to better measure and estimate true risk of a specific pollutant or mixture. Finally, understanding the interplay between toxicology and nutrition, especially concerning complex mixtures, requires the development of more complex statistical analyses and models that will allow scientists to create personalized risk assessments for individually impacted human populations.

## **Risk assessment of chemical mixtures: trends, developments and bottlenecks for integrating exposure and effects (P)**

### TU355

#### **Assessing exposure and risks levels of Biocidal Products: needs for Tier 1 screening tool and current issues**

C. Durou, CEHTRA SARL; A. Barret, CEHTRA SAS; E. Beltran, CEHTRA SARL; L. Pontal, CEHTRA SAS; s. kirkham, CEHTRA UK Ltd

The Biocidal Products Regulation (528/2012) has applied from 1 September 2013. The regulation requires an environmental risk assessment (ERA) to be performed on the active substance (AS) present in any biocidal product (BP) to be marketed on the EU market. Besides this provision for the AS, additional risk assessment, to the same standard as for the AS, shall be carried out for the precursor(s) of *in-situ* generated AS and for any substance of concern (SoC). The results from these assessments shall be integrated to produce an overall risk assessment for the BP. Finally, the assessment shall take into account any cumulative or synergistic effects. Various tools have been made available to assess the exposure of chemicals for the environment. Among these tools, EUSES has been extensively used for the assessment of risks posed by AS under the review program of existing AS. The exposure assessment shall address the typical use claimed on the label alongside a realistic worst-case scenario. Generic product type exposure scenarios have been developed (RIVM/EUBES Program/OECD) and some of these biocide uses are incorporated in EUSES 2.1.2 version (2012). However, some ESDs are not updated, are not included as they were developed after the last update of EUSES, or the EUSES ESD contains errors. As an example, for disinfectants used in food and feed areas (Product Type 4), a generic ESD is publicly available but has not been included in EUSES. For many biocide uses, no ESD have been developed and will require tailor-made scenarios to be performed. CEHTRA using Microsoft Excel® has developed a unique Tier 1 tool to allow for the concurrent assessment of environmental exposure and risk of multiple substances in a single BP. In addition, the tool is developed in flexible way to meet the needs for adaptation in case of uses of BP not covered by any generic ESD or new generic ESD. The purpose of this work is to initially review the issues with ERA for biocide products, the need for an adaptable assessment tool able to handle these complexities. An example PT 4 ERA will then be presented using the tool. To conclude, the poster will compare and contrast an assessment performed using the CEHTRA-Tier 1 tool against one performed using the current standard tools.

### TU356

#### **Toxicological assessment of intentional and unintentional mixtures within the European regulations**

S. Van der Linden, Biodetection Systems BV; A. Kienzler, European Commission - Joint Research Centre / IHCP System Toxicology Unit EURL ECVAM; S. Bopp, A. Worth, European Commission Joint Research Center / IHCP Systems Toxicology Unit and EURL ECVAM; E. Berggren, European Commission Joint Research Centre (JRC) / Institute for Health and Consumer Protection IHCP and EU Reference Laboratory for Alternatives to Animal Testing EURL ECVAM

While humans and the environment are continuously exposed to a multitude of substances via different routes of exposure, current regulatory risk assessment mainly focuses on the assessment of individual substances via a single exposure route. However, adverse effects might arise from exposure to a single compound originating from several different sources (combined exposure), or from exposure to different compounds contributing jointly to the same adverse effect (mixture exposure). Due to the largely unknown exposure to individual compounds and potentially unlimited combinations thereof, the toxicological assessment of mixtures is extremely complex. Different types of mixtures are identified in current EU regulations, but currently no clear methodological approaches are defined on how to deal with the problem of mixtures. This gap in the EU regulatory assessment requirements has recently gained more attention, following a 2012 Commission Communication on the Combined Effects of Chemicals. Currently, research is undertaken to tackle the major problems in implementing a scientifically sound assessment of mixtures, which have to be based as far as possible on non-animal testing methods. Here, an overview of the current regulatory requirements for the assessment of mixtures is presented, covering over 20 different pieces of EU legislation. How and to what extent mixtures are addressed in different legal frameworks is investigated and indications of discrepancies are given. The different scientific tools to assess mixtures are presented, including their current use and how they are (or can potentially) be applied in EU legislation. The most important factors hampering current legal implementation will be summarized as well as how these different approaches could fit into the currently proposed frameworks on the toxicological assessment of mixtures.

### TU357

### Mixture toxicity of PBT-like chemicals: A relevant focus for future regulation?

K. Syberg, Roskilde University / Department of Environmental Social and Spatial Change; L. Dai, Department of environmental social and spatial changes; T. Ramskov, Roskilde University / Department of Environmental Social and Spatial Change; H. Selck, Roskilde University / Dept Environmental Social and Spatial Change

Even though most chemicals regulation is still conducted on a chemical by chemical basis, mixture toxicity is achieving increasing attention. The scientific understanding has increased substantially in the last decades, and a general consensus now seems to have been achieved that concentration addition is a suitable model for default estimations of mixture effects. One of the major challenges is therefore how to select specific chemicals for actual mixture toxicity assessments. Persistent chemicals are likely to be present in the environment for an extended period of time, thus increasing the likelihood of them being present in environmentally found mixtures. Persistent, bioaccumulative and toxic (PBT) chemicals are therefore a highly relevant group of chemicals to consider for mixture toxicity regulation. The present study evaluates to what extent a number of PBT-like chemicals possess concern beyond that of the individual components. Firstly, the effects of three chemicals with PBT-like properties (acetyl cedrene, pyrene and triclosan) was examined on the freshwater snail, *Potamopyrgus antipodarum*. Secondly, mixture bioaccumulation of the same three chemicals were assessed experimentally. Thirdly, a review of the existing literature on mixture effects of 132 PBT-like chemicals were conducted to evaluate the quantity and quality of mixture studies on PBT chemicals in order to guide future research within the field. The experimental data illustrated that no observed effect concentrations (NOECs) of PBT-like chemicals can lead to effects when mixed. Such "something from nothing" effects will be underestimated if mixture effects are not considered for environmental risk assessment. The review illustrated that the scientific knowledge of PBT-like mixtures is still limited, thus demonstrating a need for future focus on such mixtures.

### TU358

#### Can we apply concentration additive and independent action mixture effect model to species sensitivity distribution? - An experimental validation using herbicides

T. Nagai, K. Taya, I. Kitayama, National Institute for Agro-Environmental Sciences

Conventional prediction models of chemical mixture, concentration additive (CA) and independent action (IA), have been used for mixture effect assessment. The applications of CA and IA to single species toxicity have a lot of examples of experimental validation. The applications of CA and IA to species sensitivity distribution (SSD) have also been used to calculate multi-substance potentially affected fraction (msPAF) for ecological risk assessment of chemical mixture. However, msPAF calculation has not been validated experimentally. Therefore, we tried to validate the application as a case study using herbicides which are toxic to algae. We tested the mixture toxicity of herbicides on the growth of five periphytic algae, cyanobacterium *Pseudanabaena galeata*, green alga *Desmodesmus subspicatus*, diatom *Achnanthes minutissimum*, diatom *Nitzschia palea*, and diatom *Navicula pelliculosa*. Toxicity tests were conducted using 96-well microplate for 96 h, and the algal growth was monitored using fluorescence microplate reader. Five herbicides of the same mode of action (CA model can be applied), pretilachlor, butachlor, mefenacet, cafenstrole, and fentrazamide, were mixed as Mixture 1, and five herbicides of the different mode of action (IA model can be applied), pretilachlor, bensulfuron-methyl, pyraclonil, esprocarb, and simetryn, were mixed as Mixture 2. First, we tested the toxicity of each single herbicide to the five algal species, and then these data were used for SSD analysis. Three effect levels (HC5, HC10, and HC20) of each herbicide were used for further mixture experiments (Mixture 1 and Mixture 2). The fraction of species which were affected more than 50% was defined as experimentally obtained msPAF. In addition, msPAFs were calculated applying CA and IA models to each SSD. One, one, and two species were affected (corresponding to 20, 20, and 40% of msPAF) for HC5, HC10, and HC20 effect levels, respectively in Mixture 1 experiments. CA calculations agreed with the experimental results better than IA. In contrast, one, two, and four species were affected (corresponding to 20, 40, and 80% of msPAF) for HC5, HC10, and HC20 effect levels, respectively in Mixture 2 experiments. IA predictions agreed with the experimental results better than CA. These results suggest mixture effect of chemicals among same mode of action can be predicted using CA model, and that among different mode of action can be predicted using IA model, even in the application to SSD.

### TU359

#### Relevance of EDC mixture effects for ecological risk assessment - a case study of propiconazole and resorcinol with *L. stagnalis* as a model organism

A.S. Andersen, ENSPAC; T. Lee, Roskilde University; A. Palmqvist, K. Syberg, Roskilde University / Department of Environmental Social and Spatial Change; K. Jensen, Roskilde University

There is growing evidence that a number of chemicals may possess endocrine disrupting activity, and that these effects can occur at concentrations that are similar to current environmental relevant exposure levels. There are concerns that decline in wildlife species and populations might be linked to exposure of endocrine

disrupting chemicals (EDC's). When species and populations decline it may influence the ecological context by changing the composition of the biological community and the ecosystem function and services which we depend on. Traditional regulation of chemicals in EU is based on risk assessments of the individual chemicals. Since chemicals end up in mixtures in the environment the effects of these mixtures need to be accounted for, if we want to realistically and safely estimate risk for the environment. In the current study the potential EDC's propiconazole and resorcinol have been tested on the freshwater gastropod *Lymnaea stagnalis*. Partial life cycle tests, with the endpoints fecundity, egg quality, timing and survival, were performed for the two compounds individually and in mixture to explore whether they have synergistic, additive or antagonistic effects. Based on the results from this case-study the EU regulation concerning mixtures and EDC's in the environment is discussed.

### TU360

#### An online database on the ecotoxicity of pesticide and pharmaceutical binary mixtures

J. Kim, R. Pasupuleti, B.E. Lee, M. Fischer, KIST Europe / Environment and Bio Group

The interest and studies on mixture toxicity among chemicals are continuously increasing in ecotoxicology because the mixture toxicity can be provoked by combined effects of two or more substances even at their no-observed-effect concentrations in the environment. Various mixture toxicity datasets can contribute not only to provide information of potential hazard of mixtures to risk assessors, but also to be used for developing prediction models for estimating the mixture toxicity. However, there is a lack of systematic databases on the ecotoxicity of mixtures which efficiently provide useful information on combinations of substances, toxicity effects, target organisms, toxicity end-points, literature cited, etc. Therefore, the objective of this study was to develop an online database on the ecotoxicity of mixtures with focusing on pesticide and pharmaceutical binary mixtures.

### TU361

#### Prediction of synergistic toxicity of mixtures to *Vibrio fischeri* using bioinformatic and chemoinformatic techniques

M. Fischer, J. Kim, KIST Europe / Environment and Bio Group; V. Helms, University of Saarland / Center for Bioinformatics

The interest and studies on mixture toxicity among chemicals are continuously increasing in ecotoxicology because the mixture toxicity can be provoked by combined effects of two or more substances even at their no-observed-effect concentrations. The combined effects can be divided into additivity, synergism, antagonism, and potentiation. Conventionally, concentration (CA) and independent action (IA) models have been frequently employed to estimate the additive toxicity. Integrated CA and IA models have been also developed to overcome the limitations of the conventional models. However, there is a lack of synergism models to predict the synergistic toxicity of mixtures. Therefore, the objective of this study was to develop an approach to predict the synergistic toxicity of mixtures to *Vibrio fischeri*, a luminescent bacteria, using different bio- and chemo-informatic techniques, e.g. calculations on structural similarity, chemical-protein and protein-protein interaction networks. This study highlights that the bio- and chemo-informatics based approach showed a potential to be used for predicting the synergistic toxicity. Further studies are required to evaluate this method with different organisms and target mixtures.

### TU362

#### A web-based estimation tool for classification, labelling and packaging of mixtures

J. Kim, B.E. Lee, KIST Europe / Environment and Bio Group; S. Kim, KIST Europe / Chemical Management Lab

From 1 June 2015, chemical industries are required to classify and label mixtures according to the European regulation on classification, labelling and packaging of substances and mixtures (CLP). The CLP regulation entered into force on 20 January 2009 so that existing European system on hazard classification and labelling of chemical products, e.g. Directives 67/548/EEC and 1999/45/EC, could align to the United Nations Globally Harmonised System. Under the CLP, the classification of mixtures can be estimated on the basis of hazard information of mixture itself, similar mixtures, or components in a mixture. Component-based estimation approaches appear to be practically used for the CLP estimation, due to the lack of toxicity test data on various mixtures and chemical combinations. Accurate and timely CLP estimation is important; however, technical guidance documents and CLP estimation algorithms for mixtures are extremely complicated and require expert judgement. This seems to be a burden especially to small and medium-sized enterprises. Therefore, in this study, a web-based CLP estimation tool for mixtures was developed so that it could support chemical industries to effectively comply with the CLP regulation.

### TU363

#### USEPA's Dermal Slope Factor for Benzo(a)pyrene Predicts That Skin Cancer in London is Caused by PAHs in Soil

B.H. Magee, ARCADIS; N. Forsberg, ARCADIS US Inc / IEST; K. Baker, ARCADIS

USEPA's draft toxicological assessment of Benzo(a)pyrene (BaP) was released in September 2014. The document proposed a Dermal Slope Factor (DSF) of 0.006 ( $\mu\text{g}/\text{day}$ )<sup>-1</sup>. If EPA's proposed DSF derived from mouse skin studies is true, it would predict that a large fraction of non-melanoma skin cancers in the is caused by low level dermal exposure to BaP and other PAHs that have BaP relative potency factors from soils, grilled foods, coal tar containing shampoos and pharmaceuticals, and other sources. To validate the proposed DSF, a screening level population risk assessment was performed on urban soils London. Vane et al. (2014) recently tested 76 surface soil samples from London for PAHs. The mean benzo(a)pyrene toxic equivalents (BaP-TE) using the EPA (2010) proposed Relative Potency Factors is 6.2 mg/kg. Emsbo-Mattingly, et al. (2014) have analyzed a variety of PAH mixtures with a method that includes the 16 additional proposed potentially carcinogenic PAHs. The increase in BaP-TE was 10-100 fold. It is conservatively assumed that the BaP-TE of London soils with an expanded list of PAHs is only 10 fold higher than the values reported in Vane et al. (2014), resulting in a mean of 62 mg/kg. Using this concentration, USEPA standard exposure assumptions, and the proposed DSF, the estimated lifetime cancer risk from contact with London soils is 2.8E-02. Non-melanoma skin cancer rates start to rise in people after the age of 30. The average annual risk between the ages of 30 and 70 predicted by EPA's DSF is 7E-04 per year or 70/100,000. Non-melanoma skin cancer (NMSC) incidence rates for the Thames cancer registry for 2008-2010 were 105/100,000 for males and 70/100,000 for females (National Cancer Intelligence Network (2013)). This simple validation exercise demonstrates that USEPA's DSF is scientifically invalid. It predicts that 70-100% of the non-melanoma skin cancer in the Greater London Authority can be explained by dermal contact with soils, when, in fact, dermatologists have identified ultraviolet radiation from sunlight as the major cause of human skin cancer. In addition, as summarized in Magee (2014), the scientific literature shows that human skin cancers have a sunlight genetic signature that is entirely different from the genetic signature of skin cancers in rodent skin after repeated treatment with BaP and other PAHs.

### TU364

#### Most common plant protection product mixtures in freshwater systems of the USA, France and Germany

V.C. Schreiner, E. Szöcs, Institute for Environmental Sciences; M. Bundschuh, Department of Aquatic Sciences and Assessment Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; R.B. Schaefer, University Koblenz Landau / Institute for Environmental Sciences Plant protection products (PPP) are assumed to play an important role in losses of freshwater biodiversity and ecosystem services. Ecological risk assessment primarily considers single compounds. However, in reality PPP in streams mainly occur in mixtures, possibly leading to underestimation of the toxicity of mixtures. In this context, the present study compiled monitoring data from the US, France and parts of Germany, yielding a dataset of 3030 sites, 60,255 sampling occasions and 406 PPPs and metabolites with similar effects as the parent compound. We analysed the mean and the standard deviation of the compound number of mixtures occurring in the respective areas. Additionally, we compared the number of compounds of mixtures which include different PPP types like herbicides, fungicides and insecticides. In 28,440 of the samples (~ 47%) PPPs and metabolites were detected. The percentage of sites with PPP contamination varied strongly between 96% and 70% in the different regions, which could be attributed to region specific differences in the site selection process, selection of compounds, analytical precision and farming practices. The mean of PPPs and metabolites in mixtures ranges from 3 in France to 9 in Rhineland-Palatinate (Germany), whereas the standard deviation is relatively similar at about 3. In mixtures of different PPP types, mixtures including fungicides and metabolites have about 7 compounds in mean, whereas mixtures solely composed of herbicides are only composed of 2.5 compounds on average. An underestimation of the number of PPPs and metabolites in surface waters via monitoring campaigns might be caused by the selection of target chemicals but also by relying on grab sampling as the main sampling strategy. Further analysis should scrutinise whether the regional differences in mean but also in compositions of the mixtures can be explained by considering the land use and dominant agricultural crop upstream of the sampling sites.

### TU365

#### Application of different scenarios for the impact assessment of micropollutants in mixtures under the Water Framework Directive.

N. Pucheux, F. Botta, A. JAMES-CASAS, S. ANDRES, INERIS  
The assessment of chemical status under the WFD is currently made based on a limited number of chemicals, most of them being assessed individually. In a few cases, chemicals are evaluated as a family (e.g. PBDEs) and the environmental quality standard (EQS) is compared to the sum of the compounds defined in the family, assuming that it is the addition of these compounds effect that affects a specific target. In the surface waters, chemicals occur as mixtures, and these mixtures composition varies as a function of anthropogenic pressures. In order to propose a methodology taking into account the co-occurrence of chemicals, several approaches are applied on the chemicals measured on 8 sampling points and 2 genuine stations. The sampling points have been selected as a function of pressure (agricultural, industrial, and residential). As a part of a national monitoring campaign, 182 chemicals were monitored in these stations. In order to estimate the risk at a local scale, alternative approaches are investigated, including the following

ones. The taxonomic group approach is founded on the fact that some substances may all affect a specific organism or taxon. This approach consists in identifying substances that are the most dangerous for a taxon (algae, invertebrate and fish) in order to group them together and sum up the measured concentrations. The mode of action (MoA) approach is a tentative to sum up the measured concentrations of substances that have the same effect on organisms and to calculate a threshold for the most frequently encountered MoAs. The pragmatic approach is founded on the fact that the bad water status may sometimes be linked to one or a few substances which are particularly toxic and that these contribute mainly to the toxicity of the mixture. Comparison of these alternative approaches is done, in relation to the anthropogenic pressures applied at each station, in order to highlight the approach leading to the most realistic results, in other words to evaluate if one of these approaches allows an assessment more consistent with the observed ecological status than the traditional individual or additive methods.

### TU366

#### What are relevant compounds from an effect perspective? - Mode of action considerations for compounds and mixtures detected in different European rivers

W. Busch, Helmholtz centre for environmental research - UFZ / Bioanalytical Ecotoxicology; D. De Zwart, RIVM / Centre for Sustainability Environment and Health; S. Schmidt, N. Ost, Helmholtz centre for environmental research - UFZ; T. Schulze, M. Krauss, Helmholtz centre for environmental research - UFZ / Effect Directed Analysis; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment; R. Altenburger, UFC Centre for Environmental Research / Department of Bioanalytical Ecotoxicology

Environmental risk assessment for chemicals is still based on a few regulated compounds. Nowadays, chemists are able to analyze and detect thousands of compounds even in very low concentrations. Neither the biological effects of single anthropogenic compounds in the environment nor the potential adversity of combined effects of chemical mixtures are considered within monitoring strategies and risk evaluation, so far. Chemicals can be grouped in different ways, e.g. according to their chemical structural properties (chemical group), their application domains (use group), their frequencies of occurrence or environmental concentrations, but also with respect to their biological modes of action. It is well known, that e.g. Organophosphates act as Acetylcholine Esterase inhibitors. Linking such mechanistic information with measured environmental concentrations might improve the assessment of combined effects. Therefore, we performed a literature and database research on the modes of action of about 1000 compounds that have been detected in different European river catchments. In a second step we filtered the data for compounds potentially relevant for ecotoxicity by a very rough hazard estimation using the ratios of the detected concentrations and measured (if available) or predicted effect concentrations. We analyzed whether certain modes of action are potentially predominant and how the picture is changing when similar acting compounds are considered as a group. The poster will summarize the findings of this exercise and give an outlook on how the knowledge of modes of action might be further implemented in assay development and/or compound selection on the way towards a biological effect assessment of chemical mixtures.

### TU367

#### Initial risk assessment and effects of mixtures of plant protection products

K. Petersen, Norwegian Institute for Water Research; M. Stenrod, Bioforsk; T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment  
From a study conducted in 2013, it was found that the measured concentrations of co-occurring plant protection products (PPP) in selected agricultural streams in Norway might pose an environmental risk based on an initial cumulative risk assessment. The scenarios having the highest predicted environmental risk were chosen for a follow up study including laboratory tests and chemical analysis to validate the approach for cumulative risk assessment and to evaluate the use of assessment factors. A synthetic mixture based on the measured concentrations of detected PPPs in a stream with one of the highest predicted environmental risks was prepared. The ratio between the compounds in the synthetic mixture was made to reflect the ratio detected in the environment and was kept constant over all mixture concentrations. A concentration series of the mixture, including the environmental concentrations, was tested on *clamydomonas reinhardtii*, *daphnia magna* and *lemna minor* to investigate potential effects as indicated by the predicted environmental risk. Chemical analysis was performed on the highest and lowest mixture concentration in addition to controls. Dose-response curves were developed, making it possible to evaluate at which mixture concentrations effects were first observed for the different species. In order to study potential synergistic effects of PPPs, a second stream was chosen for the follow up-study. No compounds with known synergistic effect were detected in concentrations above limit of quantification in the stream, but two compounds with known synergistic effect were reported to be much used in the area. Therefore it was of interest to include these two compounds in a fractionated factorial design together with the synthetic mixture based on the environmental concentrations in the stream. The different mixture combinations of the synthetic mixture and the two additional compounds were tested on *daphnia magna*. The initial predictive risk assessment was improved by filling data gaps for missing effect data. A comparison of ad hoc derived PNECs, derived EQSs from the literature and environmental hazard values

was performed to identify if the difference in the values between these approaches was due to use of different effect data or by different use of assessment factors. The results are believed to contribute to the validation of the cumulative predictive risk assessment approach and to evaluate the use of assessment factors in this approach.

## Science communication - Concepts and activities from past and current research projects (P)

### TU368

#### **A conceptual framework for solutions-oriented prioritization and management of chemical pollutants**

J. Munthe, IVL Swedish Environmental Research Institute Ltd; E. Brorström-Lundén, IVL Swedish Environmental Research Institute; M. Rahmberg, T.V. Rydberg, IVL Swedish Environmental Research Institute; W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect Directed Analysis; A. van Wezel, KWR Watercycle Research Institute / Chemical Water Quality and Health; G. Engelen, Vlaamse Instelling voor Technologisch Onderzoek NV VITO; F. Slegers; B. Gawlik, EC JRC Ispra, Italy; D. Bunke, Öko-Institut e.V. / Sustainable Products Material Flows Division; J. van Gils, DELTARES; J. Slobodnik, Environmental Institute; R. Altenburger, UFC Centre for Environmental Research / Department of Bioanalytical Ecotoxicology; L. Posthuma, RIVM / Centre for Sustainability Environment and Health SOLUTIONS is a project based on a solutions-oriented approach. This approach includes the development of a logical framework and guidance on how analytical tools and models can be applied to provide answers to specific questions and to achieve results which form the basis for risk assessment and decision-making. The solutions-oriented approach requires that management options and stakeholder and regulatory views and problems should be addressed already at the problem-formulation stage and not only after completing the risk assessment and prioritisation. One of the primary tasks in the project is to develop a conceptual framework for this solutions-oriented approach for surface water contamination. The conceptual framework for this solutions-oriented approach will clearly demonstrate: tools, models and key expertise required; the requirements for accuracy, validation and application scales; the sequence of application; and abatement measures. Its early design and its application should improve the utility of the risk assessments which are done. The solutions-oriented approach means identification of proper technical and non-technical management options to reduce risks or negative impacts on ecosystem or human health in every step. This solution oriented approach has a central role in the framework and identifying possible abatement measures will be an additional task in all research activities, focussed on identifying chemical contaminants, their effects and their transport in different environmental media. In this approach, a classical risk assessment is thus combined with a parallel evaluation of alternative and realistic abatement scenarios. By applying a solutions-focussed conceptual framework to organise and visualise the research and expected results from the SOLUTIONS project, the applicability and completeness of the performed research will be ensured. The conceptual framework will also form the basis for the development of the decision support tool RiBaTox which will be the main route to the project results for stakeholders and end-users.

### TU369

#### **Interdisciplinary collaborations and risk communication**

A. Hunka, University of Twente / Faculty of Behavioural Sciences; M. Meli, Rifcon GmbH; A. Palmqvist, Roskilde University / Department of Environmental Social and Spatial Change; V.E. Forbes, University of Nebraska Lincoln / School of Biological Sciences

Environmental risk communication draws upon environmental and human toxicology findings, utilises methods of social science, natural science and media studies and impacts the area of public perception, understanding of science and risk management. Also outside a research lab, social, cultural and economic facets of risk are inseparably present in decisions made under uncertainty. Risk communication clearly requires interdisciplinary approaches. Interdisciplinarity, especially in the area of climate change and environmental hazards, is gaining in popularity. Still research teams that cross several disciplines face many challenges at the institutional level, such as limited access to funding as well as communication obstacles. The aim of our study is twofold. First, we identified benefits and potential challenges to interdisciplinary work in the area of environmental risk communication. Second, we compared several written samples related to risk communication (scientific papers, popular science, outreach material) written by experts in different fields: sociology, ecology, media studies, political science, chemistry and by interdisciplinary teams, in order to identify whether interdisciplinary work improves the accessibility of communication about risk. We chose a single topic of pesticide risk, as it tends to generate interest among scientists from different disciplines. It is also widely covered by the popular press, which can be used as a benchmark for risk communication accessibility, as the general public increasingly turns to the internet and other media in search of information about risks. Our preliminary findings show that different disciplines remain disparate, using their own terminology, methods and jargon even if the studied topic is identical. Interdisciplinary studies tend to be popular in applied science, where the goal is to address a practical problem, rather than advance fundamental knowledge. Interdisciplinary teams, on the one hand, often produce more accessible output,

since researchers with different background have to collaborate and understand each other. On the other hand, it is not uncommon that only one of the contributing discipline's terminology dominates in such projects. We conclude that it is necessary to address institutional obstacles to interdisciplinary research and provide early training in interdisciplinary communication to promote interdisciplinary collaborations and, in turn, better risk communication.

Heiss, general aspects of water and soil protection; T. Seiler, RWTH Aachen University / Ecosystem Analysis; P.Y. Kunz; C. Kienle; V. Dulio, INERIS; S. Valsecchi, Water Research Institute - Italian National Research Council IRSA-CNR; m. carere,

**Regulatory and risk assessment background and needs:** In the context of the European Union (EU) Water Framework Directive (WFD) it is recognised that pharmaceuticals may pose a risk to the quality of European water bodies. Three substances with pharmaceutical use are included in the first so-called "watch list". However, monitoring of steroidal estrogens may be difficult because of the detection limits of most existing routine analytical methods and the high cost of high-end analytical methods. Sensitive effect-based methods are of reducing the current monitoring difficulties by measuring the estrogenic activity of environmental samples in a cost-efficient way. **Project description:** The project will focus on specific effect-based methods and best possible analytical methods related to the watch list substances EE2, E2 and E1. For this purpose, 20 l surface water and 20 wastewater samples across Europe will be collected and analysed. Approximately 20 institutes or agencies from 13 nations will be involved in the project. **Detection methods covered:** Best possible chemical analysis (Joint Research Centre (JRC), IT, and Federal Institute of Hydrology (BfG), DE) and eight effect-based methods. Some of the effect-based methods applied here are currently going through the OECD validation process or being developed as ISO standards. **Results and discussion:** We mainly discuss project characteristics and objectives in this abstract: a) Promoting reliable screening methods to support the monitoring of endocrine disrupting activity in wastewater and surface water b) Harmonizing monitoring options across Europe c) Linking reliable effect-based tools with regulatory needs d) Linking effect-based tools with chemical analysis for estrogen monitoring e) Supporting national and EU monitoring for endocrine disruptors **Conclusions and expected outcomes:** Only a limited number of institutes in Europe currently have the capacity to quantify the steroidal estrogens EE2 and E2 at their suggested EQS levels. This could cause problems for the EU watch list mechanism, where reliable exposure data are required. In this project we will provide harmonised methods for sample collection, sample extraction and data evaluation, and screening and risk assessment. This activity will provide a proof-of-concept for integrated monitoring of estrogenic substances and aims to bridge the gap between conventional analytical and effect-based monitoring.

### TU371

#### **Advances in ecological risk assessment of multiple stressors**

C.B. Choung, Environment Canada Canadian Rivers Institute / Department of Biology; P.J. van den Brink, Alterra and Wageningen University; W.G. Landis, Western Washington University / Institute of Environmental Toxicology; M. Mayer-Pinto, University of New South Wales / Evolution Ecology Research Centre School of Biological Earth and Environmental Sciences; V.J. Pettigrove, The University of Melbourne / Zoology; P. Scanes, NSW Office of Environment and Heritage; R.A. Smith, DSITIA; J.L. Stauber, CSIRO

One of the biggest challenges of environmental sciences is how to assess the effects of multiple stressors, both natural and anthropogenic, on ecosystems. Ecosystems are highly complex and interconnected, with many interactions among multiple stressors, multiple exposure pathways and multiple receptors. Moreover, responses of aquatic communities to stressors are often context dependent and vary along environmental gradients. These characteristics make assessment and prediction of risks from multiple stressors highly challenging. Current approaches fail to incorporate this complexity needed to reliably predict effects on natural systems. With recent advances in key areas such as ecological modelling, biomonitoring science, ecogenomics and earth observation technologies - many of which are truly ground-breaking - significant new opportunities for the study of complex stress regimes are now available. In order to assess how emerging science and new tools can be applied to study multiple stressors at a large (ecosystem) scale and to facilitate greater integration of approaches among different scientific disciplines, a

workshop was organised on 10-12 September 2014 at the Sydney Institute of Marine Sciences, Sydney, Australia. This workshop aimed to explore the potential offered by these new approaches to characterise stressor regimes, to explore stressor-response relationships among biota, to design better early-warning systems and to develop smart tools to support sustainable management of human activities through more efficient regulation. This presentation will discuss the limitations of the current assessment approaches and how multiple stressors at large scales can be better evaluated in ecological risk assessments to inform the development of more efficient and preventive management policies based on adaptive management in the future. At the same time, a future risk assessment paradigm that overcomes these limitations will be presented. It is envisaged that through greater integration of approaches among different scientific disciplines, together with the application of new and emerging tools such as 'Big Data', ecological modelling and incorporation of ecosystem services endpoints will make this achievable.

#### TU372

##### **DERIVING ENVIRONMENTAL QUALITY STANDARDS FOR PERFLUOROOCTANOIC ACID (PFOA) AND RELATED SHORT CHAIN PERFLUORINATED ALKYL ACIDS**

S. Valsecchi, Water Research Institute - Italian National Research Council IRSA-CNR; S. Polesello, Water Research Institute- CNR / Water Research Institute; S. Capri, Water Research Institute - National Research Council; E. Preziosi, IRSA-CNR Water Research Institute; m. carere; L. Lucentini, E. Ferretti, R. Crebelli, ISS Istituto Superiore di Sanità; D. Conti, S. Balzamo, Istituto Superiore per la Protezione e la Ricerca Ambientale ISPRA; M.G. Simeone, ISPRA- Institute for Environmental Protection and Research; F. Aste, MATTM Ministry of the Environment Land and Sea

The evidence that in Northern Italy significant sources of perfluoroalkylacids (PFAA) are present induced the Italian government to establish a Working Group on Environmental Quality Standard (EQS) for PFAA in order to include some of them in the list of national specific pollutants (Ministerial Decree 260/2010) for surface water monitoring and classification in the context of the Water Framework Directive (2000/60/EC). The substances have been chosen by considering the statistical distribution of concentrations and frequency of detection in the Italian surface and ground waters. The substances in the list included perfluorooctanoic acid (PFOA) and related short chain (number of carbon < 7) perfluorocarboxylic acids such as perfluorobutanoic acid (PFBA), perfluoropentanoic acid (PFPeA) and perfluorohexanoic acid (PFHxA). Perfluorobutanesulphonic acid (PFBS), which is a common substitute of perfluorooctanesulphonic acid (PFOS), has been included too. For each of these substances a dossier has been prepared which collects available data on regulation, physico-chemical properties, emission and sources, occurrence, acute and chronic toxicity on aquatic species and mammals, including humans. Quality standards (QS) have been derived for the different protection objectives (pelagic and benthic communities, predators by secondary poisoning, human health via consumption of fishery products and water) according to the protocol recommended by the Technical Guidance Document on deriving EQS (CIS-WFD Guidance n. 27). The most protective QS has been chosen as the national EQS. For all compounds it is not possible to derive a QS for sediments because in some cases compounds do not accumulate in sediment and in other cases data on toxicity on benthic community are lacking. For PFBA, PFPeA, PFHxA and PFBS it is not possible also to back-calculate a QS for water from QS for biota because they have low bioaccumulation properties or data on bioconcentration factors (BCF) are lacking. For these compounds limits derived for the protection of human health by drinking water consumption are adopted as EQS. In the case of PFOA it is possible to derive a QS for biota both for the protection of predators and human via fish consumption and back-calculate QS for water. The calculation resulted in a QS for secondary poisoning of  $0.1 \mu\text{g L}^{-1}$  which has been proposed as EQS for PFOA in internal surface waters.

## **Soil and water pollutants' assessment, monitoring and remediation (P)**

#### TU373

##### **Spatial and temporal variability of the water and sediments quality in the Alqueva reservoir (Guadiana Basin; Southern Portugal)**

P. Palma, Instituto Politécnico de Beja / Department of Technologies and Applied Sciences; L. Ledo, Instituto Politécnico de Beja; S. Soares, Polytechnic Institute of Beja; I. Barbosa, Centro de Estudos Farmacêuticos, Faculdade de Farmácia, Universidade de Coimbra; P. Alvarenga, Polytechnic Institute of Beja / Department of Technologies and Applied Sciences

The purpose of this work was to evaluate the dynamic of the water quality from the Alqueva reservoir (Guadiana River Basin, Portugal) and identify the most important parameters that influence its ecological and chemical status. The results could indicate preventive and/or remediation actions that are necessary to improve its quality and status. Water and sediment samples were collected between 2011 and 2012, at five sampling stations, and analysed for: (i) water - pH, temperature, dissolved oxygen, electrical conductivity, chloride, total phosphorus, total nitrogen, ammonium, nitrate, nitrite, biochemical and chemical oxygen demand, total Fe, Mn, and As; and (ii) sediments - pH, electrical conductivity, organic matter, total nitrogen, total phosphorus, major and trace elements. The results from the water

column showed that the organic descriptors exceeded the Portuguese guideline values for water quality for multiple uses at most of the sampling stations. As for nutrients, Ajuda is the station where the concentrations of the total nitrogen and total phosphorus exceeded the guideline values in most months. Ammonium achieved concentrations above the allowed, during the study, in all locations. Trace elements were more abundant in the sediments, surpassing the maximum levels for the protection of aquatic life for As, Cd and Pb, at Alcarache, Lucefecit and Álamos, respectively. The use of multivariate analysis showed that the major parameters that explained the water quality variability were the nutrients in the water column, and trace elements in the sediments. Comparing the results from this study with results obtained since 2006, we can observe an obvious increment of the organic descriptors and nutrients in the water body. Further, several parameters and observations indicate an increase of the eutrophication process. So, it is urgent to develop preventive actions and remediation processes to stop the degradation so as to improve the quality of the water in this reservoir.

#### TU374

##### **Experimental study on reduction in rain water penetration through industrial windows used for natural ventilation**

K. Prueksakorn, Changwon National University / Environmental Engineering; S. Dahal, Changwon National University / Department of Environmental Engineering; C. Piao, H. Ha, Changwon National University / Ventech Corp; T. Kim, Changwon National University / Department of Environmental Engineering

Windows are commonly used in industrial, residential and other buildings for ventilation purpose which helps to save energy as well as costs. Several industrial buildings install windows which is continuously open for dilution of pollutants. While windows are functional and efficient for natural ventilation, an amount of rain water is able to penetrate through during wind-driven rain as well. There are industries that their products are very sensitive to water and it is indispensable to prevent the appearance of needless water from external sources. The aim of this research is to ascertain the innovative design for windows to accomplish optimum combination of higher ventilation and lower rain penetration. For this purpose, a model with two-stepped window [800×800 mm] was prepared. Mimic rain of 50 mm/hr and wind velocity of 8 m/s were created to represent the average rainfall and wind velocity in Korea. Generally, louver type, 90° and 45° open windows are widely used in industries. Ventilation capacity was measured for these three types of windows and found that 90° open window gave the best result; hence, it was used for further experiments on rain penetration. Initially, visual observation of rain penetration trajectory was made through high-speed shooting and the results were used to test various methods of control. The control techniques included changing the angles of windows and use of (1) window extension up to 50% of the window width, (2) rain collector, (3) buffer material for soft landing cushion and (4) guide vanes. These methods were tested individually and were further investigated for different combinations of the techniques. For each case, intensity of rain penetration was measured and its reduction compared to basic 90° open windows was analyzed. The maximum reduction in rain penetration of about 98% was attained by 50% increment of window width, installation of rain collector and addition of buffer material on the upper surface of bottom step in 90° open window. For other combinations, reduction of rain penetration was around 90% compared to the best set of 90° open window. The experimental results explain that by using windows with appropriate combination of components, it is possible to achieve best possible ventilation capacity without significant amount of rain penetration into internal space of building.

#### TU375

##### **Assessment of various contaminants present in sediments and water in Khalid Khor, Shajah, United Arab Emirates**

F. Samara, B. Soghomonian, S.L. Knuteson, American University of Sharjah / Biology Chemistry and Environmental Sciences

Over the last 20 years the United Arab Emirates (UAE) has been going through several changes and improvements which have led to rapid urbanization of the country especially in cities such as Dubai, Abu Dhabi and Sharjah. Samples were collected from Khalid Khor port and Khalid Khor Lake to assess the water quality. The water quality measurements were taken on site by using various meters. The Elemental Analysis for Water Samples and Sediment samples were conducted using the Inductively Coupled Plasma- Optical Emission Spectroscopy (ICP-OES) and organic analysis was conducted using Gas Chromatography- Mass Spectroscopy (GC-MS). Various parameters such as pH and alkalinity indicated normal water quality levels. On the other hand, bacterial contamination was detected in the port ranging between 300-10140 organisms/100ml. The concentration of heavy and trace metals in sediments ranged from 0.066- 12668 mg/Kg, indicating low to average inorganic contamination. Organic compounds such as Benzene, Benz[a]anthracene, Benzo[j]fluoranthene and O-Xylene were qualitatively detected in the sediments, thus, indicating that Khalid Khor has some contamination that could potentially affect the health impacts to residents in Sharjah.

#### TU376

##### **Filter-feeding polychaete Sabella spallanzanii as bioremediator of aquaculture wastes**

L. Granada, Escola Superior de Turismo e Tecnologia do Mar - Instituto Politécnico

de Leiria; S. Lopes, Polytechnic Institute of Leiria / ESTM; M.F. Lemos, Instituto Politécnico de Leiria / Dept Biology

Aquaculture practices, like most other human activities affect the environment in different ways. Recently, some attention has been dedicated to the effects of discharges of effluents from certain types of aquaculture. Aquaculture operations cause the release of metabolic waste products which is considered one of the most important factors causing organic and inorganic loading in the vicinities of aquatic farms. Suspended solids have been considered one of the most important waste products affecting the quality of the receiving waters and their environment. Also, both in aquaculture facilities and in natural aquatic environment, the occurrence of several diseases have emerged as a serious economic and ecological issue, and are a significant constraint to the expansion of the industry. The control of endemic diseases imposes severe year-on-year costs on producers. Integrated Multi-trophic Aquaculture (IMTA) has been proposed to achieve environmental sustainability through biomitigation of aquaculture wastes which has advantages that may include economic stability by product diversification and risk reduction, and social acceptability through best management practices. IMTA is a practice in which the by-products from one species are recycled to become inputs for another through the cultivation, in the right proportions, of fed aquaculture species (e.g. finfish/shrimp) with organic extractive species (e.g. suspension and deposit feeders), and inorganic extractive aquaculture species (e.g. seaweeds). The reduction of microbial pollution within aquaculture can be achieved by the use of living organisms. Filter-feeding marine macroinvertebrates filter large volumes of water for their food requirements and exert high efficiency in retaining small particles including bacteria. Some authors showed that the Mediterranean polychaete *Sabella spallanzanii* has ability to filter, accumulate and remove suspended solids in waste waters to which bacteria can be attached. The aim of the present study was to assess the bioremediation potential of the filter-feeding polychaete *S. spallanzanii*, by its ability to remove bacterial groups including *E. coli* and presumptive vibrios, co-cultured with the highly valued marine fish *Sparus aurata*.

### TU377

#### Comparison of the measured threshold permeate flux values during NF purification of 2-phase and 3-phase olive mill wastewater

J. Ochando-Pulido, University of Granada / Chemical Engineering; M. Víctor-Ortega, Chemical Engineering; A. Martínez-Ferez, University of Granada

This paper deals with the measurement of the critical and threshold flux for determination of incurring fouling issues of a batch membrane in series process, in detail ultrafiltration followed by nanofiltration, for the purification of olive mill wastewater streams exiting the 2-phase (OMW-2) and 3-phase (OMW-3) olive oil extraction processes. The analysis of the experimental data suggests the existence of threshold flux values for the NF membranes. NF suffers less fouling (~54.4%) if compared to previous UF. Moreover, threshold fluxes are sensibly affected by the adopted pretreatment processes: the best method appears to be a pH-T flocculation process, followed by photocatalysis with ferromagnetic-core titanium dioxide nanoparticles under ultraviolet irradiation (UV/TiO<sub>2</sub>). The magnetic nanocores were used due to their improved efficiency in oxidating organic matter as well as for their ease to recover them back by a magnetic trap and to reuse the catalyst in subsequent batches without additional costs. In this way, fouling is confined and guarantees COD values in the purified permeate stream of about 1.3 g L<sup>-1</sup>. This value complies with irrigation water quality standards. Moreover, the adoption of this treatment sequence leads to a reduction of the required membrane area, equal to 104.6 m<sup>2</sup> and 81.4 m<sup>2</sup> for the UF and NF membranes, respectively. As a consequence, a limited overdesign of the membrane plant is needed. Additionally to this, the longevity of the membranes sensibly increases, reducing the capital and operating costs of the treatment, which results to be economically feasible.

#### Performance modelization of an ultrafiltration membrane in the final purification of olive mill wastewater by the boundary flux theory

J. Ochando-Pulido, University of Granada / Chemical Engineering; M. Víctor-Ortega, Chemical Engineering; M. Stoller, University of Rome / Chemical Engineering; A. Martínez-Ferez, University of Granada

In 2011, Field and Pearce introduced a new concept called threshold flux to distinguish low fouling and high fouling operating conditions for both continuous and batch membrane operation modes [1]. Moreover, it was observed that compared to the sustainable flux, which embody only economic criterions, the threshold flux is somehow connected to the critical flux at its basis level, which is the appearance of fouling phenomena. Indeed, the latter concept extends the previous theory of the critical flux, previously introduced by Field et al. [2] and

successively merged together by Stoller and Ochando [3] in a common term, that is, the boundary flux [1-3]. Many studies already showed that a decrease of the boundary flux values occur when the suspension concentration rises. This appears to be a critical aspect, especially in the treatment of real wastewater, where the nature of the particles leading to fouling issues is widely heterogeneous. This study is focused on the modelization and control of the fouling issues of a ultrafiltration (UF) membrane process for the reclamation of olive mill wastewater from a two-phase extraction process (OMW-2) [2, 4]. Previously, OMW-2 was conducted to a secondary treatment comprising whether by gridding plus pH-T flocculation and TiO<sub>2</sub>/UV photocatalysis (FS<sub>1</sub>) or simply (ii) gridding and pH-T flocculation (FS<sub>2</sub>). Results were compared on the basis of the boundary flux modelization of the UF membrane. In the present study, the applied UV/TiO<sub>2</sub> photocatalysis process helped reducing the constant fouling parameter (a), that is 37.5% lower, and ensured higher J<sub>b</sub> values on the UF membrane (13.2 L h<sup>-1</sup> m<sup>-2</sup>). Moreover, 17.1% minor membrane area is required when UV/TiO<sub>2</sub> photocatalysis is performed as pretreatment after pH-T flocculation. These results imply lower energy costs and capital costs and can help rendering the reclamation of OMW-2 by membranes economically feasible. **Keywords:** olive mill wastewater, membranes, nanofiltration, advanced oxidation. **References** [1] R.W. #### Photo-Fenton treatment eliminates drugs of abuse pollution in natural waters and reduces toxicity

M. Catala Rodríguez, N. Domínguez, A. Mígens, Universidad Rey Juan Carlos / Biology and Geology Physics and Inorganic Chemistry; R. Molina, F. Martínez, Universidad Rey Juan Carlos / Energy Chemical Environmental Mechanical Technology and Analytical Chemistry; Y. Valcárcel, Universidad Rey Juan Carlos / Department of Preventive Medicine Public Health Immunology and Medical Microbiology; N. Mastroianni, Institute for Environmental Assessment and Water Research / Environmental Chemistry; M. López de Alda, Institute of Environmental Assessment and Water Research IDAEA CSIC / Environmental Chemistry; D. Barcelo, IQAB-CSIC / Institute for Environmental Assessment and Water Research; Y. Segura, Universidad Rey Juan Carlos / Energy Chemical Environmental Mechanical Technology and Analytical Chemistry

This paper investigates the elimination of drugs of abuse 25 from six different chemical classes and their metabolites in natural fluvial waters (nearby the output of the sewage system). Mineralization of these substances and toxicological characterization before and after treatment by a heterogeneous photo-Fenton process has been evaluated. According to the results, the photo-Fenton treatment significantly reduced the concentration of drugs of abuse in all the conditions tested. However, toxicological analysis demonstrated that whereas 0.6 g/L of the Fe catalyst allowed a complete elimination of acute and chronic toxicity measured as inhibition of fern spore mitochondrial activity, lower catalyst loadings were not efficient for toxicity elimination. These results evidence that the combination of toxicological tests with chemical analysis is mandatory in order to establish the effectiveness of the water treatment technologies based on advanced oxidation processes.

#### Optimization of the azo dye Disperse Yellow 3 oxidation by heat-activated persulfate using Box - Behnken design

J.E. Silveira, Ingeniería Química; X. Xu, G. Pliego, J. Zazo, J. Casas, Universidad Autónoma de Madrid

Response surface methodology (RSM) based on Box-Behnken (BBD) design was successfully applied to the optimization in the operating conditions of the oxidation of the azo dye Disperse Yellow 3 (DY3). All experiments were performed in the glass water-jacketed and the temperature was maintained by circulating the water through the jacket around the reactor. The initial DY3 concentration of 70 mg L<sup>-1</sup> was used. It was employed the factorial design with 3 independent variables: S<sub>2</sub>O<sub>8</sub><sup>2-</sup> (mM), temperature (°C) and reaction time (min) upon the Total Organic Carbon (TOC) and absorbance removal were evaluated λ max=369 nm. Optimized conditions were obtained for the highest desirability at 4.26 mM without residual persulfate, 59.61 min and 90°C. Under the optimal conditions, 99.40% of TOC and 100% absorbance removal was achieved and fitted with the Arrhenius equation (apparent activation energy of 280.58 kJ mol<sup>-1</sup>). In addition the treatment provided total elimination of toxicity by *Vibrio fischeri* bioassays (28 units toxicity). A kinetic model was proposed for describing the evolution of TOC. The best correlation coefficients were obtained by fitting the experimental data obtained by pseudo-first-order kinetics. The influence of the operating conditions on the kinetic constants was also studied by evaluation of main effects and Pareto diagram. **Keywords:** Response Surface Methodology (RSM), Disperse Yellow 3, sulfate radical, toxicity, *Vibrio fischeri*

### TU381

#### Integrating biomedical intervention strategies with novel pollutant remediation platforms to address POP risk reduction

B.J. Newsome, University of Kentucky / Chemistry; B. Hennig, University of

Due to their relative chemical stability and ubiquity in the environment, chlorinated organic contaminants such as polychlorinated biphenyls (PCBs) pose significant health risks and enduring remediation challenges. Addressing associated needs, though, relies on both effectively removing pollutants from contaminated sites as well as modulating toxicity induced by existing pollutant body burden. This work highlights a sustainable approach to addressing a pervasive global health concern, employing research in biomedical intervention strategies and platform development for pollutant removal and remediation. A polyphenol-functionalized, nanocomposite system has been developed which combines the biomimetic binding capabilities of nutrient polyphenols with the separation and heating capabilities of superparamagnetic iron oxide NPs for the capture/sensing of organic contaminants in polluted water sources. Magnetic nanocomposite microparticles (MNM)s incorporating the fluorescent polyphenols quercetin and curcumin exhibit high affinity for model organic pollutants followed by rapid magnetic separation, addressing the need for sustainable pollutant remediation. Further, a membrane-based, redox-mediated system for organic pollutant dechlorination has been developed to work in tandem with the pollutant capture/removal system in an attempt at more complete and environmentally conscious remediation. Further work has been performed to both better understand health concerns associated with environmental toxicants such as PCBs and to determine effective methods for modulating their toxicity. This research has shown that PCB remediation through dechlorination is a viable technique for decreasing endothelial inflammation, although complete dechlorination to biphenyl is necessary to effectively eliminate superoxide production, NF $\kappa$ B activation, and induction of inflammatory markers. Additionally, the nutrient polyphenol EGCG, found in green tea, has been shown to serve as a biomedical modulator of *in vivo* PCB toxicity by up-regulating a battery of antioxidant enzymes transcriptionally controlled by AhR and Nrf2 proteins. This work combined with research translation efforts to inform regulators, transfer remediation technologies, and engage trainees in communication to diverse stakeholders, this approach serves as a model for increasing researcher and stakeholder environmental health literacy as we seek to more effectively address needs of affected populations.

### TU382

#### In situ biological treatment of nitrate-polluted groundwater for drinking water production

I. Jubany, Fundacio CTM Centre Tecnologic / Environmental Technology; M. Calderer, Fundacio CTM Centre Tecnologic / Environment Technology Area; E. Vilanova, J. Font-Capo, J. Molinero, Amphos21 Consulting S.L.; R. Grau, E. Pinto, Catalana de Perforacions; M. Rovira, Fundacio CTM Centre Tecnologic  
This study was conducted in the framework of Life+ InSiTrate project which is developing an in-situ treatment technology for drinking water production from nitrate-polluted groundwater with the aim to recover drinking water wells especially for small communities with a lack of other available freshwater sources. Initially, the most appropriate organic matter for denitrification was selected. The selection of the organic substrate is a crucial point when implementing biological treatments since it directly affects the feasibility of the technology. To define the optimal organic substrate for in situ denitrification, technical (laboratory experiments), economic (cost analysis) and environmental criteria (LCA) were taken into account in this project. Acetic acid showed the most promising results. At the same time, the site for the pilot plant implementation was characterized to design the pilot plant based on predictive modeling. Predictive modeling and optimization of the plant design require detailed hydrologic characterization and moreover, remedial actions depend on adequate characterization of the hydraulic properties of geologic material at the sites. In the alluvial aquifer placed above granitic basement where the plant was to be installed, different characterization tasks were conducted: hydrogeological study, piezometric maps, drilling of new boreholes, periodical characterization of the groundwater quality and pumping and tracer tests. These data together with the results of lab experiments were included in a numerical model which considers reactive transport of contaminants. Using this tool and considering the physical constraints of the specific site the pilot plant configuration was defined. It consisted of one extraction well and two injection wells for the organic matter supply located at 30 and 35 m, respectively, from the extraction well. Two control wells in between the injection wells and the extraction well were also built in order to monitor the biological process. Injection of organic matter was performed continuously for three months and fast nitrate depletion was observed. Continuous monitoring of nitrate concentration in the extraction well was performed by means of a nitrate sensor. Periodic sampling of control wells and other surrounding wells was performed to monitor main parameters of the process: pH, redox, nitrate, nitrite, organic matter and metals. This work will show the results of the first three months operation.

### TU383

#### Evaluation of the mutagenicity of the dye Acid Red 114 using HepG2 cells, after and before biodegradation process.

N.A. Corroqué, Unesp - Institute of Biosciences / Biology; R.V. HARA, UNESP - UNIV ESTADUAL PAULISTA / Department of Biology; M. Hoshina, Unesp - Institute of Biology / Biology; M.A. Marin-Morales, UNIVERSIDADE ESTADUAL PAULISTA - UNESP / Department of Biology  
Water bodies have been discharge targets of several industries, among them the

textile industries. Among the most widely used textile dyes there are the azo dyes and within them the Acid Red 114. Biodegradation processes and biological adsorption have shown to be very promising to remove the colour and toxic effects of the dyes. This study aimed to evaluate the genotoxic and mutagenic potential of the dye Acid Red 114, by the micronucleus test in HepG2 cells, before and after biodegradation process by microorganisms isolated from the sludge of a textile industry. To assess the genetic toxicity, the cells were exposed to 3 hours to the dye Acid Red 114 (concentrations of 50  $\mu$ g/mL; 25  $\mu$ g/mL; 2.5  $\mu$ g/mL; 0.25  $\mu$ g/mL and 0.025  $\mu$ g/mL). The effects of dye were evaluated before and after the biodegradation process. The negative control – NC and positive control – PC were carried out, respectively with culture medium - MEM and PBS and culture medium - MEM and MMS. Two biodegradation processes were tested: biodegraded 1 (B1), performed with inoculum of *Alcaligenes faecalis* and *Enterococcus faecali*; and biodegraded 2 (B2), performed with inoculum of *Achromobacter denitrificans*. The significance analysis was done by the statistical test ANOVA: one way/Dunnett ( $p < 0.05$ ). For the assays performed before the biodegradation, only the concentrations of 25  $\mu$ g/ml and 0.25  $\mu$ g/mL were not mutagenic for the HepG2 cells. After the B1 biodegradation process, the concentrations tested were still mutagenic, indicating that the products generated by the biodegradation did not reduce the mutagenicity of the dye. However, the concentrations tested in B2 were not mutagenic, showing that the degrading bacterium was effective to eliminate the dye toxicity. Regarding the nuclear abnormalities (NA), the majority of the concentrations were genotoxic before the biodegradation but after biodegradation (B1 and B2), they did not present genotoxic activities. According to these data, it is possible to conclude that the dye Acid Red 114 is potentially genotoxic and mutagenic. The B1 biodegradation process was partially genotoxic and mutagenic. The B1 biodegradation process was partially effective in the removal of the dye toxicity, while B2 was totally effective in this removal.

### TU384

#### Evaluation of heavy metal effect on phenol oxidation by manganese dioxide

J. Jiang, College of Environmental Science and Engineering / College of Environmental Science and Engineering; G. Sheng, Tongji University  
As synthetic manganese oxides are effective for heavy metal adsorption and organic contaminant oxidation, their performance as decontamination agents for combined heavy metal and organic systems has not been fully evaluated. This study determined the adsorption of Co, Ni, Cu, Zn, Cd and Mn ions on synthetic MnO<sub>2</sub> and its subsequent effect on the phenol oxidation. Single- and binary-metal adsorption experiments showed that the adsorption of these metals on MnO<sub>2</sub> followed the order of Cu<sup>2+</sup>>Co<sup>2+</sup>>Ni<sup>2+</sup>≈Mn<sup>2+</sup>≈Cd<sup>2+</sup>>Zn<sup>2+</sup>. The adsorptive selectivity increased monotonically with the adsorption quantity of the metals, except that Mn<sup>2+</sup>, which had an intermediate adsorption among the selected ions, exhibited the highest selectivity on MnO<sub>2</sub>. With coexisting with phenol, all the metal ions suppressed the oxidation of phenol by MnO<sub>2</sub> while the degree of suppression varied. Over the metal concentration range examined, the relationship between phenol oxidation reaction constant ( $k$ ) and metal equilibrium adsorption amount ( $q_e$ ) consisted of two distinct linear segments. At low metal adsorption (approximately  $q_e < 0.6$  mmol/g for Co, Ni, Cu, Cd and  $q_e < 0.1$  mmol/g for Zn, the  $k$  linearly decreased rapidly with increasing metal adsorption. The  $k$  further decreased comparatively more slowly thereafter at higher metal adsorption. By comparison, the suppression effect of Mn adsorption exhibited a single straight  $k$ - $q_e$  line, which might be attributable not only to the coverage of MnO<sub>2</sub> active sites by Mn<sup>2+</sup> but also to the reduction of redox potential of the reaction. These results suggest that manganese oxide oxidation be coupled with additional process(es) to reduce or even eliminate the metal effect for effective decontamination of multi-contamination waters. **Keywords:** Manganese dioxide; Phenol; Adsorption; Oxidation

### TU385

#### Electroflotation applied in the treatment of wastewaters containing chlorimuron-ethyl, a sulfonylurea herbicide

R.R. Rachide Nunes, Universidade de São Paulo / Instituto de Química de São Carlos - IQSC; G.M. Morão, USP - Universidade de São Paulo / IQSC - Instituto de Química de São Carlos; M.d. Rezende, IQSC-USP  
Electroflotation (EF) is an electroanalytical technique commonly used for the separation of substances suspended in an aqueous phase. However, these studies are limited to the separation of wastes or contaminants, without destroying its contaminants. In this study, EF was applied as an advanced oxidation process, aiming to decontaminate wastewater containing sulfonylurea herbicides (chlorimuron-ethyl). Electroflotations were performed in an electroflotator reactor developed in the Laboratory of Environmental Chemistry, Institute of Chemistry of São Carlos - University of São Paulo, Brazil. The reactor was built in acrylic and was endowed of aluminum electrodes. In addition, the anion electrode also was an agitation bar, that ensured the homogeneity of the solution during the process. Four assays were performed with varying salt concentrations (electrolyte - NaCl) and the direct electric current (I) applied on the electrodes. Chemical monitoring was performed to determine the efficiency of the electrochemical process. Analysis of water samples by HPLC allowed the electrochemical reaction to be monitored, indicating a disturbance of the reaction medium (presence of byproducts of degradation). Gas chromatography coupled with mass spectrometry (GC/MS) (Shimadzu GC-2010 MS QP2010 Plus model, Kyoto, Japan) was used to elucidate

a mechanism of degradation and assisted in the identification of the byproducts. According to the chromatograms obtained by HPLC/UV, EF process changed the reaction medium, resulting in a displacement of the herbicide chromatographic peak and the appearance of bands without defined structure, related to generated byproducts. Based on the mass spectrum obtained, a mechanism of degradation was proposed, showing that EF does not totally destroy the chlorimuron-ethyl molecule, but it was successful in breaking important chemical bonds, responsible for the connection sulfonyl-urea. In all, this study provides important information about the possibility of promoting the oxidation of toxic organic compounds by electroflotation, generating less toxic and environmentally adjusted effluents.

#### TU386

##### **Effect of resin dosage on sodium and chloride removal from olive mill wastewater by means of ion exchange**

M. Víctor-Ortega, Chemical Engineering; J. Ochando-Pulido, University of Granada / Chemical Engineering; A. Martínez-Ferez, University of Granada  
Sodium and chloride ions are responsible for the high salinity of olive mill wastewater from an olive mill working with the two-phase decanting technology exiting a primary-secondary treatment (OMW-2ST) [1]. In this research work, the removal of sodium and chloride ions as a function of the resin dosage by Dowex Marathon C (strong acid cation exchange resin) and Amberlite IRA-67 (weak base anion exchange resin), respectively, was investigated. In both cases, the resin dosage was varied from 10 g/L to 175 g/L. Ion exchange (IE) experiments were carried out for 4 hours (until equilibrium was reached) and at room temperature. The experimental results revealed that sodium and chloride removal efficiency increases up to the optimum dosage beyond which the removal efficiency has no change with the resin dosage. As expected, the equilibrium concentration decreases with increasing adsorbent doses for given initial sodium and chloride concentrations, because for a fixed initial solute concentration, increasing adsorbent doses provide greater surface area or adsorption sites [2]. In this sense, a minimum resin dosage is 100 g/L for complete removal of sodium ions by means of Dowex Marathon C (about 97 % removal efficiency), whereas 175 g/L resin dosage was needed to completely uptake chloride ions (around 95 % adsorption efficiency). The studied resins showed high IE capacity for the removal of both sodium and chloride ions as well as reversible uptake of the studied pollutants. Thus, both IE resins have good application potential for the purification of OMW-2ST. [1] Martínez Nieto, L., Hodaifa, G., Rodríguez Vives, S., Giménez Casares, J.A., Ochando, J., 2011. #### TU387

##### **Breakthrough curves study for adsorption of iron on Dowex Marathon C from olive mill wastewater**

M. Víctor-Ortega, Chemical Engineering; J. Ochando-Pulido, University of Granada / Chemical Engineering; A. Martínez-Ferez, University of Granada  
A ferric catalyst is used during the secondary treatment of olive mill wastewater (OMW) by means of advanced chemical oxidation process based on Fenton reaction [1]. For this reason, final olive mill effluent presents traces of iron and thus a complementary treatment, such as ion exchange, is needed. Ion exchange involves the use of synthetic resins where a presaturant ion on the solid phase (in this case  $H^+$ ) is exchanged for the unwanted ions in the water [2]. In the present research work, an adsorption study was carried out using a strong acid cation exchange resin (Dowex Marathon C) as adsorbent in a fixed-bed column for the removal of iron from OMW after secondary treatment. Continuous experiments were performed by setting operating temperature, flow rate and resin amount at 298 K, 10 L/h and 350 g, respectively. After each operational cycle, the resin was washed with diluted HCl. Then, the hydrogen form of the resin was washed with double distilled water to remove all the excess of acid. The dynamics of the adsorption process was modeled using the Adams-Bohart, Thomas, and Clark models. The models were used to predict the breakthrough curves of adsorption systems and to determine the characteristic design parameters of the column. The adsorption data were observed to fit well with all three models. Breakthrough curves were obtained for 50 mg/L and 100 mg/L initial iron concentration with each studied adsorption model. Column performance permits multiple service and regeneration cycles, thus enabling the treatment of considerably large volumes of OMW during the resin service life. #### TU388

##### **Color removal of domestic sewage in urban poor communities by artificial wetlands.**

O.P. Amarante Jr, IFMA / PACA; T.C. Barros, R.T. Paulo, C. Rocha Jr, L. Moura, IFMA; N.M. Brito, IFMA / DAQ; T.R. Franco, UFMA

One of the biggest environmental problems in cities of any size, is the water pollution caused by the disposal of domestic sewage. These effluents have high content of organic matter and nutrient load that can affect the natural dynamics of

water bodies. This impact can transform aquatic environments on land, decreasing the supply of water, food and changing the dynamics of the landscape. An alternative to conventional procedures are called artificial wetlands or phytoremediation which are used in wastewater treatment to remove organic matter and nutrients, or for absorption of essential metals or stroke. These alternative methods may have advantages such as low cost of deployment and maintenance, little need for mechanization and easy operation. The objective of this research was to evaluate the efficiency of removal treatment system of color based on artificial wetlands to be employed in low-income communities. We opted for the banana employment because they have better cost/benefit. Built a prototype pilot scale artificial wetland, in a residence, using plastic sheet for waterproofing and PVC pipes. The liquids were transferred after treatment of the reservoir by gravity, ensuring low operating costs. The effluent used with high load of organic carbon, phosphorus and nitrogen, was from the wastewater of a residence. There was previously a hole where residents cast solid waste. The place area was 13x17 m. The depth ranged between 70 and 100 cm. Plastic sheeting were placed for waterproofing. Six banana seedlings were planted. It was observed that the residents maintained practice to dispose solid waste in wastewater treatment area. Was told that they do not throw the waste treatment system. After three months of operation, five seedlings died. It was observed that the changes that remained was one that was not in the left trees, do not fall fruits over the next area to this change and the effluent of the contribution was related to that individual as well as being located in the region more depth. The seedlings that died were further from the effluent inlet, were shallower, there was shade and fruit trees fall directly on these seedlings. The tarps were attacked by ants causing several holes. The effluent from the outlet pipe was removed by unknown and unauthorized person. There was no evidence effluent treatment efficiently due to the reported facts.

#### TU389

##### **Aquatic humic substances and heavy metals**

M. GONZALEZ GUADARRAMA, M. ARMIENTA HERNANDEZ, Universidad Nacional Autonoma de Mexico / RECURSOS NATURALES INSTITUTO DE GEOFÍSICA

Organic matter has an important role in the chemical speciation of heavy metals. Aquatic humic substances (ASH) are products of degradation of biomolecules and its structure is conformed by monosaccharides, amino-acids and lignins. The complex formation between ASH and heavy metals depends on physicochemical conditions such as pH, redox potential, temperature and others. Environmental implications of this study are the analysis of mobility of As, Cu and Mn, with high ecological importance. The aim of this study is to calculate complexation constants under different conditions of pH, to compare the complexation degree. In addition, we compare reactivity in relation with the source of the AHS :SorocabaRiverandItapanhaúRiverin Brasil andXochimilcoLakeinMexico. These locations have different characteristics, and inputs as industrial discharges, urban runoff, or a pristine site. In this work we present a simple experimental method for determining the complexation constants between AHS from the three places with As, Cu and Mn. Preliminary findings show: a) The complexation constant increases with decreasing pH. b) The AHS show similar values and percentages of complexed metal and complexation constants regardless of the origin. c) The complexes formed vary their properties such as solubility, thus modifying the potential interaction with the aquatic system and its organisms.

#### TU390

##### **Dredging marine sediments in Catania harbour: options for a differentiated use**

F. Pilato, ISPRA-Institute for Environmental Protection and Research; M. Secci, ISPRA Italian Institute for Environmental Protection and Research; S. Macchia, ISPRA Institute for Environmental Protection and Research; D. Sartori; L. Morroni, ISPRAInstitute for Environmental Protection and Research; S. Giuliani, ISPRA; T. Cillari, V. Vitiello, B. Stancanelli, ISPRA Italian Institute for Environmental Protection and Research; d. Pellegrini, ISPRAInstitute for Environmental Protection and Research  
Since 2004, the Institute of Environmental protection and research ISPRA is involved in a series of technical and scientific activities related to the dredging of marine sediments within the new commercial port of Catania, Sicily (Italy). In 2010, ISPRA started to carry out a new **characterization of dredging materials**, with the aim to find **sustainable solutions** to allocate the dredged sediments, in alternative to the undifferentiated discharge at sea. Solutions were identified in agreement with the guidelines given by the technical- scientific "*Manual handling of marine sediments* ." APAT - ICRAM 2007 and based on the environmental data obtained over the last decade. Sediment characterization and subsequent environmental monitoring activities were carried out using an integrated approach. In addition to traditional chemical and physical analysis, were performed Mussel Watch campaigns, study of benthos community and different batteries of bioassays (*Paracentrotus lividus*, *Acartia tonsa*, *Phaeodactylum tricornutum*, *Vibrio fischeri*). The results of characterization allowed to identify **different quality classes of materials**, according to the their physical, chemical and ecotoxicological properties. Then, a selective dredging was suggested to differentiate the final destinations of sediments to be removed (about 1.5 million cubic meters ), with clear socio- economic and environmental benefits. **Three different solutions** have been adopted: 1 - Reuse of sand within the building process of new docks and port

yards: 350,000 m<sup>3</sup> of material were employed, otherwise extracted from quarries land; 2 - Nourishment of beaches of the Catania gulf and subjected to erosion: 350,000 m<sup>3</sup>; 3 - Discharge at sea in a specific site authorized by the Environmental Minister: 800,000 m<sup>3</sup> representing the remaining material. In this study, management criteria and detailed results of the physical, chemical and ecotoxicological characterization of dredging materials are reported.

### TU391

#### **Sorption of selected pharmaceuticals and personal care products (PPCPs) in agricultural soils**

N. Torres-Fuentes, [c. corada](#), E. Gonzalez-Mazo, University of Cadiz / Physical Chemistry; D. Alvarez-Muñoz; P. Lara-Martin, University of Cadiz  
A wide variety of pharmaceuticals and personal care products (PPCPs) are produced extensively and, after use, a fraction of these chemicals may end in terrestrial ecosystems, mainly due to contamination by both treated and untreated wastewater discharges and/or by application of biosolids to agricultural soils. Their transport and fate in soils and aquifers depends on the molecular structure of the contaminant and the environmental conditions. In this study, we have selected several PPCPs that have been previously detected by our research group in soils and/or groundwater from the aquifer of Jerez de la Frontera (SW Spain): hydrochlorothiazide (HCTZ), metoprolol (MTP), clarithromycin (CLTM), mefenamic acid (MEF), and triclocarban (TCC). We have carried out several sorption assays at different temperatures (5, 15, 25 and 35 °C), pH values (from 2 to 12) and water/soil ratios to compare the sorption capacity of these chemicals in agricultural soils from that sampling area. First, physico-chemical properties of soil samples were determined in the laboratory: pH, organic carbon content, water holding capacity and texture. Sorption assays were performed using the batch equilibrium method according to OECD guidelines (TG 106). Briefly, 80 mL polypropylene tubes were filled with soil (0.5 – 2 g) and HPLC water (50 mL) spiked with target compounds at concentrations from 0.1 to 500 ng/L. After agitation (steady state was reached within 48 h), both phases were separated by centrifugation and determination of the concentration of the analytes was carried out by liquid chromatography - time-of-flight - mass spectrometry (LC-ToF-MS). Data for each pharmaceutical were fitted to a Freundlich isotherm model ( $R^2 > 0.95$ ). Freundlich sorption constants (K<sub>f</sub>) for the selected compounds ranged between: 10 and 158 L/kg for HCTZ, 31 and 104 L/kg for MTP, 783 and 6045 L/kg for CLTM, 21 and 55 L/kg for MEF, and 1014 and 5106 L/kg for TCC. Most of these PPCPs show relatively high leaching potential, especially when compared with most well-known hydrophobic persistent organic pollutants (i.e., DDT). However, their sorption capacity may change dramatically depending on environmental conditions such as temperature (which was evaluated by calculation of thermodynamic parameters such as  $\Delta H^\circ$ ,  $\Delta G^\circ$ , and  $\Delta S^\circ$ ) and pH. This was evident for those compounds such as CLTM, showing positively charged groups in their molecular structures (if pH > 6) that enhance their interaction with clays in soils.

### TU392

#### **Improved understanding of triphenyltin sorption on cultivated soils**

X. xiaoyu, School of Life Sciences

**Abstract:** Organotin compounds, especially triphenyltin (TPT), have been widely used as wood preservatives, pesticides and fungicides since the 1960s because of their high effective toxicity, which resulted in a large number of TPT directly introduction into the soil and aquatic environment. Inadequate knowledge of TPT sorption on soil has hindered an accurate evaluation of its environmental fate that is mostly complicated by the dual metal-hydrophobic nature of TPT. An improved understanding of TPT sorption and its influential factors is in much need to fully assess the ecological risks of TPT in the soil environment. In the present study, TPT sorption on five Chinese cultivated soils, named black soil (A), calcareous soil (B), lateritic red soil (C), brown soil (D) and red soil (E), respectively, was estimated using the batch equilibration method as influenced by pH and biochar (BC) amendment. The results showed that all sorption isotherms of TPT fitted well by linear equation in the five soil samples, implying partitioning is the dominant mechanism. TPT sorption increased with the increase of the organic carbon content on soils with their sorption coefficients (K<sub>D</sub>) in the sequence of A (1708.6–4194.7 L/kg) > B (276.2–574.5 L/kg) > C (217.1–497.5 L/kg) > D (88.3–155.7 L/kg) > E (27.4–75.4 L/kg). In addition, the higher CEC of the soils may also enhance the TPT sorption. The changes of pH influenced intensively the species of TPT, resulting in the maximum sorption of TPT occurred at pH 5.27 (the pK<sub>a</sub> of TPT) due to enhanced ion exchange. Moreover, TPT was one orders of magnitude more effectively sorbed by BC than by total organic carbon of A. BC fraction was considered to be the primary contributor to TPT sorption on soils. **Key words:** soil; triphenyltin; sorption; pH; biochar

#### **Behavior of seven selected pharmaceuticals in thirteen different soils**

R. Kodesova, M. Kocarek, A. Klement, Czech University of Life Sciences Prague / Dept of Soil Science and Soil Protection; R. Grabic, University of South Bohemia in CB / Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses; M. Fer, Czech University of Life Sciences Prague / Dept of Soil Science and Soil Protection; O. Golovko, University of South Bohemia in CB / Lab of Environmental Chemistry

Biochemistry; A. Nikodem, O. Jaksik, Czech University of Life Sciences Prague / Dept of Soil Science and Soil Protection; V. Kodes, Czech Hydrometeorological Institute / Section of water quality

Knowledge of contaminant behavior (e.g. its adsorption onto soil particle, degradation etc.) is essential when assessing contaminant migration in water environment. This study was focused on evaluating adsorption isotherms and half-lives for 7 pharmaceuticals (clarithromycin, trimethoprim, metoprolol, atenolol, clindamycin, carbamazepine, sulfamethoxazole) on 13 soils of different soil properties. Adsorption of ionizable compounds was highly affected by soil pH. The adsorption coefficient of sulfamethoxazole was negatively correlated to soil pH and thus positively related to hydrolytic acidity and exchangeable acidity. Adsorption coefficients for clindamycin and clarithromycin were positively related to soil pH and thus negatively related to hydrolytic acidity and exchangeable acidity and positively related to base cation saturation. Adsorption coefficients for the remaining pharmaceuticals (trimethoprim, metoprolol, atenolol, and carbamazepine) were also positively correlated with the base cation saturation and cation exchange capacity. Degradation rates in some degree reflected adsorption of studied pharmaceuticals on soil particles and increased with decreasing adsorption. The highest mobility in studied soil was observed for sulfamethoxazole, but this pharmaceutical was relatively quickly degraded. The second highest mobility was found for carbamazepine, which mostly did not noticeably degrade during our experiments. Thus this pharmaceutical has the highest potential to migrate in water environment. The lowest mobility was observed for clarithromycin. However, this pharmaceutical due to its stability may be retained in the environment for long time.

### TU394

#### **Environmental fate of a micro granular form of the insecticide cypermethrin in sunflower cultivated field plots**

N. Mantzos, Technological Educational Institute of Epirus / Faculty of Agricultural Technology; A. karakitsou, [D. Hela](#), University of Patras; E. Leneti, Technological Educational Institute of Epirus; I. Konstantinou, Department of Environmental and Natural resources Management

A field dissipation and transport study of a micro granular form of the insecticide cypermethrin (CYP) has been conducted in a sunflower cultivation under Mediterranean conditions. The experimental field area (700 m<sup>2</sup>) (silty clay soil) was divided in two groups of six plots each with a plot dimension of 4x10 m<sup>2</sup>. One group of plots was used for sunflower cultivation when the other one as control plots (bare soil plots). Two different slopes (1% and 5%) were formed in each group. In the lower side of every plot a surface runoff collection reservoir was established. Soil samples were randomly taken at two depths: 0–10 and 10–20 cm. Runoff water and sediment samples were collected after rainfall or irrigation events. CYP was applied at sowing, in sowing rows (3 to 5 cm depth), as micro granules of a commercial MG formulation at a rate of 96 g/ha. The dissipation of CYP in soil was monitored for a period of 191 days. In the upper soil layer, 2 days after application (DAA), CYP residual concentrations ranged from 0.53 to 0.73 µg/g when the maximum values observed at 9 DAA, ranged from 1.06 to 1.23 µg/g. The dissipation rate was better described by single first-order kinetics. The average half-life in cultivated plots was 23.07 and 24.24 days for soil slopes 5% and 1%. In uncultivated plots the respective values were 22.01 and 22.37 days. CYP was found below the 10 cm soil layer occasionally in few samples at low concentrations (< 0.09 µg/g) while it was never detected in runoff water. In sediment, in the first runoff event (12 DAA) the concentrations ranged from 0.019 (cultivated 1% soil slope) to 0.035 µg/g (cultivated 5% soil slope). The maximum values were observed 57 DAA, when they were reached 0.097 and 0.143 µg/g in cultivated plots with soil slopes 1% and 5%; and 0.394 and 0.500 µg/g in uncultivated plots. The CYP concentrations felt below LOQ levels after 133 DAA. The cumulative losses in sediment from tilled and untilled plots with 5% soil slope was estimated at 0.039% and 0.069% of the initially applied active ingredient, while for 1% slope the losses were 0.005% for tilled and untilled plots. **Acknowledgments:** This research has been co-financed by the European Union (European Social Fund - ESF) and Greek national funds through the Operational Program "Education and Lifelong Learning" of the National Strategic Reference Framework (NSRF) - Research Funding Program: ARCHIMEDES III. Investing in knowledge society through the European Social Fund.

#### **Effects of forest fires on the levels and distribution of polycyclic aromatic hydrocarbons in soils and ashes**

I. Campos, Universidade de Aveiro / Department of Environment; N. Abrantes, University of Aveiro / CESAMDAO; J. Keizer, Department of Environment Centre for Environmental and Marine Studies CESAM University of Aveiro Aveiro Portugal; C. Vale, IPMA Instituto Portugues do Mar e da Atmosfera; C. Micaelo, IPIMAR; P. Pereira, Department of Biology and CESAM Polycyclic aromatic hydrocarbons (PAHs) are widespread ubiquitous environmental contaminants, which had received major concern regarding public health and environmental impact due to their toxic, carcinogenic, mutagenic and tetragenic activity, as well as their environmental persistence and tendency for bioaccumulation. Although forest fires have been identified as an important source of PAHs little data is available concerning the effects of forest fires (including the role of ash) on the soil PAH content. To address this issue, we investigated the

temporal trends and profiles of fifteen priority PAHs according to the United States Environmental Protection Agency in soil and ash samples collected immediately, 4, 8 and 15 months after a forest fire (IAF, 4,8, 15MAF, respectively) in Ermida, North-centre of Portugal. Analyses of PAHs were performed on a gas chromatography-mass spectrometry (GC-MS). IAF the concentrations of PAHs in burnt soils were higher than in the corresponding non-burnt soil samples (70%). However, 4, 8 and 15MAF these levels decreased considerably to those of the non-burnt soil. In the non-burnt soil, no temporal differences were recorded. The burnt soils and ashes were characterized by higher levels of light PAHs with three to four rings, reflecting direct emissions from biomass burning. Moreover, the three rings showed a pronounced decrease over time-since-fire. For the non-burnt soils, phenanthrene (PHE) and fluoranthene (FLT) were the most abundant compounds, 20% each, followed by pyrene (PYR) with 16%. For the burnt soils, we observed 40% of PHE, followed by FLT (15%) and PYR (10%). The ashes samples showed high fractions of PHE (35%), fluorene (FLU; 24%), FLT (10%) and PYR (10%), with a temporal decrease of FLU (14%) and a slightly increase of PHE (40%). The levels of PAHs in ashes were consistently enriched in PAHs relatively to corresponding soils, suggesting that soil were contaminated by ash-derived PAHs. Our results clearly suggest that PAHs produced by the forest fires seems to be adsorbed by soil and ash, being ash one of the main agent influencing the concentration of PAHs in the soil. Moreover, the decrease in PAHs levels over time, mainly due to the washout of the ash, may indicate that PAHs can be transport downstream by soil/ash runoff. This study point out the importance of further studies to assess the impact of PAHs in aquatic systems downstream to burnt areas. Keywords: Wildfire; PAHs; Assessment; Soil

### TU396

#### Characterization of a fuel contaminated site for the implementation of combined decontamination techniques

R. Millán, CIEMAT / Department of Environment; M. RODRÍGUEZ-RASTRERO, M. Sierra, T. SCHMID, F. DÍAZ-PUENTE, N. ARÉVALO, O. ESCOLANO, CIEMAT / Environmental  
Fuel spills is a global concern problem that affects soil and water and need of an innovative an environmental friendly solutions. When a heterogeneous media is affected, the combination of different technologies could be recommended. In this framework, the Life Bioxisoil Project (Life ENV 11/ES/505) develops a combination of chemical and biological based technologies to be applied in an aged contaminated site located in SW of Spain. The complex characteristics of the site, an operative industrial facility in a saltmarsh area within a military area had required of an exhaustive characterization of 1.5 Ha to be treated. Physicochemical and biological parameters have been studied in surface and in depth, taking into account pedological and sedimentological criteria. The obtained results show a wide range of THPs affection (in surface and in depth); salt content variability and high calcium carbonate content among others. Furthermore, this area shows a relevant seasonal influence and a critical anthropogenic impact. The selected techniques are: "in situ" chemical oxidation, fitotechnology and enhanced natural attenuation that have been adapted taking into account these specific characteristics and are currently being tested simultaneously. The obtained data will be the base in order to develop an adequate protocol to recuperate this site and can be extrapolated to similar contaminated areas. Keywords: Fuel contamination, site characterization, remediation

### TU397

#### The MINETOX project: a multidisciplinary approach to assess the effects of biochar on the fate and toxicity of mine wastes under changing hydrology using bioassays with plants and soil invertebrates

Díez-Ortiz, Leitat Technological Center; J. Martínez-Sánchez, M. Vicente, Escuela Técnica Superior de Ingeniería Agronómica Universidad Politécnica de Cartagena / Producción Vegetal; I. García, F. del Moral, Universidad de Almería; H.M. Conesa, A.A. Calderón, M. Ferrer, M. Tercero, I.M. Párraga-Aguado, Escuela Técnica Superior de Ingeniería Agronómica Universidad Politécnica de Cartagena / Ciencia y Tecnología Agraria; J.A. Sánchez, Universidad de Almería / Department of Agronomy; S. de Haro, Universidad de Almería; M. Delgado, Universidad de Murcia / Q Agrícola Geología y Edafología; V. Gonzalez, Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR; J.A. Franco, Escuela Técnica Superior de Ingeniería Agronómica Universidad Politécnica de Cartagena / Producción Vegetal; C. van Gestel, VU University Amsterdam / Ecological Science; M. González-Alcaraz, Faculty of Earth and Life Sciences, VU University / Ecological Science

MINETOX is a coordinated project financed by the Ministerio de Economía y Competitividad of Spain that aims to evaluate the effect of biochar from urban wastes and sewage sludge on the fate and toxicity of mine wastes. The project comprises three sub-projects developed by Spanish research centres: Universidad Politécnica de Cartagena (subproject CGL2013-49009-C3-1-R), Universidad de Almería (subproject CGL2013-49009-C3-3-R), and Acondicionamiento Terrasense-LEITAT (subproject CGL2013-49009-C3-2-R), with the collaboration of the VU University, Amsterdam. The overarching aim of this project is to assess the toxicity of mine tailings from old mine exploitations before and after

amendments with different types of biochars. To achieve this objective, this study will address the following aspects: \* The viability of the soil seed bank from the mine tailings area will be studied, and further recommendations pointing at a recovery of the vegetation cover will be established. \* Column experiments with acid and basic mine wastes will be set up. The treatments tested include additions of different types of biochars, presence/absence of plants, and changing hydric conditions, in order to ascertain the fate of metal(loid)s. The pH and redox potential (Eh) will be regularly monitored, and soil pore water and leachate samples extracted from the columns to determine their metal(loid) concentrations before and after the amendments. \* The biogeochemical mechanisms implied in the role of biochar to immobilise metal(loid)s will be studied by means of specific equilibrium trials with mixtures mine wastes vs. biochar. \* The effectiveness of the treatments to reduce the toxicity of the soil pore water, leachates and the solid phase will be evaluated by means of a battery of ecotoxicity tests which include seeds germination, plantlets development, genotoxicity, and earthworms and enchytraeids survival and reproduction. \* At the end of the experiment, the plants will be collected from the columns and concentrations of metal(loid)s in leaves and roots analysed to evaluate the effect of biochar on its absorption and translocation. In addition, the stress of the plants will be assessed by physiological markers. \* Finally, a sequential extraction of soil metal(loid)s will be performed in order to determine how the different treatments influenced its speciation and to relate it with its fate, bioavailability and toxicity. The poster will present the outline and first results of the project.

### TU398

#### Reduction in phytotoxicity of hydrocarbon contaminated soil by remediation using agricultural wastes

D.D. Davis, Newcastle University / Civil Engineering and Geosciences; M.D. Jones, Newcastle University / School of Civil Engineering Geoscience; I. Singleton, Newcastle University / School of Biology  
The growing interest in composted materials demand the measuring of their toxicity to determine if human risk-based criteria are met. As a result, plant sensitivity is increasingly being used as a bioindicator in the assessment of the efficacy of remediation treatments. This study uses phytotoxicity tests to assess the ecological health of coal tar-contaminated soil which has undergone bioremediation by composting with agricultural wastes (spent mushroom compost and straw) as feedstock. The total petroleum hydrocarbon (TPH) and polycyclic aromatic hydrocarbon (PAH) concentrations where measured before, during and after the composting duration. Corn, pea and mustard seeds were used for testing seed germination and plant growth of the pre- and post-composted matrix. After 56 days of composting, the TPH concentrations were significantly reduced by 78% to 387µg/g while those of the total PAHs reduced from 681 to 242µg/g. Comparing fertility of the compost matrices, the germination rate increased by 78% and 33% for the corn and pea seeds, respectively, 5 days after planting and 92% for the mustard seed 3 days after planting. The results generated from the chemical and toxicity assays revealed that the health of the contaminated soil was significantly improved after the compost-bioremediation.

### TU399

#### Oxyfluorfen dissipation and its impact on microbial communities in sunflower field study cultivation

N. Mantzos, Technological Educational Institute of Epirus / Faculty of Agricultural Technology; S. Nikolaki, University of Patras / Department of Environmental and Natural resources Management; D. Hela, University of Patras; G. Tsiamis, University of Patras / Environmental and Natural Resources Management; K. Bourtzis, University of Patras / Department of Environmental and Natural resources Management; I. Konstantinou, Department of Environmental and Natural resources Management

A field dissipation study of oxyfluorfen (OXY) herbicide and its impact on soil microbial communities has been conducted in a sunflower cultivation under Mediterranean conditions. The experimental field area (silty clay soil) was divided in two groups of six plots each of 4x10 m<sup>2</sup> area. One group of plots was used for sunflower cultivation while the other one was the group of control plots. Two slopes (1% and 5%) were carved out in each group. Soil samples were randomly taken at two depths: 0–10 and 10–20 cm. OXY was applied pre-emergently as a water emulsion of a commercial EC formulation at a rate of 233 g/ha. The dissipation of OXY in soil was monitored for a period of 191 days. The initial OXY concentrations (3 h after application) ranged from 0.142 (cultivated 1% slope) to 0.149 µg/g (uncultivated 5% slope). The half-life in the cultivated plots using first-order kinetics was determined to 45 and 46.5 days for slopes 5% and 1%. In uncultivated plots the respective values were 50.9 and 52.9 days. The impact on soil microorganisms has been assessed at population level by deploying a 16S rRNA Illumina amplicon sequencing approach. Pyrotags assays were carried out using universal primers U341F/805R targeting the V3-V4 variable regions. 16S rRNA sequences were analyzed as follows: (a) the reads were trimmed to remove sequencing adaptors, low quality base calls (< 30 Phred score) and size-selected (between 350 and 500 bp) using the QIIME pipeline filtering scripts, (b) high quality sequence reads that have not been flagged as chimeras have been clustered into operational taxonomic units (OTUs), based on a sequence identity threshold of 97%, using Uclust, (c) drawing of one sequence for each OTU as representative was performed and then aligned to the Greengenes database using PyNast, (d) the

sequence representatives of each OTU has been taxonomically classified by BLASTn-based comparisons to the Greengenes and Silva databases within QIIME. The resulting set of OTUs will be used in diversity analyses. This approach will enable us to characterize in detail the impact of the OXY on the soil bacterial communities. **Acknowledgments:** This research has been co-financed by the European Union (European Social Fund - ESF) and Greek national funds through the Operational Program "Education and Lifelong Learning" of the National Strategic Reference Framework (NSRF) - Research Funding Program: ARCHIMEDES III. Investing in knowledge society through the European Social Fund.

#### TU400

##### MITIGATING EFFECT OF HUMATE ON MICROMYCETE COMMUNITIES IN COPPER CONTAMINATED SOIL

V. Terekhova, Institute of Ecology and Evolution RAS / Lab Ecological Soil Functions; A. Ivanova, Lomonosov Moscow State University; E. Fedoseeva, A.N. Severtsov Institute of Ecology and Evolution; M. Akulova, Moscow State University / Department of Soil Science; K. Kydralieva, Institute of Chemistry and Chemical Technology; O. Yakimenko, Moscow State University / Soil Science Faculty

In contaminated soils within a micromycetes complex the depletion of species composition, the increase of eurytops' part and the species which are not authentic to the zonal soil conditions, and also the raise of potentially pathogenic species occur. Humic substances (HS) are used as agents for remediation of contaminated soils. They are able to influence metabolic pathways of organic and nonorganic ecotoxicants and show usually mitigating effects. Influence of combinations heavy metals and humate on micromycetes poorly understood. The aim of this experimental work is to study the effect of copper and humic substances on the dynamics the fungal biodiversity. Mycobiota of the artificial soils with the addition of heavy metal (Cu) 264 and 528 mg/kg as well as 0.1 and 1.0 g/kg humate (potassium humate produced from peat) was investigated. In our experiments the presence of Cu and humate in the growth medium caused a significant change in the community composition of cultivated fungi. It was primarily indicated by low values of the *Sørensen*-Chekanovsky index in comparison with the control samples. The addition of Cu and humate in different degrees stimulated the growth of metal-resistant genera *Aspergillus* and *Penicillium*, dark-colored genera *Chaetomium* and *Paraconiothyrium* and potentially pathogenic *Fusarium*. At the same time the addition of any components resulted in the elimination of genus *Pseudogymnoascus*. Humate had a positive effect on species composition of micromycetes communities. It was shown in the decline of the part of potentially pathogenic fungi included in the list of Biosafety Levels BSL1 and BSL2 (<http://www.absa.org/resriskgroup.html>). In the case when lower metal concentration (264 mg/kg) and humate (0.1 and 1.0 g/kg) presented in growth medium the part of pathogenic fungi included in both levels decreased. However, in the samples with combined addition of higher metal concentrations (528 mg/kg) and humate in both concentrations was noted a slight increase in the proportion of fungi included in the list of BSL2. Thus, it was shown that copper leads to qualitative disturbances of a natural community of cultivated fungi, and an addition of humate able to mitigate these consequences to some degree, but not completely. **Acknowledgements:** This study is supported by Russian Foundation for Basic Research (12-04-01230a) and ISTC (Project # KR-2092).

#### TU401

##### Is *Eisenia fetida* a suitable species to monitor environmental soil genotoxicants ?

S. Lemièrre, Fonctionnement des Ecosystèmes Anthropisés; A. Deram, University of Lille 2 / Laboratoire des Sciences Végétales et Fongiques Faculté de Pharmacie; F. BERNARD, LGCgE, Université de Lille 1 / Laboratoire des Sciences Végétales et Fongiques; A. Lepretre, LGCgE - EA 4515; F. VANDENBULCKE, LGCgE, Université de Lille 1 / LGCgE EA Univ Lille Fonctionnement des Ecosystèmes Terrestres Anthropisés Cité Scientifique SN Rdc F Villeneuve d'Ascq France As well as for air and waters, not only chemical analyses have to be taken into account to monitor anthropic contamination of soils. Biological responses of exposed organisms should be considered too and particularly for environmental genotoxicants such as PAHs or metals. Soil contaminations are complex. For instance, environmental availabilities, the environmental and toxicological bioavailabilities of contaminants may be influenced by soil parameters, ageing phenomena, organic matter content, and their concomitant presence at often low concentrations... Thus, an integrated vision of their toxicity (and genotoxicity) has to consider their potential interactions. For these reasons, classical genetic toxicology (indirect testing, unrealistic exposure...) did not seem fully satisfactory. Several years ago we developed an environmental genotoxicity marker with *Eisenia fetida*: the comet assay. This is a technique allowing the evaluation of DNA damage (single and double strand breaks, alkali-labile sites) in a cellular population and it was validated on cœlomocytes of this biological model largely used in soil ecotoxicology. In this poster presentation, we will present obtained results in different contexts with this environmental genotoxicity marker: exposures to field-contaminated soils (1), to soils spiked with a mixture of metals (2) and to soils after a remediation treatment (3). In a first work (1), *in vivo* short-term exposures of *E. fetida* were conducted using soils sampled in two different areas in the North of France: from the vicinity of a former smelter and from a suburb zone close to a

battery plant still in activity. In the second (2), in order to better understand metal interactions, *in vivo* short to mid-term exposures (3, 10 and 56 days) were performed using an urban-surrounding soil spiked with cadmium or/and lead at concentrations found in french contaminated soils. In the last work (3), *in vivo* short-term exposures of *E. fetida* were conducted using a contaminated soil sampled in the field and a reference soil contaminated or not by a mixture of lead, zinc and cadmium. Effects of remediation agents (biochars from two origins) at two concentrations were evaluated. In all cases, obtained genotoxicity results after these exposures will be detailed. We will try to discuss the interests and limits of our environmental genotoxicity marker and to conclude if it is useful and relevant to monitor anthropic contaminated soils.

#### TU402

##### Aided phytostabilisation : Influence of fly ashes on metal mobility, microbial viability and oxidative stress of tree species grown in Pb, Cd and Zn highly contaminated site

A. Verdin, Université du Littoral Côte d'Opale / Unité de Chimie Environnementale et Interactions sur le Vivant UCEIV EA; J. Fontaine, S. Firmin, S. Labidi, Université du Littoral Côte d'Opale; F. Douay, LGCgE - EA 4515; P. Shirali, A. Lounes Hadj Sahraoui, Université du Littoral Côte d'Opale

Combined use of *in situ* stabilization and energy production from forest biomass is a cost effective technique being explored to confront the problem of phytomanagement of metal contaminated sites. Between different amendments studied, Coal Fly Ash (CFA) has been shown to reduce metals mobility and to limit physico-chemical characteristics modifications of the soils due to the afforestation. Moreover, others studies revealed CFA efficiency to impair metal accumulation and to alleviate stress in several plants species. However, little is known about the plant health promoting action of these amendments, especially benefits on tree species growing in TE's polluted sites. This *in situ* study aimed at evaluating the long-term effects of CFA as metal immobilizing agent in aided phytostabilization of a former agricultural field highly contaminated with cadmium, lead and zinc, affected by the activity of the Metaleurop Nord smelter (Noyelles-Godault, North of France), using four tree species (*Alnus glutinosa* L., *Acer pseudoplatanus* L., *Salix Alba* L., and *Robinia pseudoacacia* L.). Before being planted with a tree mix in 2000, the site was divided in a reference plot (R) with no amendment and two plots amended with silico-aluminos (FA1) and sulfo-calcic fly ash (FA2). Eleven years after plantation, antioxidants systems (glutathione status, superoxide dismutase and peroxidase activities) and oxidative damages (malondialdehyde production and 8-hydroxydeoxyguanosine formation) in leaves were monitored as biological indicators of the trees health. Metallic stress was also evaluated by analysis of lipid composition and content, the determination of saturated fatty acids/unsaturated fatty acids ratio and omega 3 index: C18:3/(C18:0+C18:1+C18:2). Taken together, information on physiological response of trees to metallic pollution will help us to select species and soil amendments suitable for the phytoremediation of the experimental site.

##### Polyurethane Rigid Foam from Vegetable Polyol with Residual Inorganic Load Applied to Removal of Oleophilic Contaminants.

V.R. Silva, O.S. Santos, Federal University of Minas Gerais / Chemistry Department; M.C. Silva, Federal University of Itajubá / Materials Engineering; M.I. Yoshida, Federal University of Minas Gerais / Chemistry Department Solid extractor materials have emerged as a powerful tool in extracting pollutants in water. Among these materials, polyurethane foam (PUF, a polymeric cellular material) gained importance in the recent times, as solid extractors in toxic substances sorption processes. Due to the high porosity and presence of potential active sites such as amine, carbonyl and carboxyl groups, and hydrophobic carbon chains, PUF is present as a versatile alternative to removal of hydrophilic as well hydrophobic substances. Regarding to fats and oil removal, are considered good absorbent materials that show hydrophobic groups and high rates of absorption and retention of oleophilic substances. The PUF presents these important characteristics. This paper presents some results of the use of polyurethane rigid foams (PURF), with and without inorganic filler, as car engine oil absorber. The PURF used in this study were synthesized from vegetable oil (castor oil, widely available in tropical countries such as Brazil), replacing petrochemical polyols, which gives them a biodegradability character. This is an important feature, since after the use of a material as a solid extractor for several cycles, is necessary a properly dispose of it. The possibility of biodegradation is an alternative to minimize the residual material accumulation after sorption processes. The inorganic filler used is an industrial residue from alumina production (*P3 Residue*), rich in  $Al_2O_3$  and  $Al(OH)_3$ . The use of *P3 Residue* as a filler is an attempt to contribute to reduce the environmental impact caused by the accumulation of solid industrial waste and add value to a residual material. The absorption studies showed a three fold increase in the load foam sorption capacity, when compared with foams without inorganic filler. The introduction of waste as inorganic filler, besides improving the flame retardancy characteristics of the foams, increased their average cell size of about 40%. Despite not oleophilic characteristics of the inorganic filler, the increase of average cell size and open/broken cells contributes to higher oil absorption by the foam.

#### TU404

## REMEDICATION POTENTIALS OF PLEUROTUS FLORIDA ON SPENT LUBRICATING OIL CONTAMINATED SOIL

O.O. Fadina, University of Ibadan, Nigeria / crop protection and environmental biology

Soil and surface water contaminations by spent lubricating oil (SLO) are common occurrences in most developing countries where agriculture is the mainstay of rural inhabitants, especially in the oil producing ones. This is rapidly increasing due to global rise in use of petroleum products. The white-rot fungus, *Pleurotus florida* was investigated for its ability to mineralize heavy metals, improve soil nutrients and reduce the Total Petroleum Hydrocarbon (TPH) in spent lubricating oil contaminated soil after 2 months. 4kg of top soil was thoroughly mixed with 100ml, 200ml, 400ml, 800ml and 1600ml of the oil to give 2.5%, 5%, 10%, 20% and 40% contamination levels respectively and a set of control was kept (0%). 10g of vigorously growing spawn of the fungus was added and observed at 1 and 2 months of incubation. After 2 months, the total petroleum hydrocarbon (TPH) reduced from 265.33ml/kg to 232 ml/kg for 10% contaminated soil and from 52.33ml/kg to 35ml/kg for 2.5%. Nutrient contents were high at 1 month, followed by a decrease after 2 months. Levels of heavy metals like Mn, Ni, Pb, Cr and Zn fluctuated at 1 month but were followed by significant decreases after 2 months. The levels of Mn and Ni reduced from 9.53mg/kg to 8.81mg/kg, and 9.51mg/kg to 8.23mg/kg respectively for 40% contamination by the end of 2 months. The improvement of nutrient content value, bioaccumulation of heavy metals and reduction of TPH at all levels of SLO concentrations tested through inoculation with *P. florida* is of importance for mycoremediation of spent oil polluted soils. Key words: Total Petroleum Hydrocarbons, remediation soil.

## TU405

**PHYTOREMEDIATION OF METALS and PETROLEUM PRODUCTS FROM INDUSTRIAL WASTEWATER OF PLANTS AT RLIC, QATAR**  
M.Y. Al-Sulaiti, ExxonMobil Research Qatar / Water Reuse; E.M. Abdel Bari, Environmental studies Center- QU; C.S. Warren, ExxonMobil Research Qatar / Advanced Environmental Scientist; I.M. Al-Shaikh, Environmental Studies Center-QU

Qatar is an arid country with limited water resources. LNG activities generate considerable amount of industrial wastewater (IWW). Turning this nuisance into beneficial resource will contribute to sustainable environmental, economic development and facilitate disposal alternatives. Phytoremediation is in use in many countries. It can clean soils and water. The objectives of the native plants experiments were: 1- Set up a system of native plants growth in soil, sand or /and water using IWW, 2- Study the impact of the IWW and the accumulation of organic and inorganic components on growth of some native species, and 3- Identify some microorganisms in IWW or soils that can play a role in the bioremediation processes. Plants growth in sand media containing IWW greatly inhibited seed germination and the subsequent growth of seedlings of *Medicago sativa*, *Hordeum vulgare*, and *Chloris gayana*. Growth of *Phragmites Australis* rhizomes and *Sporobolus ioclados* were hindered considerably. Plants growth in soil, on the other hand, was different from that in sand. The reduction in the germination of barley seeds was considerable and the prophylls of most plants became dry as a sign of toxicity. Growth of seedlings of alfalfa and Rhodes and rhizomes of *Sporobolus ioclados* was slightly affected in soil plots irrigated with IWW. On the other hand reeds seemed promoted by IWW. Significant reduction in the photosynthetic pigments and soluble sugars was caused by IWW in plants studied. Proline, as a stress indicator, did not show any consistency with IWW treatment. Such findings might indicate that the adverse effect of IWW on plants did not have any effect on the proline metabolism. The concentrations of essential elements and heavy metals in the garden soil or sand under all treatments were at acceptable ranges. Moreover, the concentration of essential elements and heavy metals in plant tissues were also at normal range under all the treatments. However, in some samples elements including Cu, Zn and Cr were accumulated considerably. This finding needs further investigation. The reduction in growth of plants in response to IWW cannot be attributed fully to the accumulation of heavy metals and/or the ions that are found normally in saline environment such as Na and/or Cl. For example, although the growth reduction of barley plants under IWW treatment was significant, the concentration of heavy metals and Na and Cl were at normal range.

## TU406

**Plant-microbe interactions in a PCB contaminated soil in the presence of *Medicago sativa* and compost**

M. Di Lenola, National Research Council / Water Research Institute; P. Grenni, National Research Council of Italy (CNR) / Water Research Institute; F. Catteni, V. Ancona, National Research Council of Italy / Water Research Institute; A. Massacci, National Research Council of Italy / Institute of Agro Environment and Forest Biology; A. Barra Caracciolo, National Research Council / Water Research Institute

Polychlorinated biphenyls (PCBs) are persistent pollutants (POPs), exclusively manufactured for industrial applications. Although their production and use was banned almost all over the world more than 30 years ago, they are still commonly found in many ecosystem compartments owing to their high persistence. They are complex technical mixtures of about 30–60 congeners (e.g. Apirolito, produced in Italy and used for electrical transformers). Their biotic degradation can occur through aerobic and anaerobic microbial processes, by metabolism or

co-metabolism (where microorganisms need other sources of carbon and energy and the transformation of pollutants occurs as a concurrent process), but the poor contaminant bioavailability and the requirement for an inducer may hinder microbial degradation. These problems may be overcome through processes based on the interactions between plants and their associated rhizobacteria (Bioassisted phytoremediation or rhizoremediation). Plant may help the contaminant removing, releasing exudates that may serve as growth substrates for the rhizospheric bacteria. Multitudes of soils are considered degraded for both contamination and low organic matter content; in this case, the remediation of contaminated soil by planting and compost addition are essential for improving soil quality. In particular, selected plant species, which are able to promote microbial community activity through the formation of a thick rhizosphere and, consequently, to enrich soil in nutrient content, together with the compost addition can be a useful green remediation technique for promoting contaminant degradation. In order to investigate the interactions between plants and autochthonous microorganisms in the rhizosphere, soil samples were collected from a PCB contaminated area and used for greenhouse microcosm experiments in the presence of the forage species *Medicago sativa* and/or in the presence of Apirolito and municipal solid waste (MSW) compost. Microbiological and chemical analyses were carried out at different times in order to evaluate the changes in the structure and function of microbial populations in relation to the different experimental conditions.

## TU407

**Phytoremediation strategies for dehydration and quality improvement of a manure digestate sludge**

P. Grenni, National Research Council of Italy (CNR) / Water Research Institute; S. Tariciotti, National Research Council of Italy / Water Research Institute; M. Di Lenola, A. Barra Caracciolo, National Research Council / Water Research Institute; A. Massacci, National Research Council of Italy / Institute of Agro Environment and Forest Biology; P. Sconocchia, ARPA Umbria / Servizio Suolo Rifiuti e Bonifiche; D. Liberati, Università degli studi della Tuscia - Viterbo; P. De Angelis, Università degli studi della Tuscia - Viterbo / Dipartimento per la Innovazione nei sistemi Biologici Agroalimentari e Forestali DIBAF

An artificial pond (about 2.6 hectares and 4 meters depth) was filled with the liquid and solid fine residual fraction from a biogas system located in an agricultural area (Central Italy). The resulting sludge consisted of about 80% of water; the fine fraction (20%) was characterized as: sand 15%, silt 60% and clay 25%, without any significant vertical stratification in the pond. The pH and the electrical conductivity were about 8 and 2.5 mS cm<sup>-1</sup>, respectively. The heavy metals detected at high concentrations were copper (1200 mg kg<sup>-1</sup>) and zinc (4000 mg kg<sup>-1</sup>). Zoocompost Project, funded by Umbria Region (Italy), aimed to test a green remediation technology for the treatment of this sludge by using phytoremediation and water phytoextraction. A phytoremediation pilot system was set up in a greenhouse for testing the effectiveness of different plant species and planting methods for sludge dehydration, as well as the quality improvement of the sludge. The tested plants (cuttings or rooted cuttings) were *Tamarix gallica*, *Tamarix africana*, *Phragmites australis* and a combination of *Juncus effusus*, *Iris pseudacorus* and *Carex gracilis*. The plant growth, the sediment water content, the main physico-chemical parameters and the pathogen occurrence in the sludge (*E. coli* and *Enterobacteriaceae*) have been analyzed in the greenhouse experiment. At the same time, the evolution of the microbial community after the plant addition has been evaluated by measuring its abundance, viability, activity (dehydrogenase activity) and diversity (Fluorescence In Situ Hybridization). The results of the first year of experiments are here reported.

**Phytoremediation process for contaminated soils: a life cycle assessment approach**

C. Sablayrolles, INP-ENSIACET; L. Tanfin, INP-Toulouse (Ensiacet) / Laboratoire de Chimie Agro industrielle; C. Vialle, Université de Toulouse / INP-ENSIACET LCA Laboratoire de Chimie Agro industrielle INRA UMR CAI; G. Vilarem, INP-Toulouse Ensiacet / Laboratoire de Chimie Agro industrielle; J. Kallerhoff, Ecolab / Ecolab Laboratoire écologie fonctionnelle et environnement; L. Thannberger, VALGO

Context & Objective A large number of brownfields from former industry remain in France, presenting health and environmental hazards. In the current context, where conventional treatment methods (*ex situ* or *in situ*) are expensive and energy intensive<sup>[1]</sup>, alternative methods have been developed over the past few years such as phytoremediation. After a trial period on the ability of pelargonium to remove trace metals, a decontamination pilot called “*Phytoterre*®” has been set up out of the lab. The objective is to test the functioning of the pilot and to fine-tune the process, in order to be able to extend it to a larger scale. **Methods** The process combines phytoextraction by pelargoniums and leaching of metals with EDTA as chelating agent. Within the *Phytoterre*®, the polluted soil is contained within a watertight membrane and plants are irrigated with water containing 5 mM EDTA. Leachates are recovered through a drainage system and stored in a buffer tank. Throughout the treatment process, metals are eliminated from leachates by a precipitation step and treated water is neutralized before reuse for irrigation. The settled sludge containing metals is collected and sent to a local hazardous waste landfill. Before winter, pelargoniums are harvested and can afterwards be exploited to produce essential oils. The remaining biomass will be sent to the landfill. \n \n

**Results** A Life Cycle Assessment[2] (LCA) was implemented, firstly to assess the environmental impact of the process, and secondly to compare its performances with regards to the traditional excavation and containment method. A cradle-to-grave approach was used, and the whole process was modelled. Stages with high impact on the environment were identified and adjusted in order to improve the process. **Session:** Soil and water pollutants' assessment, monitoring and remediation **Keywords:** Pelargoniums, Trace metals, Life Cycle Analysis, Contaminated soils **Presentation preference:** Poster presentation <br clear="all" /> <sup>[1]</sup> Arshad et al., 2008, A field study of lead phytoextraction by various scented Pelargonium cultivars. ##### **Maximisation of oil recovery from an oil sludge washing process with surfactants considering surfactant type and concentration, and surfactant to oil sludge ratio**

**D.F. Ramirez Guerrero**, University of Reading / Department of Geography and Environmental Science; **C.D. Collins**, Reading University / Soil Research Centre Oil sludges are a complex mixture composed mainly of crude oil, water and sediments. These are hazardous wastes generated in the petroleum extraction and refining processes. Treatment of oil sludges to date has been focused on physicochemical remediation and bioremediation techniques. Oil recovery methods have been applied for obtaining the extracted oil for reuse, and oil sludge washing (OSW) with surfactants are starting to be used. This method consists of using surfactants in order to remove and recover the oil from the sludge matrix. This study aims to maximise the oil recovery considering three important parameters in OSW: surfactant type and concentration, and the surfactant to oil sludge (S/OS) ratio. Four synthetic surfactants [Sodium dodecyl sulphate, SDS (anionic); Tween 80 (T80), Triton X-100 (TX100), and Triton X-114 (TX114) (non-ionics) and one biosurfactant (rhamnolipid)] were used in this study. These surfactants were characterised before OSW. Characterisation included micelle size determination by dynamic light scattering (DLS), critical micelle concentration (CMC) determination by the pendant drop method, and surface activity assessment by the oil displacement test. By confirming the CMC, absolute concentrations in terms of CMC were established for the oil sludge washing study. Toluene was used as co-solvent in the OSW in order to aid in the separation of oil. Due to the high number of possible experimental runs in this study with three factors and five levels, a Taguchi design of experiment methodology was applied for the experimental design to reduce the amount of experimental runs from 125 to 25 per Taguchi replicate. Three replicates of the Taguchi orthogonal array were tested and the recovered oil was measured gravimetrically. S/OS ratio was the factor with the largest effect. The levels with the maximum oil recovery were 1:1 of S/OS ratio, 1CMC of surfactant concentration and TX100. Also, RL and TX114 showed a high effect similar to TX114. In conclusion, low surfactant ratios (1:1) and low surfactant concentrations (1CMC) can be used to reduce costs while maximising the amount of recovered oil. Further treatments may then continue with other remediation techniques to ensure that the sludge have contaminant concentrations below the legal limits if required.

#### TU410

##### **Insolubilizing Effect of Heavy Metals in Soil by Calcium Polysulfide**

**Y. Kawabe**, National Institute of Advanced Industrial Science and Technology (AIST) Japan; **T. Komai**, Tohoku University

Soil contamination by heavy metals such as arsenic or lead have been increasing in Japan. According to ministry of the environment government of Japan, the number of the groundwater or the soil contaminated site of heavy metals is 11,539 cases at the end of 2012. The main cause of those contaminants were natural origin heavy metals, which were widely observed around mine area or hot spring area. As the contamination area by the natural occurring heavy metals was widespread, an in situ treatment method such as insolubilization or bio-treatment would be effective in those area. In this study, leaching behavior of the heavy metals from soil by using calcium polysulfide were evaluated. A long-term soil leaching batch experiment were carried out under various environmental condition. The leaching behaviors were different between aerobic and anaerobic condition. As the leaching values of copper, chromium, zinc, lead and cadmium were below Japanese criteria, those heavy metals were strongly insolubilized in soil as metal sulfide by addition of the calcium polysulfide under the anaerobic condition. In the case of aerobic condition, almost all of heavy metals were initially insolubilized in soil. However, the heavy metals were slowly leached from soil with time, because metal sulfate which has higher solubility were formed by the oxidation of the metal sulfide. In this case, heavy metals were re-insolubilized by changing the environmental condition from the aerobic to anaerobic condition. These results indicate that the calcium polysulfide would be effective for the insolubilization of heavy metals in soil. \n

#### TU411

##### **Bioremediation of benzene, toluene, ethylbenzene, and xylene (BTEX) using non-pathogenic bacterium**

**H. Kim**, S. Lee, Kyonggi University

In recent years, there have been many studies on how to biodegrade poly-aromatic compounds as the benzene, toluene, ethylbenzene, and xylene using various

methods. In this study utilizes high efficient non-pathogenic bacteria such as photosynthetic bacteria and/or LAB (lactic acid bacteria) for remediation of BTEX contaminated soil. Their non-pathogenic characteristics allow them to be a reliable solution for similar groundwater and soil contaminations due to oil-spills. Purple non-sulfur bacteria, *Rhodospirillum rubrum*, showed efficient degradation of 20mg/L of BTE. 1g/L (w/v) of cell mass was inoculated to MSM (Mineral Salts Media, pH 6.8±0.2) with 0.1 % di-sodium succinate as electron donor under aerobic condition. In 8 days, 85.51% of BTE was removed. The case of LAB, 2 strains of *Lactobacillus* and 1 strain of *Leuconostoc* showed up to degradation 50% degradation of BTEX in 7 days. 1g/L (w/v) of cell mass was inoculated to MSM with 0.01 % yeast extract under facultative aerobic condition. Analysis of degradation efficiency was performed using headspace method via GC-FID (Gas Chromatography-Flame Ionized Detector). Gene expression experiments, such as real-time PCR were also used to identify and confirm the target gene responsible for the degradation of BTE/BTEX. Target genes were benzene monooxygenase (BMO), benzene dioxygenase (BED), toluene dioxygenase (TOD) and benzoyl-CoA reductase subunit A and B. Mono/dioxygenase and reductase were commonly located in the degradation pathway of BTEX. Extracted mRNA was converted to cDNA as template for real-time PCR. The *R. capsulatus* was expressed different level of benzoyl-CoA reductase gene according to substrates. However *R. capsulatus* did not expressed oxygeanse gene. Based on this study, when non-pathogen bacteria LAB applied for remediation of BTEX contaminated soil, biologically risk was low. Further studies have to be performed to optimize and enhance the removal efficiency and it gives a gateway for the bioremediation of aromatic compounds.

#### TU412

##### **Remedy Effectiveness Design Construct: Strategy for determining remedy effectiveness at large-scale contaminated sediment sites**

**R.R. Otter**, Middle Tennessee State University / Biology; **D.M. Walters**, USGS / Fort Collins Science Center; **A.P. Mucha**, U.S. Environmental Protection Agency / Great Lakes National Program Office

Remedy effectiveness of contaminated sediments is focused on understanding the impact a specific remedy (e.g., dredging). Though simple in principle, designing such studies can quickly become very complicated due to multiple factors including multiple contaminants of concern, the location of the site, and complex river dynamics. In order to better design remedy effectiveness studies a Remedy Effectiveness Design Construct (REDC) was developed. This approach was developed specifically for contaminated sediment sites, however, the general principle may be adapted as necessary. The REDC consists of three main components: physical, chemical, and biological. The physical component focuses on three site factors: sediment characterization, hydrology, and sediment transport. The chemical component focuses on concentrations in the surface water, pore water, sediment and biology. The biological component focuses on both laboratory and field-based indicators, including standard sediment and pore water toxicity tests, feral organisms, and passive samplers. Each of these components have inherent attributes that must be well understood before any proper experimental design can be constructed, such as which contaminant of concern is the priority and a good geospatial understanding of the site. The REDC provides a framework for ecotoxicologists working on remedy effectiveness of contaminated sediment sites and highlights the key factors and attributes necessary to include in the study design.

#### TU413

##### **Vermicomposting as an advance biological treatment of industrial waste from leather industry (tanneries)**

**R.R. Rachide Nunes**, Universidade de Sao Paulo / Instituto de Química de São Carlos IQSC; **R.M. Bontempi**, **G. Galetti**, **G. Mendonça**, USP - Universidade de São Paulo / IQSC Instituto de Química de São Carlos; **M.d. Rezende**, IQSC-USP The leather industry (tanneries) generates high amounts of toxic wastes, including solid and liquid effluents, rich in organic matter and mineral content - with emphasis on chromium due to its carcinogenic effect. Without the correct treatment, when these residues reach soil, sediments, water bodies, and the atmosphere they could cause contamination of fauna and flora, disturbing their ecosystems. This work presented vermicomposting as an alternative to the reuse of the wastes from tanneries. Vermicomposting is the transformation of organic matter into humic substances through chemical, physical and biological processes that occur in the digestive tract of earthworms during the composting of any organic substratum. Therefore, the present study aims to show vermicomposting as an advanced biological treatment of tannery industrial wastes. Vermicomposts were produced from the following residues: tanned chips (VRC-C), sludge from liquid residue treatment station (VRC-S), and a mixture of both (VRC-CS). Vermicomposting was performed in 25 L plastic barrels and the amount of each residue was calculated based on the C:N ratio mixture, between 20-30. Five hundred earthworms (*Eisenia fetida*) were added into each barrel. During 135 days the following parameters were evaluated: pH, total organic carbon (TOC), organic matter (OM), cation exchange capacity (CEC), C:N ratio, and chromium content (Cr<sup>+3</sup> and Cr<sup>+6</sup>) at times: 0, 15, 30, 45, 60, 90, and 135 days. As a result, the expectation that vermicomposting is an alternative for the treatment of tannery industrial waste was confirmed. Results of pH, TOC and OM content showed a decrease in its values during the processes, indicating the efficiency of the process;

the opposite trend, an increase for the values of CEC and total nitrogen also showed good results. The results of  $\text{Cr}^{+3}$  and  $\text{Cr}^{+6}$  were 8.05 and 0.78  $\text{mg L}^{-1}$ , respectively in all treatments. At 135 days, all values of  $\text{Cr}^{+6}$  were below the limit of quantitation. Therefore,  $\text{Cr}^{+6}$  content probably was biologically transformed into  $\text{Cr}^{+3}$ , confirming the use of this technique as an advance biological treatment. In all, this study reinforces the general idea that vermicomposting could be introduced as an effective technology applied to the treatment of industrial waste and production of agricultural inputs. As a future perspective, the vermicomposts will be applied to green bell peppers, evaluating in practice their fertilizing potential.

#### **TU414**

##### **Which is the remediation degree of vermicompost from filter cake in contaminated soils by glyphosate and deltamethrin?**

F. Benetti, L.B. Pigatin, IQSC-USP; M.M. Kanashiro, University of São Paulo; M. Rezende, Universidade de São Paulo / Chemistry

Bioremediation is a process in which living organisms are used to remove or reduce (ameliorate) environmental pollutants, especially organic compounds, and it can be used in places where the dopant is present. Bioremediation presents effective results in the medium term with a relative low cost. The aim of the study was to evaluate the degree of remediation of vermicompost in contaminated soils with glyphosate (the most widely used herbicide in the world) and deltamethrin (used for controlling flies and cockroaches). Acute toxicity, biomass and reproduction tests were performed according to ASTM, ISO 11268-1 and ISO 11268-2. Every test was performed with five repetitions, each result being the arithmetic mean of these replicates, and performed with soil collected in rural area. To evaluate the vermicompost remediation potential, 3% of vermicompost (w/w) was mixed to the soil. For glyphosate (GLY), 3 different samples (REFERENCE, SOIL + GLY and SOIL + GLY + FCV (filter cake vermicompost) were prepared. Already for deltamethrin (DELTA), two treatments were prepared (with and without deltamethrin solution - the suspension without the active ingredient (DISP) was provided by the manufacturer, for academic purposes), with 4 different samples (REFERENCE, SOIL + DISP or DELTA, SOIL + DISP or DELTA + FCV and SOIL + DISP or DELTA + OPV (orange peel vermicompost). In each vase, the humidity was maintained at 60%, and 10 adult earthworms were placed. To monitor acute toxicity, earthworms were weighed initially and on days 7 and 14. To monitor biomass, the weighing continued until 28<sup>th</sup> day. After, the earthworms were removed of the vases and young earthworms were counted after 56<sup>th</sup> day. The results obtained in the toxicity tests were analyzed by the ANOVA and Dunnett test, with assurance of 95%. It can be observed that the addition of 3% of vermicompost in experiments involving glyphosate improves the development of the earthworms since it decreases the mortality rate, it improves the biomass gain and the number of earthworms that can be developed in this experiment is higher than those where the vermicompost is not present. For deltamethrin in a commercial formulation the reproduction of earthworms is completely nullified, even in the presence of hummus in soil, so, a study should be developed to achieve similar results for the remediation of contaminated soils with deltamethrin.

#### **TU415**

##### **Changes in physical and chemical properties of soil by soil washing of metal-contaminated soil**

S. Jeong, Kunsan National University / Dept of Environmental Engineering; J. Kim, K. Ahn, Kunsan National University; Y. An, Konkuk University / Department of Environmental Science

There was a famous copper smelter in Korea, Janghang smelter. The Janghang smelter was operated from 1936 to 1989, emitting smelting gases to the vicinity of the gas stack. It has been known that soils near the smelter stack were highly contaminated by arsenic and major metals. Metal-contaminated soils were observed within 4 km of the gas stack. Land uses of the metal contaminated soils were cropland and woodland. The Korean government and the smelter company began soil washing of the metal contaminated soils from the beginning of this year, 2014. The soil washing processes consist of particle separation, acid-washing, neutralization, and dewatering. This study collected soil samples at three different soil washing plants. Soil samples were regularly taken from the excavated soil waiting for soil washing and the finally dewatered soil after soil washing. Physical and chemical soil properties, such as soil pH, organic matter content, cationic exchange capacity, total nitrogen, available phosphate, water holding capacity, and bulk density were analyzed to evaluate changes in these properties before and after soil washing. This study found significant changes in organic matter and nutrient contents after soil washing. This study also evaluated feasibility of amendments of the soil-washed soil for reuse as cropland. (This study was supported by the GAIA project (2014000560001) funded by Korea Environmental Industry & Technology Institute and Korean Ministry of Environment.) *Keywords: metal contamination, soil, arsenic, soil washing*

##### **Priority contaminated site: Nubarashen obsolete pesticides burial site (Armenia)**

A. Aleksandryan, Hazardous Substances & Waste Policy Division / Head of Division; A. Khachatryan, Waste Research Center; V. Frangulyan, Center of Disease Control and Prevention

The problem of obsolete pesticides became urgent for Armeniasince late 1970s. In

1980s a special place was allotted to bury them in the Nubarashen obsolete pesticides burial site. Approximately 500 tons of obsolete pesticides were finally disposed of which 250 tons were organochlorine pesticides, mostly DDT. After thirty years of storage it was discovered that the burial is located in the zone of active landslides, which can damage the containers and obsolete pesticides may be released from the site. Later a secondary pollution occurred on the site, as some of the cells were opened. In 2010 the Ministry of Nature Protection performed activity on conservation of the burial site. To assess the pollution scales, sampling and analyses of soil from neighboring sites were done. The burial site localization was taken into consideration and average samples were analyzed for organochlorine POPs pesticides using "Gas-Chromatograph/Mass-Spectrometer GCMS-QP2010 (Shimadzu Corporation, Japan). Soils from the outward nearest plots on the average contained 1.4 mg/kg DDT, while soils from the same plots, if taken from the depth of 20 cm, contained on the average 2.3mg/kg DDT. Soil taken directly from the burial site contained about 59 mg/kg DDT, while soil near the drainage tube outgoing from the burial averaged to 13.5 mg/kg. Below the burial, at the fence from the outward part, at the depth of 1 m soil contained on the average 1.6 mg/kg p,p'-DDE and 6-8 mg/kg p,p'-DDT. In the same direction at a distance of 20-100 m the amount of DDT made appropriately 1.1 and 0.2 mg/kg. At the plots of summer-houses below the burial (>500 m) the residual amount of p,p'-DDE made 0.008 mg/kg, whereas p,p'-DDT = 0.0 mg/kg. In samples of soils taken at the near-by settlements Mushavan and Jrashen the amount of DDT on the average, made from 0.005 to 0.01 mg/kg. The conclusion was drawn: pollution was caused by disintegration of the burial site and the follow-up recovery works. As a result, there occurred a certain spread of pesticides into the soil of near-by plots; to this latter indicated the analyses of soils from the plots in the direct vicinity to the burial site.

#### **TU417**

##### **Benzene and hydrocarbon derivatives of benzene in ambient air of Novi Sad, Serbia**

L. Torovic, Institute of Public Health of Vojvodina / Department of Hygiene and Human Ecology; S. Bijelovic, University of Novi Sad Faculty of Medicine / Department of Hygiene and Human Ecology; S. Bobic, B. Mihajlovic, Institute of Public Health of Vojvodina / Department of Hygiene and Human Ecology

Quality of ambient air is an important environmental factor influencing human health. High concentrations of volatile aromatic hydrocarbons, especially benzene (IARC group 1 carcinogen), in urban areas produced mainly by traffic, may impose serious human health risk. Ambient air monitoring program in the City of Novi Sad was conducted by Institute of Public Health of Vojvodina. Monitoring of BTEX (benzene, toluene, ethylbenzene, xylenes) in 2013 included five sampling sites: A, C and E – urban background, B – industrial, D – urban traffic, with sampling frequency of 10 samples per month per site. Air samples were collected on charcoal sorbent tubes and, after solvent desorption, analyzed by gas chromatography/mass spectrometry, as described by reference method EN 14662-2. Based on 586 samples, collected in 229 days in 2013, annual mean concentration of BTEX was in the following range: benzene 0.8-1.7  $\mu\text{g}/\text{m}^3$ , toluene 3.2-23.8  $\mu\text{g}/\text{m}^3$ , ethylbenzene 0.7-1.9  $\mu\text{g}/\text{m}^3$ , xylenes 1.8-2.8  $\mu\text{g}/\text{m}^3$ , depending on sampling site. When all monitoring sites were aggregated, annual average concentration of benzene was 1.4  $\mu\text{g}/\text{m}^3$ , substantially below the limit value of 5  $\mu\text{g}/\text{m}^3$ . Maximum concentration of benzene and toluene was recorded on sites B (31.2  $\mu\text{g}/\text{m}^3$ ) and A (340.5  $\mu\text{g}/\text{m}^3$ ), respectively. Temporal and spatial distribution were investigated by comparison of monthly mean concentration of BTEX on each monitoring site across the year and between sites, respectively. The month with the highest mean level of benzene was December, on all monitoring sites (site B had the highest mean), while mean toluene concentration showed very prominent peak in summer on site A. Finally, data obtained for 2013 were introduced into a database of BTEX measurements in the City of Novi Sad, available from 2011 for sites A and B, and from 2012 for sites C and D (method and frequency of sampling, as well as analytical method, were the same as described in 2013 monitoring program). Three-year average benzene concentration on sites A and B were 1.5 and 1.2  $\mu\text{g}/\text{m}^3$ , respectively, with a notice that 2013 annual mean on site A was the lowest, but on site B was the highest. With regard to benzene level on sites C and D, increase of 45% was observed on site C, and there was no change on site D, when 2013 and 2012 were compared. Monitoring program is continued in 2014, with the aim to enable evaluation of long-term BTEX levels.

#### **TU418**

##### **Native Oxy-PAHs, N-PACs, and PAHs in Historically Contaminated Soils from Sweden, Belgium, and France: Their Soil-Porewater Partitioning Behavior, Worm Bioaccumulation and Bioavailability**

H.H. Arp, NGI / Environmental Engineering; S. Lundstedt, Umea University / Department of Chemistry; S. Josefsson, Swedish University of Agricultural Sciences / Dept of Aquatic Sciences and Assessment; G. Cornelissen, NGI; A. Enell, Swedish Geotechnical Institute; A. Allard, Swedish Environmental Research Institute; N. Morin, NGI; D. Kleja, SGI

PAHs are commonly assessed in polluted soils, but co-occurring oxygenated-PAHs (oxy-PAHs) and nitrogen-containing-polycyclic aromatic compounds (N-PACs) are ignored. We developed a method to simultaneously assess porewater PAH, oxy-PAH and N-PAC concentrations using the equilibrium passive sampler polyoxymethylene (POM). We employed this method on twenty-one soil samples

contaminated with PAHs, oxy-PAHs and N-PACs were obtained from 6 locations in three countries: a) a former gasworks plant in Karlstad, Sweden (5 samples); b) a former wood tar production site outside Stockholm (Riksten), Sweden (10 samples); c) a coke oven plant in France (3 samples); d) a coke oven and metallurgy site in France (1 mixed sample); e) a gasworks site in France (1 mixed sample); f) a gasworks site in Belgium (1 mixed sample), g) and a wood preservation site, Holmsund, Sweden (1 mixed sample). In addition, with these soils we determined the total soil concentrations, enabling an analysis of the partitioning behaviour, and conducted worm bioaccumulation bioassays (with *E. crypticus* according to ISO 16387), enabling an analysis of biouptake and bioavailability. Porewater concentrations, in combination with total soil concentrations and worm concentrations (*Enchytraeus crypticus*) agreed with expectations from independent partitioning and bioaccumulation models. However, they disagreed with recommendations of risk assessments in Europe and the United States, as these are based on reference soils, and the soils on this study, coming from contaminated areas, are quite unique in their sorption properties compared to reference soils. For instance, the organic carbon in contaminated areas sorbs similarly to coal tar, but in reference soils sorbs similarly to humic acids. The results call into question the conservative nature of existing soil risk guidelines.

#### TU419

##### **Bioelectrochemical systems for sustainable bioremediation**

J. Monier, O. Sibourg, ENOVEO

The recent discovery of microorganisms that can directly use electrodes as a sink or as a source of electrons has led to the development of innovative approaches for the remediation of polluted environments. Bioelectrochemical systems are emerging technologies which use microorganisms to catalyze oxidation reactions at an anode and/or reduction reactions at a cathode where pollutants serve as electron donors or electron acceptors. Accelerating remediation processes using such technologies has been demonstrated for several pollutants including reduction of toxic metals and chlorinated compounds, oxidation of aromatic hydrocarbons, phenol and potentially for any contaminants that microbes have been shown to anaerobically oxidize. This presentation will describe, through different case studies, how such systems work, their advantages and how they can be implemented in order to optimize or design new remediation strategies. Electrode-based strategies used to monitor microbial activity in real time will also be addressed.

## **Adverse outcome pathway concept in research and risk assessment (P)**

#### TU421

##### **Towards animal free human safety assessment - Adverse Outcome Pathway descriptions as a backbone for integrated testing strategies**

T. Gocht, University of Tuebingen / Institute for Experimental and Clinical Pharmacology and Toxicology; E. Berggren, European Commission Joint Research Centre (JRC) / Institute for Health and Consumer Protection IHCP and EU Reference Laboratory for Alternatives to Animal Testing EURL ECVAM; M. Schwarz, Austrian Agency for Health and Food Security / Department for Data management; M. Whelan, European Commission DG Joint Research Centre / European Union Reference Laboratory for Alternatives to Animal Testing EURL ECVAM

SEURAT-1 is a major European research consortium that was established to develop the science needed to evaluate the safety of chemicals for repeated exposure in humans without using animals. Inspired by the fundamental considerations published in the report of the U.S. National Research Council (NRC) entitled 'Toxicity Testing in the 21<sup>st</sup> century: A Vision and a Strategy', SEURAT-1 aims to use the mechanistic understanding of toxicological effects for the development of innovative testing methods and, ultimately, improved safety assessment. A research strategy was formulated based on the guiding principle to adopt a toxicological mode-of-action framework to describe how any substance may adversely affect human health. The proof of the initiative will be in demonstrating the applicability of the concepts on which SEURAT-1 is built. This is done on three levels: (i) theoretical prototypes for adverse outcome pathways were formulated based on knowledge already available in the scientific literature on investigating the toxicological mode-of-actions leading to adverse outcomes (addressing mainly liver toxicity); (ii) adverse outcome pathway descriptions are used as a guide for the formulation of case studies to develop integrated testing strategies for the prediction of certain toxicological effects, which also as a consequence might further elucidate the theoretical model; (iii) further case studies targeting the application of knowledge gained within SEURAT-1 in the context of safety assessment. The ultimate goal would be to perform safety assessment based on *ab initio* predictions grounded on a sufficient understanding of toxicological mechanisms. In the near-term, it is more realistic that data from innovative testing methods will support in strengthening read-across arguments.

## **Midpoint or single score for decision making? (P)**

#### TU422

##### **How to communicate environmental impacts? Approaching LCA results to**

##### **consumers for urban food products**

e. sanye-mengual, Institute of Environmental Science and Technology ICTA; J. Oliver-Solà, Universidad Autònoma de Barcelona / Inèdit Innovació; J. Montero, IRTA; J. Rieradevall, Institute of Environmental Science and Technology ICTA, Universitat Autònoma de Barcelona / sostenipra

Labeling schemes provide consumers with data to include environment as a decision-making criterion in purchasing, such as energy consumption or carbon emissions. Notwithstanding the easier communication through single indicators, the use of them can cover up other environmental impacts. In Life Cycle Assessment (LCA), impact assessment methods vary from single endpoint indicators to methods with a set of almost 20 midpoint indicators. But, what is the equilibrium between consumers' understanding and the reliability of LCA results? Urban food production in new Rooftop Greenhouses (RTGs) is used as case study to test the comprehension of different LCIA indicators among consumers. The study aims to compare consumers' preferences with LCA results for multiple indicators (both midpoint and endpoint). First, surveys will be done to consumers of the university community that will participate and consume local lettuces from the RTG-Lab (Universitat Autònoma de Barcelona, in Bellaterra, Spain), during the community harvesting day. Surveys aim to identify the environmental indicators that consumers perceived as preferable. Second, lettuce production will be assessed from a cradle-to-farm gate perspective through different LCIA methods. Consumers' preferences will be contrasted to LCIA results to observe whether significant environmental impacts of products are hidden through certain indicators.

## **Alternative approaches for ecotoxicity assessments (P)**

#### WE001

##### **Combined ecotoxicological and hydrological methods for on-line contamination event detection in water distribution systems**

L. Nuesser, RWTH Aachen University, Institute for Environmental Research / Institute for Environmental Research; S. Steffens, RWTH Aachen University, Institute for Environmental Research / Institute of for Environmental Research; R. Doering, RWTH Aachen University / Institute of Hydraulic Engineering and Water Resources Management; M. Brinkmann, RWTH Aachen University, Institute for Environmental Research / Institute for Environmental Research; T. Seiler, RWTH Aachen University / Ecosystem Analysis; C. Cofalla, RWTH Aachen University / Institute of Hydraulic Engineering and Water Resources; E. Salomons, N. Olikar, Technion Israel Institute of Technology; H. Schuettrumpf, RWTH Aachen University / Institute of Hydraulic Engineering and Water Resources Management; A. Ostfeld, Technion Israel Institute of Technology; H. Hollert, RWTH Aachen University / Institute for Environmental Research

Drinking water quality and availability are key elements of water security and may be compromised by instances of accidental or deliberate contamination. Hence, it is required to detect, identify and manage any negative, unforeseen and sudden change in drinking water quality to ensure urban water security and management. The collaborative project W<sup>3</sup>-Hydro combines ecotoxicological and hydrological methods and aims to (i) detect, understand and finally numerically simulate the governing physical, chemical and biological processes underlying a peak contamination and (ii) to set-up a risk based management framework for event detection. Within the project two risk scenarios are investigated, in order to simulate scenarios in water basins, remobilization scenarios of contaminated sediments were conducted and for event detection in water distribution systems two on-line bio-units were developed. Native sediment spiked with permethrin, cadmium and quinolone, respectively, in environmental concentrations was monitored using a water sediment system in an annular flume. The hydrotoxicological experiments provided data about bed shear stress, temperature, dissolved oxygen, pH value, conductivity and redox potential and suspended particulate matter. This enabled the detection of interactions of relevant parameters in the system after the remobilization of contaminants from the sediment. In order to detect contamination events in water distribution systems two on-line bio-units with high sensitivity and accuracy were developed. The combination of two biological monitors allows for the verification of alarm signals from the first instrument with the signal of the second, thereby reducing false alarm rates. Both bio-units were developed to use *Danio rerio* (zebrafish) embryos and larvae until the age of 120 hours post fertilization (hpf) as an alternative to animal testing. The first bio-unit is a custom designed flow-through well plate in which 72 hpf to 120 hpf zebrafish larvae are exposed to a continuous water flow. Swimming activity is continuously monitored and analyzed in comparison to a negative control. The second bio-unit is a custom made pipetting robot which is equipped with a multi-pipette that automatically exposed zebrafish embryos aged 8 hpf to 48 hpf in a multi well plate. First experiments were conducted aiming to test both tools regarding their functionality and sensitivity.

#### WE002

##### **Using a low cost pipetting robot to investigate the influence of the medium exchange frequency on the toxicity of substances in the fish embryo toxicity assay (FET)**

S. Steffens, RWTH Aachen University, Institute for Environmental Research / Institute of for Environmental Research; L. Nuesser, RWTH Aachen University,

Institute for Environmental Research / Institute for Environmental Research; R. Doering, RWTH Aachen University / Institute of Hydraulic Engineering and Water Resources Management; M. Brinkmann, RWTH Aachen University, Institute for Environmental Research / Institute for Environmental Research; T. Seiler, RWTH Aachen University / Ecosystem Analysis; C. Cofalla, RWTH Aachen University / Institute of Hydraulic Engineering and Water Resources; E. Salomons, N. Olikar, Technion Israel Institute of Technology; H. Schuettrumpf, RWTH Aachen University / Institute of Hydraulic Engineering and Water Resources Management; A. Ostfeld, Technion Israel Institute of Technology; H. Hollert, RWTH Aachen University / Institute for Environmental Research

Drinking water quality and availability are key elements of water security and may be compromised by contaminations. To ensure urban water security, it is required to detect any change in drinking water quality. The pipetting robot used in the current study was developed for the W<sup>3</sup>-Hydro joint research project that has the objective to ensure water quality, availability and security. As part of an on-line bio-unit for drinking water monitoring, it automatically replaces the test solution in a multi well plate containing zebrafish embryos aged 8 hours post fertilization (hpf) to 48 hpf. The robot was constructed from customized parts, a spindle drive, Open Beam aluminum extrusion kits and motors and mechanical guide elements from Adafrit. The control electronics as well as the programming are based on Arduino. The robot is equipped with a multi-pipette. It is able to exchange the test solution in a multi well plate at selectable time intervals and also, to prepare serial dilution series. The present study is part of the validation process for the application of the robot within W<sup>3</sup>-Hydro. Acute toxicity of cadmium, quinoline and permethrin on zebrafish (*Danio rerio*) embryos was investigated, with special focus on the influence of the medium exchange frequency on resulting EC<sub>50</sub> values. The FET was performed under three different exposure conditions. Substances were tested in a stationary test, in a semi-stationary test with exchange of the test-medium every 24 h and with the robot, where half of the test-medium was exchanged at hourly intervals. All tests were performed in 24-well plates in triplicates. The EC<sub>50</sub> values were calculated to allow for the detection of a shift in EC<sub>50</sub> values between the exposure types. For cadmium and quinoline the LC<sub>50</sub> values were calculated according to the embryo mortality after 48 h of exposure. Resulting LC<sub>50</sub> for the stationary fish embryo test were 11.78 mg/L for cadmium and 39.31 mg/L for quinoline. Embryos exposed to permethrin showed no concentration-dependent mortality, but abnormal swimming-behavior, which was classified as a behavioral sublethal effect. After exposure for 120 h, the resulting EC<sub>50</sub> for the stationary fish embryo test was 0.55 mg/L. The pipetting robot provides - once validated - a sensitive, cost efficient, low maintenance monitoring tool. For on-line event-detection, it will be combined with a second bio-unit to reduced false positive alarm rates.

#### WE003

##### **Can laboratory-based biotests mirror health impairment of fish in effluent-burdened streams? Results of the project SchussenAktivplus**

R. Triebkorn, University of Tuebingen / Animal Physiological Ecology; M. Benisek, L. Blaha, Masaryk University, Faculty of Science / Faculty of Science RECETOX; S. Giebner, Johann Wolfgang Goethe Univ Frankfurt am Main / Aquatic Ecotoxicology; H. Anja, University of Tübingen / Animal Physiological Ecology; B. Kuch, Institute for Sanitary Engineering Water Quality and Solid Waste Management University of Stuttgart; D. Maier, University of Tübingen / Animal Physiological Ecology Group; J. Oehlmann, Johann Wolfgang Goethe-Universität Frankfurt / Aquatic Ecotoxicology; K. Peschke, P. Thellmann, Tübingen University / Animal Physiological Ecology; H. Köhler, University of Tübingen / Animal Physiological Ecology

Aquatic organisms are continuously and simultaneously exposed to all chemicals present in their habitats – not only to those which are detected, but also to those which are present in concentrations lower than the detection limits, and, in addition, to those which are not analyzed. Thus, their health status is an integrative measure for the consequences of chemical impact exerted by different concentrations of chemicals and by varying duration and complexity of exposure. The health status of organisms can be assessed by means of biomarkers pointing e.g. at histopathological alterations of organs or biochemical modulations of metabolic processes. Analyses of these health markers, however, usually require the sacrifice of a defined number of organisms, a task that has to be approved by the Protection of Animals Act. In addition, time- and cost-intensity of such practice should not be disregarded. In contrast, cost- and time-efficient effect-based laboratory tests designed to map toxic and endocrine potentials in environmental samples are available today. Many of them have recently been evaluated with respect to their sensitivity (Escher et al., 2014; Environ Sci Technol.). Up to now, however, it still remains vague, whether positive or negative responses of these tests can be correlated to real-world reactions of feral organisms under field conditions. Along with that, the necessity and justification of sample enrichment, which quite often is required for bioassays, needs to be addressed. In the project SchussenAktivplus we compared biomarkers in fish and invertebrates with biotests conducted with water, sediment, and sewage plant effluent samples to which organisms were exposed. By this approach it was possible to show the suitability of several *in vitro* and *in vivo* assays (YES, YAES, E-Screen, reporter gene assays for genotoxicity, dioxin-like toxicity, zebrafish early life stage test) to mirror (1) endocrine effects (vitellogenin levels or gonadosomatic index in fish, fertility index in gammarids) in free living or field-exposed organisms, (2) genotoxic effects as indicated by micronuclei formation in red blood cells of fish, (3) dioxin-like toxicity resulting in Cyp1A1

induction, and (4) embryotoxicity for brown trout and rainbow trout.

#### WE004

##### **Use of in-vitro bioassays to characterize the environmental quality of sediments from the Adriatic and the Black Sea**

E. Pérez-Albaladejo, CSIC-IDAEA / Environmental Chemistry; J. Rizzi, Federal University of Paraná / Hydraulics and Sanitation; D. Fernandes, Institute of Environmental Assessment and Water Research IDAEACSIC; R. Lille-Langøy, A. Goksøyr, University of Bergen / Biology; C. Porte, CSIC - IQAB / Environmental Chemistry

The health of the marine ecosystem can be measured by the quality of the sediments since they are the main cycling compartment of aquatic pollutants. Sediments contain complex mixtures of organic compounds that could create stressful conditions for aquatic life, representing a risk to both ecosystem and human health. In this work, the environmental quality of marine sediments from the mouth of the Po and Danube rivers was assessed by combining the use of the PLCH-1 cell line, PXR-transfected COS7 cells and ovarian subcellular fractions from sea bass (*Dicentrarchus labrax*). This approach allowed us to perform different in-vitro bioassays and to determine multiple endpoints: cytotoxicity, generation of oxidative stress, presence of CYP1A inducing agents, detection of endocrine disruptors that inhibit ovarian CYP19 activity and the detection of compounds that activate zebra fish PXR. Sediment extracts from Constanta harbor showed the highest cytotoxicity, CYP1A induction and PXR activation, followed by those collected in the mouth of the Danube and Po Rivers, and Mangalia harbor/WWTP (Black Sea). A gradient from the mouth of the rivers to the open sea was evidenced. This study highlights the usefulness of in-vitro bioassays to identify those sediments that could pose risk to aquatic organisms and that require further action to improve their environmental quality.

#### WE005

##### **The Biotransformation Potential of Zebrafish Embryos**

A. Tierbach, Eawag; K. Groh, Eawag Swiss Federal Institute of Aquatic Science and Technology; K. Schirmer, Eawag / Environmental Toxicology; M. Suter, Eawag

The zebrafish embryo toxicity test (zFET) is increasingly explored as an alternative test model to replace conventional fish toxicity tests. One important requirement for the establishment of an alternative test model is that the toxicological outcomes can be directly extrapolated to the test system it aims to replace. This implies that both models have similar toxicity targets but are also comparable in terms of uptake, bioactivation and detoxification mechanisms. Although a strong correlation between zebrafish embryo and adult fish acute toxicity could be shown for most of the tested compounds, concerns have been raised with regard to the biotransformation capacity of the fish embryos. A limited expression of biotransformation enzymes at early developmental stages can lead to an over- or underestimation of the toxicity of compounds which are targets of Phase I and II metabolism. However, little is known about the time resolved expression of xenobiotic metabolizing enzymes in zebrafish and thus about the chemical groups which might display different patterns of toxicity within different life stages or different species. In this study, we use a targeted proteomic approach to characterize the expression of Phase I and Phase II enzymes during the zebrafish development. Enzymes which are involved in the biotransformation of xenobiotics are monitored in zebrafish embryos by mass spectrometry with the use of proteotypic peptides and peptides characteristic for the enzyme families of interest. To investigate the ability of zebrafish embryos to activate specific biotransformation pathways in response to chemical exposure, the expression of selected Phase I and Phase II enzymes is monitored in unexposed embryos and embryos exposed to reference chemicals. The results collected in this study will help to fill some of the existing knowledge gaps regarding the comparability of metabolic capacity of fish at different life stages. A better understanding of the expression of biotransformation enzymes will improve the validity of zFET and help to increase its acceptance as an alternative testing system to predict toxicity to fish and mammals.

#### WE006

##### **Performance of the avian acute oral guideline (OECD 223) in delivering desired endpoints and reducing the number of test subjects.**

P.J. Edwards, Central Product Safety Dept; A. Leopold, Wildlife International, ChemEco Division, EAG, Inc. / Wildlife International Ltd.; J.B. Beavers, Wildlife International; T.A. Springer, Wildlife International, Ltd.; P.M. Chapman, Chapema Environmental Strategies Ltd; S. Maynard, Syngenta; C. Hartless; P. Hubbard, Wildlife International; B.A. Rattner, USGS-Patuxent Wildlife Research Ctr / USGS The OECD guideline 223 was published in 2010. The validation report (Series on Testing and Assessment, No. 131: Report of the Test Method Validation of the Avian Acute Oral Toxicity Test OECD Test Guideline 223) included simulation based assessments of the reliability of LD50 estimates obtained using the test design. Factors studied included the numbers of birds required, need for control birds, the consequences of background mortality and the impact of delayed mortality on the estimate of the LD50. However, some regulatory authorities have expressed a need for additional information on the effect these factors have on the reliability of LD50 estimates. Since TG 223 was adopted, a number of studies have been conducted using this design which allows further evaluation of these

concerns as well as animal welfare benefits. In this poster, we evaluate results from 186 recent studies with quail performed in 5 laboratories: 104 studies according to the US EPA guideline and 82 studies to the OECD 223 guideline. Approximately 70% of the studies included in the evaluation had an LD50 of > 2000 mg/kg. Of the 1763 control birds used in all the evaluated studies, there were only 2 control mortalities (0.11%). Furthermore, 78% of all mortalities recorded in all the studies combined occurred on days 0 to 3 of the trials. These data are being used to confirm the assumptions and utility of the validation simulations, and provide an empirical basis for comparison of the observed performance of the test designs, particularly with regard to the previously mentioned factors and animal use.

#### WE007

##### **Development of high-throughput screening method for single and multi-generational developmental and reproductive toxicity of chemicals using the nematode *Caenorhabditis elegans***

H. Kim, M. Kim, J. Kim, University of Seoul; J. Choi, School of Environmental Engineering Graduate School of Energy and Environmental system Engineering  
The EU Regulation on chemicals and their safe use has been made a provision to minimize the number of animal tests required in implementing the REACH (Registration, Evaluation, Authorization and Restriction of Chemical substances) regulation. Large-scale US research programs (e.g. ToxCast, Tox21) also outlined the need for non-mammalian toxicological models to test the potential health effects of a large number of chemicals while also reducing the use of traditional animal models. In this study, we developed high-throughput screening (HTS) method for developmental and reproductive toxicity of chemicals using the nematode *Caenorhabditis elegans*. The screening methods were optimized for the measurement on a single, as well as, on multi-generational effects of chemicals. *C. elegans* is an attractive alternative model because of its well characterized and evolutionarily conserved biology, low cost, and ability to be used in HTS. For developmental toxicity screening, *C. elegans* were exposed to chemicals from age-synchronized L1 stage for 96 hrs and the growth measurement was conducted at 12 hrs of time interval using COPAS Select, whereas for reproductive toxicity, *C. elegans* were exposed to chemicals from young adults for 72 hrs and their offsprings were counted. Method for multi-generational effects of chemicals was also optimized. To validate the optimized methods, the predictive value of the *C. elegans* was assessed against mammalian *in vivo* reproductive toxicity data. 12 chemicals having endpoints indicative of reproductive toxicity were selected from US EPA Toxicological Reference Database (ToxRefDB) as positive controls, while 8 chemicals that do not have such indications were used as negative controls. We found significant reduction on the number of offspring in *C. elegans* exposed to positive control chemicals, while no effect by negative control chemicals. Overall results suggest COPAS-based *C. elegans* developmental and reproductive toxicity screening test possesses prediction power for mammalian reproduction toxicity hence has a considerable potential for development of first-tier HTS of reproduction toxicity. As Korean-REACH will come into force in 2015, we are conducting the experiments against chemicals on K-REACH registration list. Acknowledgement : This work was supported by the grant from the Korea Ministry of Environment as "Environmental Health R&D Program"(2012001370009).

#### WE008

##### **Biotransformation of chemicals in 3-D hepatic fish spheroids**

M. Baron, School of Biological Sciences; K. Mintram, R. Cumming, AstraZeneca Safety, Health & Environment; J. Moody, University; W. Purcell, S. Jackson, Plymouth University / School of Biomedical Biological Sciences; S.F. Owen, AstraZeneca / Safety Health Environment; A.N. Jha, Plymouth University / Biological Sciences

The use of fish *in vitro* models for the bio-accumulation assessment of environmental pollutants is beginning to receive wider attention, partly due to increased pressure from regulators to replace, or at least reduce, the number of animals used in regulatory tests. Regulations such as REACH have made calls for the use of existing information from standard and non-standard methods, *in vitro* methods, *in silico* methods, read-across, and weight-of-evidence in an integrated testing strategy for assessing the bio-accumulative potential of a chemical (ECHA 2011). However, whole animal assessment of chemical bioaccumulation remains the 'gold-standard' for the environmental risk assessment of chemicals. Pharmaceuticals in particular, are designed to act on specific enzyme pathways and transporters in target organs and that these are often conserved across vertebrate phyla. Therefore, the capacity of aquatic organisms (in particular vertebrates) to metabolise compounds is a key piece of information required to understand potential risks in these animals. Here we describe further evidence of how 3-D hepatic spheroid tissue cultures obtained from rainbow trout (*Oncorhynchus mykiss*) can be used to measure the biotransformation of several widely-prescribed pharmaceuticals that have been detected at the ng-µg L<sup>-1</sup> range in the environment. The amount of chemical depletion was quantified by LC-MS/MS; rate constants (*k*) were calculated, and data incorporated into established pharmacokinetic models for fish to calculate intrinsic clearance rates. EROD activity was also measured for each chemical. In conjunction with this biological data, the homology of biotransformation systems between fish and mammals was compared and predictions of chemical metabolism in fish based on 'read-across' to human metabolism data were made. We suggest that this model may be useful in investigating the bio-accumulative potential of other persistent chemical classes

e.g. POPs, PCBs and PAHs. Keywords: 3-D spheroids, liver, bioaccumulation, alternative testing strategies

#### WE009

##### **Biosensor parameters optimization for rapid identification of environmental pollution**

M. Buckova, R. Licbinsky, Transport Research Centre; B. Sebestova, J. Krejci, BVT Technologies

Chemical analysis and toxicity tests on living organisms are used for monitoring of individual environmental component quality. For toxicity tests, plants and animals of different trophic levels are used. These were selected due to their sensitivity to chemical compounds and environmental pollution. The advantage of bioassay is capturing the total toxic effects of all substances presented in the samples. Their disadvantage is particularly time consuming, because of a few days cultivation of organism with toxic substance or environmental samples. And time plays significant role in case of unexpected accidents because you need to know quickly, if sample is dangerous for the environment or not. New device is based on the principle of the biosensor and allows practical and rapid indication of environmental contamination. This biosensor uses the green algae that are very sensitive and are also used in the standard test described in ISO 8692. The principle consists of measurement of life cycle of algae. The life cycle is monitored by oxygen production after algae illumination. If the toxicity occurs, the oxygen production decreases. Measurement conditions were optimized for temperature, the ratio of light and darkness and the selection of suitable organism in order to achieve a short measuring time with sufficient sensitivity. The green algae *Scenedesmus quadricauda* and *Pseudokirchneriella subcapitata* were chosen for measurement. Measurements were made both on the selected chemical compounds and natural environmental samples of runoff waters and soil water leachates. Results of single measurement by this device were obtained within one hour, approximately 100 times faster than in the case of the 72-hour test according to 8692.

##### **Scientific approaches to support the waiving of chronic fish tests**

A. Kienzler, European Commission - Joint Research Centre / IHCP System Toxicology Unit EURL ECVAM; M. Halder, European Commission Joint Research Centre / DG Joint Research Centre IHCP EURL ECVAM; A. Worth, European Commission Joint Research Center / IHCP Systems Toxicology Unit and EURL ECVAM

Regulatory aquatic risk assessment schemes require toxicity testing of chemicals on a limited number of laboratory species; thus, extrapolation from the obtained toxic responses to all species representing that trophic level in the environment is a fundamental tenet of regulatory ecotoxicological risk assessment. To derive the PNEC for aquatic toxicity, safety factors are applied to the laboratory data. These factors are intended to account for interspecies differences in sensitivity, extrapolation from acute to chronic effects, the physicochemical complexity of natural water versus laboratory test media, and the complexity of the ecosystem versus single species laboratory tests. The choice of the factor (10, 100 or 1000) depends on the quality and quantity of the available data. EU chemicals policy (industrial chemicals, biocides, etc) encourages the use of all available information for hazard and risk assessment before new tests on vertebrates are proposed or conducted. EURL ECVAM is currently exploring whether interspecies extrapolations and acute-to-chronic relationships can be used for supporting the waiving of chronic fish tests. For this purpose, we have extracted data (LC<sub>50</sub>, NOEC) for *Daphnia magna* and fish from various databases (US EPA Ecotox, Aquatic Japan MoE, Aquatic ECETOC, Aquatic OASIS and ECHA CHEM). We are analysing: 1) *Daphnia* (acute and chronic) to fish chronic toxicity relationships, and 2) fish acute to chronic toxicity relationships, both on the whole dataset and classified by their mode of action (MOA). Our preliminary results suggest that when fish acute toxicity data are available they could be used to predict fish chronic toxicity; however, if fish acute data are not available, then *Daphnia* data could be used, as long as the predictive accuracy for different MOAs is kept in mind. Our findings show the potential of data-based approaches. Keywords: REACH, waiving of tests on vertebrates, interspecies correlations, acute-to-chronic relationships

##### **Size DOES matter - determination of the critical molecular size for the uptake across the chorion of zebrafish (*Danio rerio*) embryos**

K.E. Schneider, University of Heidelberg / Aquatic Ecology and Toxicology; K. Henn; B. Kais, A. Keck, B. Sapel, University of Heidelberg; T. Braunbeck, University of Heidelberg / Centre for Organismal Studies

The chorion surrounds the unhatched fish embryo and has repeatedly been discussed as a potential barrier for the uptake of chemical substances. Since in July 2013 the new guideline 236 "Fish Embryo Acute Toxicity (FET) Test" for testing chemicals has been approved by the OECD, more detailed information on uptake mechanisms and a possible critical molecular size of chemicals for the uptake across the chorion is required. For this purpose, zebrafish embryos were exposed to high concentrations of a hydrophilic non-toxic polymer, polyethylene glycol (PEG). The molecular weights of the 6 different PEGs ranged from 2000 to 12000 D and were used as a parameter for the respective size. High concentrations of a

solute, which might not be able to pass the chorion, should evoke effects similar to osmosis. As a result, the chorion should shrink due to water efflux and restricted reflux during the equalization process, serving as an endpoint to determine a *critical molecular size* of PEGs to cross the chorion. To gain more information about the time-dependency of the movement across the chorion, two different steps were investigated: (1) the time-course of water efflux out of the perivitelline space subsequent to the transfer to the high PEG concentration; (2) the equilibration process until the chorion has reached its final shape. Within 5 minutes after transfer into the solutions, the chorion of zebrafish eggs showed strong shrinkage due to extreme water efflux unrespectable of PEG. The extent of shrinkage could be shown to depend on (a) the solute concentration, (b) the molecular weight and (c) the duration of exposure. All eggs exposed to 9.76 mmol/L showed a stronger depression of the chorion than eggs exposed to 1.67 mmol/L. While for PEG 2000 the chorion fully recovers within 5 hours after start of exposure, for PEG 3000 the chorion still shows minor depressions after 24 hours. For PEGs  $\geq 4000$  D, the chorion showed size-dependent, heavy deformations of the chorion after 24 hours. Therefore, a reflux of water and PEG molecules into the chorion and a resulting re-shaping of the chorion could only be observed for eggs exposed to PEGs  $\leq 4000$  D. This indicates a barrier function of the chorion for molecules from a size between 3000 and 4000 D.

## WE012

### Extrapolation of aquatic hazard information to soil and sediment: do we capture all the risks?

C. Bögi, BASF Aktiengesellschaft; M. Lampi, ExxonMobil Biomedical Sciences, Inc.

Within a regulatory context, environmental risk assessments typically rely on aquatic ecotoxicity data only. However, whether or not aquatic hazard information of a substance sufficiently captures hazards towards other environmental compartments as well, remains a point of discussion. Under REACH for instance, the performance of an environmental risk assessment of a substance is triggered by its environmental classification. As the current classification system only covers aquatic hazards, this is leading to cautionary approaches as to when and how environmental risk assessments are undertaken. For example, the discussion on the scope of Exposure Assessment under REACH could not be settled due to the ongoing debate on whether the existing classification for aquatic hazards captures the risks to organisms in the soil and sediment compartments. This poster will summarise the findings of an ECETOC Task Force on the matter. A database of substances for which aquatic, soil and sediment ecotoxicity data are simultaneously available, has been established. In the current phase, the performance of equilibrium partitioning (EqP) theory to extrapolate aquatic hazard information to the soil and sediment compartments – an approach typically used within regulatory frameworks such as REACH – is assessed for different trophic levels. The accuracy of EqP in predicting toxicity towards soil and sediment organisms is discussed in light of different physical-chemical parameters, substance mode of action and other parameters. Finally, the discussion will cover cases where the existing aquatic data is sufficient to capture hazards/risks for all the compartments, and on the opposite, where it is not. Some proposals to remedy these insufficiencies will be made.

## WE013

### Development of an enzyme-linked immunosorbent assay (ELISA) for assessing vitellogenin content in the skin mucus of Perciformes (Teleostei : Acanthopterygii)

B. Allner, GOBIO GmbH; M. Hennies, Tecomedical Development; M. Willner, IBACON GmbH; T. Schmidt, Hochschule Fresenius; C. Lerche, P. Stahlschmidt-Allner, Gobio-GmbH

Vitellogenin (VG) is usually synthesized in females under the control of 17 $\beta$ -estradiol and serves as nutrient for the developing embryos and larvae. Its induction in males and juveniles is considered as a reliable indicator of estrogenic disruption, and is widely used as bio indicator for xenoestrogens in the aquatic environment. Traditional assays for assessing VG induction and screening for endocrine active substances are basing on body homogenates and/or serum samples and therefore need a large number of animals. Herein we report a novel enzyme-linked immunosorbent assay (ELISA) specifically designed to measure VG content in swab samples of the skin mucus of perciform fishes, allowing a non-destructive sampling procedure that enables parallel studies to be performed concomitantly with the determination of VG induction. The assay is sensitive enough to detect VG levels as low as 0.5 ng/mL, even allowing the detection of basal VG values expressed in the mucus of female bluegills (*Lepomis macrochirus*). Exposure to 17 $\beta$ -estradiol (E2) at 1  $\mu$ g/L showed high levels of VG induction already at the 1<sup>st</sup> day, and a noticeable induction of VG even at 200 ng/L. To demonstrate the feasibility of the mucus VG test in comparison to the Fish Juvenile Growth Test (OECD 215), exposure of bluegills to bisphenol-A (BPA) was maintained for 28 days. This exposure to 600  $\mu$ g/L and 1000  $\mu$ g/L showed induction of VG even at the lowest tested concentration already at day 4, with the highest values obtained at day 7. These results proved that swab sampling employed for the ELISA permits other assay to be performed without hindrance, without depletion of the sampling pool. Our results demonstrate that a sensitive, stable and reliable ELISA has been developed to measure VG induction in the skin mucus of Perciformes with a non-destructive and simple sampling technique, with tremendous potential for novel approaches in toxicological assessment of

estrogenic disruption.

## WE014

### Global data requirements for vertebrate testing of pesticides: Opportunities for best practise and harmonisation

n. burden, NC3Rs; S.K. Maynard, Syngenta / Environmental Safety; L. Weltje, BASF SE / Agricultural Centre; M. Fryer, CRD HSE; J.R. Wheeler, Dow Agrosciences

Most new pesticide active substances and their products are developed for global use. Consequently, environmental data packages are developed to meet all the data requirements of the regions and countries for which registration is intended. These different geographies often have varying needs, requiring different and sometimes duplicative testing. Such requirements can greatly increase the number of vertebrate animals used without necessarily increasing the quality or utility of information for decision making. Here we review the global vertebrate data requirements for the major regions. This analysis is used to inform: (a) Recommendations for best practise to reduce the overall numbers of animals within current requirements, and (b) Highlight priorities for better global harmonisation. Such approaches could contribute to the development of short- and long- term strategies to reduce vertebrate animal testing for the global registration of pesticides, without compromising environmental protection.

## WE015

### PBT assessment of Personal Care Products

S. Cassani, University of Insubria / DiSTA; A. Sangion, DiSTA; F. Marzetta, University of Insubria / QSAR Res Unit Environ Chem Ecotox Department of Theoretical and Applied Sciences DISTA; P. Gramatica, University of Insubria / DiSTA

During the last years, several organic ingredients in Personal Care Products (PCPs) became compounds of increasing environmental concern, mainly because they are commonly detected in receiving waters. PCPs are widely used all over the world in order to obtain benefits in everyday life and to improve the quality of several products. However, there is limited understanding of how these emerging contaminants may affect aquatic wildlife communities. Some of these PCPs contain also endocrine disrupting compounds, and many of their other adverse effects are essentially unknown. In fact, data on persistence, bioaccumulation and toxicity are lacking and their environmental behavior need to be further investigated. Moreover, the determination of all the dangerous properties, required by REACH and Cos-me-tics Directive (Council Directive 76/768/EEC), is a long and difficult task and thus it is very important to have tools to quickly highlight the most hazardous compounds, focusing the experiments only on the prioritized compounds. Quantitative Structure-Relationship (QSAR) models, can predict missing data for the unknown activities and properties necessary to prioritize chemicals. Using QSAR models, in this study we have screened the potential cumulative PBT (persistence, bioaccumulation, toxicity) behavior, the persistence and the (eco)toxicity of hundreds of PCPs. More than 500 chemicals such as flavor and fragrance agents, hair dyes ingredients, parabens, phthalates and sunscreen agents have been screened with different models and tools. The PBT assessment has been carried out with the Insubria PBT Index and the US-EPA PBT Profiler. The PCPs identified as PBTs in agreement by the two methods have been specifically evaluated for their persistence by the Global Half-Life Index (GHLI) model included in QSARINS and for toxicity by a specific QSAR model, developed ad-hoc for personal care products, for the prediction of acute toxicity in *Pimephales promelas*. Particular attention has been devoted to the study of Applicability Domain of our models. Concluding, the potential environmental hazard of a big number of PCPs ingredients has been studied assessing their potential PBT behavior, persistence and fish toxicity. A priority list is therefore proposed, including the potentially most hazardous personal care products ingredients.

## WE016

### Use of a holistic approach in validation: QSAR models versus experimental data

P. Bichere, F. BAUER, KREATiS; F. Sahigara, P. Thomas, CEHTRA SAS

There is a strong and recognised relationship between fugacity, chemical activity and toxicity for narcotic substances (MoA 1 and 2)<sup>1,2</sup>. High Accuracy Quantitative Structure Activity Relationships models (HA-QSARs)<sup>3</sup> have been developed such that these thermodynamic laws are embedded in the algorithms. Thus using a cascade approach each endpoint (eg. Water Solubility) can be determined from another endpoint (eg. log K<sub>OW</sub>) providing results as good as those from quality experimental studies. One of the uses of HA-QSARs is to use a combination of several experimental endpoint values (eg. fish and algae toxicity, log K<sub>OW</sub> and water solubility) to calculate a thermodynamically related endpoint (eg. daphnid toxicity) thereby creating a set of results for the same endpoint. By combining the accuracy of the model and the reliability of the original experimental values, this method, called “the holistic approach”, can be used to validate or invalidate experimental studies. This approach can also be used as a powerful tool to increase accuracy and validate HA-QSARs. Case studies are provided. **References:** 1. *ECETOC Technical Report No. 120, 2013. Activity-Based Relationships for Aquatic Ecotoxicology Data: Use of the Activity Approach to Strengthen MoA Predictions.* ECETOC Technical Report No. 120. #### WE017

##### High Accuracy QSARs for the prediction of acute and chronic aquatic toxicity

P. Thomas, CEHTRA SAS; P. Bicherel, KREATiS; F. Sahigara, CEHTRA SAS  
The thermodynamic relationship between the chemical activity and the toxicity of narcotic chemicals has recently been hypothesised by Mackay et al in 2009<sup>1</sup>. In 2013, an ECETOC task force carried out an extensive project on a large existing dataset to validate Mackay's hypothesis that the chemical activity can be used to accurately predict the toxic effects in aquatic species. The task force tentatively proposed a relationship for acute and chronic effects for MoA1 substances and this was recently made available as ECETOC Technical Report 120<sup>2</sup>. Using these data as a starting point, KREATiS extensively reworked these tentative algorithms and created the first High Accuracy QSARs (HA-QSARs)<sup>3</sup> with  $R^2 > 0.95$  for acute ecotoxicity to Fish, Daphnia and Algae. Once the acute toxicity QSAR results had been demonstrated to be at least as accurate as experimental data for MoA1 substances, the work was then extended to MoA2 substances to see if similar levels of accuracy could be obtained. Further work was also initiated on the chronic toxicity endpoints for MoA1 substances (where metabolism and analytical issues could significantly influence the experimental results and therefore accuracy in predictions). Future developments including the understanding of Acute to Chronic Ratios (ACR) will be explored. **Keywords:** narcotics; acute toxicity; chronic toxicity; QSAR **References:** MacKay D, Arnot J, Petkova E, Wallace K, Call D, Brooke L, Veith G. 2009. #### WE018

##### Automatic counter and characterization in ecotoxicology assays

S. Abreu, University of Aveiro / Dep Biology CESAM; M. Oliveira e Silva, R.E. Martins, University of Aveiro / DETI IEETA; A.M. Soares, Universidade de Aveiro / Department of Biology and CESAM

One of the most worldwide bioassays used in ecotoxicology to evaluate effluents and contaminated waters is performed with Daphnia, where most of the acute tests require a repetitive and time consuming counting procedure, aiming endpoints such as "reproduction", "immobility" or "lethality". We present a new technology for counting organisms embedded in a solution (e.g. Daphnia in ecotoxicology assays) based on organism serialization and conduction along a tubular cell passing through an electronic optical detector. The generated analogue optical signal is then processed by a computational system to perform the organism counting and, eventually, a chromatic classification (to infer its morbidity/mortality). With this technology it is possible to adjust the light chromatic emission, aiming an enhanced organism/solution contrast for counting purposes or, alternatively, to filter away the characteristic green colour of the organism algae food (enhancing the quality of the chromatic classification of the organism). This technology allows a real-time counting of organisms present in a solution with a fully automatized procedure, thus avoiding current error-prone "manual" counting and operator fatigue; thus, enhancing data quality and significantly reducing global procedure time. Chromatic classification of organisms may also allow better data results as it will give objective indication of each organism morbidity/mortality state. It is also possible to simultaneously process several solutions in a multi-counter realization of this apparatus.

#### WE019

##### RTgill-W1 cell line assay to test for acute toxicity of effluents

M. Knöbel, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Toxicology; K. Schirmer, Eawag / Environmental Toxicology  
We established the rainbow trout (*Oncorhynchus mykiss*) gill cell line, RTgill-W1, assay as a fast and inexpensive means to predict fish acute toxicity for organic industrial chemicals. The outcome of the cell line assay compared very well not only to the fish acute toxicity test results but also to results obtained in the zebrafish (*Danio rerio*) embryo toxicity test, which has meanwhile been accepted as the OECD test guideline 236. The success of the RTgill-W1 cell line assay has led to a CEFIC-LRI/UK-NC3Rs-supported round-robin study to bring this assay closer to the same level of international acceptance as the embryo and fish acute toxicity test. One question raised in this context was if the RTgill-W1 cell line assay can also be used to predict fish acute toxicity of effluents. Assessing effluents with such an animal-free method would be highly desirable: it is estimated that in North America alone, about three millions of fish are sacrificed annually for whole effluent testing. In fact, several previous studies have indicated that, indeed, the RTgill-W1 cell line is suitable for such an application. For example, Dayeh, Schirmer and Bols [2002, Water Research, 36: 3727-3738] introduced a protocol with which they tested whole-water effluents from a paper mill over the course of one year in both the RTgill-W1 cells and the fish acute toxicity test using rainbow trout. Out of sixteen samples assessed, only one was toxic to rainbow trout and this was also the one

causing cytotoxicity in RTgill-W1 cells. In light of this and recent requests to use the RTgill-W1 cell line for whole water effluent testing, we have set-up the method in which salts of the tissue culture medium, L-15/ex, are added to pre-filtered raw effluent samples to establish isotonic conditions for direct cell exposure. Inasmuch as effluents samples nowadays are rarely acutely toxic, we spiked the effluent samples with 3,4-dichloroaniline as reference compound, demonstrating that the cell line can detect acutely toxic chemicals despite the complex matrix of an effluent sample. We are currently exploiting this method to test effluents of different origin and compare the effects observed in the cells also with those elicited by the same samples in zebrafish embryos [ISO 15088:2007(E)]. Demonstrating the ability of the RTgill-W1 cell line assay to sensitively respond to raw effluents of different origin will be an attractive complement to assessing single chemicals for acute toxicity.

#### WE020

##### Cyto and genotoxicity of two industrial wastes on coelomocytes of *Eisenia fetida*

S. Curişes; m. saenz, Universidad Nacional de Lujan CONICET; J. Alberdi, UNLU; W.D. Di Marzio, Universidad Nacional de Lujan-CONICET  
The management of industrial wastes is an important economic and environmental problem. The presence of pollutants in industrial waste can produce genotoxic activity in several species. Thus, evaluation of the toxic and genotoxic potential of industrial wastes towards organism is acquiring a particular significance. The earthworm *Eisenia fetida* is model specie in toxicity studies. Single-cell electrophoresis (SCGE) assay was used for detecting DNA damage in the coelomocytes of earthworms. Coelomocytes were exposed to *in vivo* and *ex situ* conditions to determinate the genotoxicity of two industrial wastes. The industrial wastes corresponding to foundry sand, related to metallurgical activity, and sludge produced by cosmetic industry. The objective of present work is evaluate cyto and genotoxic potential on coelomocytes of earthworms exposed to *in vivo* or *ex situ* conditions, using two industrial wastes as a whole or its aqueous leachate, respectively. For the *ex situ* exposures the coelomocytes were exposed to aqueous leachate of each waste during 1 h. For the *ex situ* exposures the earthworms were exposed to solids wastes during 7 and 14 days. The cytotoxicity was determined by Trypan blue dye. The SCGE was performed to assess the genotoxicity of aqueous leachate and solid wastes. The results shows solid wastes and its aqueous leachate increase levels of DNA damage. The study indicate the importance of implementing into environmental monitoring genotoxicity test together classical physicochemical analysis for regulate the final disposal of industrial wastes.

#### WE021

##### Genotoxic potential of insecticide imidacloprid evaluated at different test organisms

Y. Ansoar-Rodríguez, UNESP- São Paulo State University / Biology; C. Christofoletti, UNIARARAS Hermínio Ometto Foundation; A. Marcato, J. Correia, UNESP-São Paulo State University / Biology; J. Pedro-Escher, UNESP-São Paulo State University / Biology; O. Bueno, UNESPEIS-Center of Study of Social Insects; O. Malaspina, Universidade Estadual Paulista UNESP; R. Costa Ferreira, UNESPCEIS-Center of Study of Social Insects; C. Fontanetti, UNESP-São Paulo State University / Biology  
The indiscriminate use of pesticides has become a serious environmental concern. Being one of them, the imidacloprid (IMI) is one of the most widely used world wide. In Brazil, it is used in sugarcane, citrus, cotton, and coffee crops. During 2010, in Brazil, 1,934 tons of IMI were sold, mostly to be used in sugarcane crops. The aerial application of this insecticide has been associated with the death of bees, which has led to its prohibition. Currently open to re-evaluation, the aerial application of pesticides is prohibited during flowering and when bees are foraging on any type of crop due to its negative effects. Several studies have examined the toxicity of IMI as well as its possible ecological effects. However, few studies have examined its toxicity at the genetic level. This is one of the biggest challenges for the scientific community, who is concerned about the impacts of these contaminants on the environment and human health. The use of live organisms (bioindicators) can reveals the presence of stressors from environmental pollutants and allows the use for monitoring their negative effects. Among them, the plants and aquatic animal are considered as excellent genetic models to detect environmental mutagens. In this study, we evaluated the effects of IMI above the genetic material in the plants *Allium cepa* and *Tradescantia pallida* and in the fish *Oreochromis niloticus* following exposure to different concentrations of this insecticide. *Allium cepa* seeds, inflorescences of *T. pallida* and *O. niloticus* erythrocytes were used. The results in *A. cepa* assay and *T. pallida* micronuclei (MN) test, demonstrated that the IMI induced chromosomal alterations and increased the frequency of MN. The results in *O. niloticus* erythrocytes for comet assay demonstrated induction the primary damage on the DNA by increasing the frequency of strand breaks and alkali labile sites in the concentrations tested. The results from the MN and other nuclear alterations (NA) test in *O. niloticus* erythrocytes indicates the IMI did not cause a significant increase in MN frequency and if of some NA as blebbed nuclei (BL) e notched nuclei (NT) in the higher concentration used. Summarizing IMI was genotoxic in plants and induced primary DNA damage but no damage at the chromosome level in *O. niloticus* erythrocytes. These factors should be taken into account when applying this pesticide.

## WE022

### Characterisation of the *in vitro* RTgutGC spheroid model: suitability as an ecotoxicology tool?

L.M. Langan, Biological Sciences; S.F. Owen, AstraZeneca / Safety Health Environment; S. Jackson, W. Purcell, Plymouth University / School of Biomedical Biological Sciences; A.N. Jha, Plymouth University / Biological Sciences  
The bio-activation of toxicants is the physiological route by which chemicals are metabolized into reactive components. Logically, the evaluations of *in vitro* toxicology should be performed on cell derived systems which have adequate and relevant metabolic activity. Adding to this, the model should represent a relevant route of exposure. The gastrointestinal tract is the primary route of exposure to environmental toxins located in food chains and the rainbow trout gastrointestinal derived cell line RTgutGC has been suggested as a potentially suitable model for *in vitro* toxicology testing. However, its metabolic activity in terms of ability to take up and detoxify specific compounds has not been characterised. Two 3D cell culture systems were used and exposed to environmentally relevant concentrations of copper over a 72h exposure, and compared to a previous *in vivo* study. Metabolic activity in the gut cell line was quantified using EROD and epoxide hydrolase (EH) activity as indicators of the cell line's capacity for xenobiotic metabolism of both drugs and PAH's. GST activity was investigated to identify whether the cell line was capable of phase II metabolism, in both monolayer and spheroid forms. Initial results indicate that both the spheroid form and monolayer form of the cell line is metabolically active for both CYP and EH, with the spheroid form showing higher relevant activity. Copper exposure in the spheroids shows an increase over time as expected, with a similar response noted in the inserts. There was no significant differences in the recorded copper concentrations in the fluid/media of the spheroid culture and the insert culture potentially indicating a similar metabolic uptake of the metal. This will be investigated further.

## WE023

### Toxicity of the endocrine disruptor nonylphenol in plant development at environmental concentrations

M. Catala Rodriguez, P. Morales, Universidad Rey Juan Carlos / Biology and Geology Physics and Inorganic Chemistry; S. Esteban, Universidad Rey Juan Carlos / Area de Medicina Preventiva y Salud Pública; H. Cortés, Universidad Rey Juan Carlos / Biology and Geology Physics and Inorganic Chemistry; Y. Valcárcel, Universidad Rey Juan Carlos / Department of Preventive Medicine Public Health Immunology and Medical Microbiology

In recent years there is a growing concern among the scientific community about the presence of the so-called emergent pollutants in waters of different countries, especially those that have the ability to alter the hormonal system (endocrine-disrupting compounds). One of the substances found almost ubiquitously and in higher concentrations is the alkylphenol nonylphenol. The aim of this work is to assess the acute and sub-chronic toxicity of environmental concentrations of nonylphenol in riparian vascular plant development using spores of the fern *Polystichum setiferum* and a biomarker-based approach: mitochondrial activity (biomarker of cell viability), chlorophyll (plant physiology) and DNA content (growth). Mitochondrial activity and DNA content show that nonylphenol induces acute and sub-chronic toxicity at 48 h and a week. Significant effects are observed in both biomarkers in fern spores at ng/L but chlorophyll autofluorescence shows little changes. The inhibition of germination by natural allelochemicals has been reported to be related with the active hydroxyl group of phenolic compounds and largely independent of the structural nucleus to which it is attached. Results presented in this study suggest that environmental concentrations of nonylphenol could interfere with higher plant germination development by mimicking natural allelochemicals likely posing ecophysiological risks.

## WE024

### Semi-automated detection of goitrogenic compounds using transgenic zebrafish embryos and the VAST BioImager platform

S. Jarque, Masaryk University / Faculty of Science RECETOX; E. Fetter, Department of Bioanalytical Ecotoxicology; M. Pipal, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; M. Smutna, Masaryk University Faculty of Science RECETOX; L. Blaha, Masaryk University, Faculty of Science / Faculty of Science RECETOX; S. Scholz, Helmholtz Centre for Environmental Research / Department of Bioanalytical Ecotoxicology

The thyroid metabolism plays a crucial role in various metabolic, behavioral and developmental processes such as growth and maturation. However, there is very little knowledge on environmentally relevant pollutants that may interfere with thyroid signaling and corresponding mechanisms of action. Gene expression changes of thyroid hormone synthesizing genes can be used as an endpoint to detect thyroid disruption. In order to facilitate an easy and fast detection of gene expression alterations in zebrafish embryos, we used the transgenic zebrafish line tg(tg:mCherry) combined with the VAST (Vertebrate Automated Screening Technology) BioImager platform. While the strain tg(tg:mCherry) reflects the expression of thyroglobulin gene encoding the thyroid hormone precursor, the VAST system allows an easier and relatively fast handling of zebrafish embryos compared to manual procedures. The tandem was shown as efficient for the screening and detection of compounds with goitrogenic activity, as it is disclosed by the dose-response increases of fluorescence signal in fish embryos after

exposure to a number of prototypical model thyroid endocrine disruptors such as ethylenethiourea, sulfamethoxazole, potassium perchlorate, phloroglucinol, resorcinol and 6-propyl-2-thiouracil. The present approach may be also applied for the assessment of potential thyroid disrupting activities associated to environmental samples. For example, preliminary data suggest positive responses in complex extracts of cyanobacteria and their toxins (microcystins), which represent a major environmental problem during nutrient pollution induced by freshwater algal blooms.

## WE025

### Endocrine-disrupting potentials of equine estrogens in the medaka *Oryzias latipes*: *in silico* and DNA microarray studies

K. Arizono, Prefectural University of Kumamoto / Faculty of Env Symbiotic Science; M. Uchida, Mizukibiotec; H. Ishibashi, Shokei University Junior College / Department of Food and Nutrition; Y. Ishibashi, Prefectural University of Kumamoto / Faculty of Environmental and Symbiotic Science

Although several previous studies have demonstrated the presence of equine estrogens in the aquatic environment, limited data are currently available on the endocrine-disrupting potentials in fish and the risks they pose to aquatic organisms. To investigate the interactions of major equine estrogens equilin (Eq) and equilenin (Eqn), as well as their metabolites 17 $\alpha$ -dihydroequilin, 17 $\beta$ -dihydroequilin, 17 $\alpha$ -dihydroequilenin, and 17 $\beta$ -dihydroequilenin, with the estrogen receptor  $\alpha$  (ER $\alpha$ ) of medaka (*Oryzias latipes*), a three-dimensional model of the ligand-binding domain (LBD) of ER $\alpha$  was built *in silico*, and docking simulations were performed. The docking simulation analysis indicated that the interaction of 17 $\beta$ -dihydroequilenin with the ER $\alpha$  LBD is the most potent, followed by those of 17 $\alpha$ -dihydroequilin and 17 $\beta$ -dihydroequilin, whereas those of Eq and Eqn were least potent. We further analyzed gene expression profiles in the livers of male medaka exposed to Eq and Eqn. A DNA microarray representing 6000 genes revealed that 24-h exposure to Eq and Eqn (100 ng/L) upregulated the expression of 6 and 34 genes in the livers of males, respectively. Genes upregulated by Eq included the estrogenic biomarker genes vitellogenins and choriogenins, suggesting the estrogenic potential of Eq. In contrast, Eqn exposure upregulated several cancer-related genes, such as mediator complex subunit 16 and RAS oncogene family members, suggesting a carcinogenic potential for Eqn. These results suggest that equine estrogens may have not only endocrine-disrupting potentials *via* the ER $\alpha$  signaling pathway but also carcinogenic potency in male medaka.

## WE026

### Proposal for a sub-lethal toxicity test using zebrafish embryo

A. Wigh, UMR CNRS LEHNA; S. Bony, Université de Lyon; A. Devaux, Université de Lyon-ENTPE; A. Gonzalez-Ospina, Degremont / Degremont  
Respecting the principles of the 3 R's (reduce, refine, replace), the FET test, which uses the zebrafish (*Danio rerio*), was basically designed as an alternative to the fish acute toxicity test to determine acute toxicity of chemicals or environmental samples on embryonic stages. In the FET, only lethal endpoints are used to calculate a LC<sub>50</sub> value after 96h of exposure. The design of the test easily allows to record additional endpoints such as sub lethal and teratogen events. This work aims to integrate these parameters using a new calculation method resulting in a so called "FET index" (iFET). This complementary approach is proposed for the assessment of sub-acute hazards, particularly relevant to evaluate a chronic toxicity risk for low and/or multi contaminated environmental samples. The method is first tested with three different chemicals 3,4-dichloroaniline (3,4-DCA), methyl methanesulphonate (MMS) and cadmium, as well as two WWTP effluents (a Biologically Treated Effluent (BTE) and the same followed by ozonation (BTE+O<sub>3</sub>). In samples studied here, LC<sub>50</sub> was not calculable. Thus, the percentage of affected embryos based on both FET and iFET is given and the classic FET scores are compared with the iFET scores through colour grades. As a negative control, ISO water results in very similar scores with both systems. In the 3,4-DCA sample (3.7 mg/L), the average mortality (44%) results in a medium risk scoring at the end of the test. When applying the iFET calculation, this percentage rises up to 71.33% and characterizes an excessive risk. A low risk is observed with the iFET in the WWTP samples BTE and BTE+ O<sub>3</sub> (conc. from 6.875 to 100% and 27.5 to 100%, respectively) whereas some of these samples are considered without risk using the classic FET what could lead to an underestimation of the effluent toxicity risk. So the extended FET enables to detect toxicity with a higher sensitivity, due to the possibility to take into account sub-lethal effects earlier than embryo's death. Since such effects can potentially reduce zebrafish fitness by affecting growth, survival and reproduction, this extended FET offers interesting perspectives in aquatic ecotoxicology.

## WE027

### DAMIER - A research project for the development and application of high accuracy *in-silico* models for REACH

P. Thomas, CEHTRA SAS; P. Bicherel, KREATIS; P. ROUSSEAU, H. OSUNA, J. DELAFOSSÉ, Processium; S. Kent, Rovaltain Research Company / Brixham Environmental Laboratory; S. BETAT, N. DELPIT, Laboratoires des Pyrénées et des Landes; e. vaillet, ISA

Despite recommendations by the European Chemicals Agency (ECHA) to use *in-silico* approaches as an alternative to replace animal testing, the majority of existing QSAR models have been designed for screening purposes and are therefore

considered unacceptable to replace experimental studies due to lack of accuracy and strict validation. This was the basis for proposing DAMIER (stands for Développement et applications de modèles informatiques pour REACH) research project which was funded in 2014 under the 17<sup>th</sup> French FUI (Fonds Unique Interministériel) call for projects. The objective of the DAMIER project is to replace current experimental studies needed for chemicals registration under REACH regulation using computer modelling of physicochemical and ecotoxicological properties. This work will involve the development of High Accuracy Quantitative Structure-Activity Relationship (HA-QSAR) models for numerous REACH annex VII and VIII endpoints. All the HA-QSARs developed under this project will be validated following the recommended five OECD principles for QSAR models<sup>1</sup>. This poster will provide an overview of the various research activities allocated over a timeframe of three years amongst all the five project partners (Two SMEs, KREATiS (co-ordinator) and Processium; the Institut des Sciences Analytiques (ISA); the Laboratoires des Pyrénées et des Landes (LPL) and Rovaltain Research Company). A workflow will be provided to get a better understanding of the collaboration within the project partners, in particular how the laboratory-based work will be carried out throughout the project work to support the development and demonstrate the validation of DAMIER HA-QSARs, (for instance, procuration of data from new, innovative and reliable experimental methods, some of which generated by DAMIER). Finally, an overview of the validation strategy of these models will be provided to make them suitable for registration purposes under REACH. **Keywords:** DAMIER; QSAR; in-silico; REACH **References:** OECD principles for the validation, for regulatory purposes, of (Quantitative) Structure-Activity Relationship models - <http://www.oecd.org/env/ehs/risk-assessment/37849783.pdf>

## WE028

### Generation of reactive oxygen species in a fish cell line and two mammalian cell lines after exposure to acid mine water.

O.T. Iji, University of Pretoria / Department of Paraclinical Science; J.C. Serem, M.J. Bester, University of Pretoria / Department of Anatomy Faculty of Health Sciences; E.A. Venter, J.G. Myburgh, L.J. McGaw, University of Pretoria / Department of Paraclinical Science

Reactive oxygen species (ROS) production and resultant oxidative stress (OS) has been implicated as a pathway of toxicity in aquatic animals exposed to pollutants. In this study, we quantified ROS production in a cellular model, using two mammalian cell lines (C3A human liver and Vero monkey kidney cells) and a fish gill cell line (RTgill-W1) following exposure to acid mine drainage water (AMD). *In situ* physicochemical measurements were recorded and water samples collected from a typical AMD-polluted stream in the Mpumalanga Province, South Africa. Water samples were collected before (untreated water) and after the treatment (neutralised) of the stream by a crude in-stream neutralisation process. Water chemistry analyses confirmed that the stream was affected by AMD. ROS production by the three cell lines was determined using the oxidant sensitive fluorogenic probe, 2',7'-dichlorofluorescein diacetate (DCFH-DA), following exposure to varying concentrations of AMD water samples. ROS production decreased in a dose-dependent fashion with respect to AMD water concentration (100%, or whole effluent, to 0.781%) for the cell lines. Maximal toxicity index, expressed as % ROS, was recorded for Vero cells (25.3 %), C3A cells (16.4 %) and RTgill-W1 (14%) when exposed to the untreated AMD, while for the treated (neutralized) AMD water sample, values were 17.7%, 7.2% and 4.5%, respectively. ROS levels were consistently greater for untreated AMD water when compared to the treated (neutralized) AMD water samples. This may be related to the presence of metals especially (Al, Zn, Fe) from the stream which showed values that, in some cases, were much higher than maximum recommendable values established by South African legislation for receiving stream waters. This cell culture method could be used for the monitoring of ROS generation (or oxidative stress) caused by AMD.

## WE029

### Can fish embryo toxicity (FET) test with three-spined stickleback (*Gasterosteus aculeatus*) show the similar transcriptional response demonstrated in acute toxicity test?

H. Watanabe, National Institute for Environmental Studies / Center for Environmental Risk Research; M. Sebire, Cefas; T. Bean, Centre for Environment Fisheries and Aquaculture Science / Environment and Animal Health; P. Antczak, University of Liverpool / Institute of Integrative Biology; T. Williams, University of Birmingham / School of Biosciences; D. Hartnell, Centre for Environment Fisheries and Aquaculture Science / Environment and Animal Health; M. Maisano, University of Messina; I. Katsiadaki, Cefas / Environment and Animal Health The three-spined stickleback (*Gasterosteus aculeatus*) is a useful sentinel species in chemical assessment particularly for detecting endocrine disruptors (EDs). As with the other test fish species, thus far juvenile and adult fish have been mainly used in regulation for both EDs and toxicity testing; however, in compliance with animal welfare, it is necessary to develop alternative tests and reduce the use of adult fish in toxicology. For zebrafish, the fish embryo toxicity (FET) test has already been adopted as an OECD test guideline (TG236) demonstrating a good correlation on lethal toxicity data when compared to fish acute toxicity test (TG203). Here we present the three-spined stickleback FET protocol for the first time, including additional endpoints (gene expression studies) that could provide an insight not

only on toxicity but also on chemical mechanism of action. Our overall aim was to investigate if the fish embryos are capable of expressing at least partly the signalling pathway from molecular initiating event to adverse outcome. More specifically, following short-term exposure experiments using adult female sticklebacks, where hepatic global gene expression was studied (Agilent arrays) in combination with computational analysis, we identified differentially expressed genes for ten chemicals at environmentally relevant concentrations. These include benzo(a)pyrene, cadmium, dibutyl phthalate, 17 $\alpha$ -ethynylestradiol, fluoxetine, gemfibrozil, ibuprofen, levonorgestrel, polychlorinated biphenyl 118 and triclosan. Computational analysis was used to identify genes that showed high accuracy in predicting the chemical exposure to a specific chemical; this was feasible with a handful of diagnostic genes for six of the ten chemicals. In this study, we exposed fertilized stickleback eggs to the six chemicals (cadmium, dibutyl phthalate, fluoxetine, ibuprofen, 17 $\alpha$ -ethynylestradiol and levonorgestrel) at the same concentrations as in the short-term adult exposures, for 9 days (the time needed for the stickleback embryo to reach the self-feeding stage). At the end of the FET test, the hatched embryo (larvae) was subjected to real-time reverse transcription PCR for all diagnostic genes. Then the results were compared to those obtained using adult fish (liver transcriptomics), enabling us to discuss the potential replacement of juvenile/adult fish testing by embryo tests.

## WE030

### Applicability of the mode of action concept for sensitivity categorization of aquatic ecotoxicological data

M. May, Fraunhofer ITEM / Chemical Risk Assessment; W. Drost, Federal Environment Agency (UBA) / Chemicals; S. Germer, German Federal Environment Agency; T. Jufferholz, German Federal Environment Agency (UBA) / Biological and Chemical Safety; S. Hahn, Fraunhofer ITEM / Chemical Risk Assessment

For environmental risk assessment predicted no effect concentrations (PNEC) for each compartment are derived representing concentrations below which no unacceptable effects are expected. The PNECs are usually derived from laboratory effect studies by applying an assessment factor on the lowest determined effect value. Based on the animal welfare concept and to avoid animal experiments (Art. 13, Art. 25), the REACH Regulation (EC 1907/2006) provides several options to avoid the chronic fish test. 240 substances from the OECD eChemPortal and ICS database of the German Federal Environment Agency have been analysed for sensitivity differences between *Daphnia* and fish to evaluate whether and when chronic fish tests can be avoided without underestimating environmental hazard. Only studies conducted according to the European Union Technical Guidance Documents were considered. The result showed that species sensitivity in chronic testing is associated with sensitivity in acute testing. A categorization system for acute sensitivity comparison was proposed that may support the integrated testing strategy. The aim of this study was the evaluation of the mode of action (MoA) concept according to Verhaar to investigate refinement options for chemicals and to check the applicability for substances that exert a specific mode of action by interacting with certain receptors (e.g. pesticides). MoA assignments were made using OECD tool box. Substances allocated to MoA3 appeared to be more sensitive to fish in acute and chronic testing whereas substances allocated to MoA1 and MoA2 were in average slightly more sensitive to *Daphnia*. However, overall the evaluation suggested that a distinct species sensitivity is probably not associated with a specific MoA class. The results further suggested that the acute sensitivity comparison system can be applied independent of the MoA class and is also applicable for substances allocated to MoA4. Furthermore, acute to chronic ratios were derived for fish and *Daphnia* data for each MoA class.

## WE031

### The fathead minnow embryo as a model for the development of alternative testing methods in ecotoxicology

S. Böhler, COS Centre for Organismal Studies; S. Oberrauch, University of Heidelberg / COS Centre for Organismal Studies; T. Braunbeck, University of Heidelberg / Centre for Organismal Studies

The fathead minnow (*Pimephales promelas*) is one of the three most common OECD test species together with the zebrafish (*Danio rerio*) and the Japanese medaka (*Oryzias latipes*). However, relatively little is known about the development, even though the fathead minnow has extensively been used for toxicological testing. After the adoption of the fish embryo toxicity test (FET) with the zebrafish as the official OECD test guideline 236, it seems essential to adapt the zebrafish FET protocol to other OECD species to broaden the applicability of the test. Prior to standardisation, it is important to clearly identify the developmental stages from fertilization to hatching and even beyond both macroscopically and histologically which are of toxicological relevance. Therefore, the primary purpose of this study was to provide a detailed overview of fathead minnow normal development. In order to elucidate pathological variability in fathead minnow development, the adapted fathead minnow FET was carried out for the known teratogens isoniazid, ethanol, caffeine and hydroxyurea; in addition to acute and sublethal effects in embryos, data for teratogenicity were recorded. Since part of the tested teratogens are known to provoke skeletal abnormalities, the development of cartilaginous and bony elements in the head region of the fathead minnow embryo was studied by means of specific histological analyses and compared to the normal development of the fathead minnow skeleton. For this end, fish exposed to the test

chemicals were stained to identify malformations of cartilage and bone in the head region of the fathead minnow embryo after termination of the FET. Malformations were recorded and compared to existing zebrafish data. Keywords: ecotoxicology, fathead minnow embryo, FET, teratogenicity

### WE032

#### Development and characterisation of the first immortalised humpback whale cell line

M. Burkard, Griffith University / Southern Ocean Persistent Organic Pollution Program; D. Whitworth, The University of Queensland / School of Veterinary Science; K. Schirmer, Eawag / Environmental Toxicology; S.M. Bengtson Nash, Griffith University / Southern Ocean Persistent Organic Pollutants Program SOPPOP

Polar foraging humpback whales (*Megaptera novaeangliae*) are dependent on a lipid-rich diet and accumulated lipid stores to undertake the longest migration and associated period of voluntary fasting, known in any mammal. This extreme life-history leads to an elevated risk of Persistent Organic Pollutants (POPs) accumulation and toxicity. Measuring the toxicological impact of POPs on wild populations of humpbacks is a greater challenge in chemical risk assessment. New and stable methods are required to study humpback whale species-specific sensitivity and cellular responses. Herein, we report for the first time the immortalisation of humpback whale cell lines. Primary fibroblasts were derived from dermal biopsies using a primary explant method. Cells of the second passage were transfected with a plasmid encoding the simian virus (SV40) large T antigen and incorporated hygromycin resistance. Successfully selected cells were cloned and cell lines were continuously subcultured with hygromycin selection. In obtained cell lines, the presence of the introduced plasmid was verified by PCR. The cell lines have been propagated eight times and showed positive immunoreaction to mouse anti-SV40T. This indicates stable introduction of the plasmid into the chromosomal DNA. Cloned cell lines will be further characterized including telomerase activity and telomere length. Further, the comparison to non-immortalised fibroblasts of different passages will reveal the natural telomere length and its temporal shortening dynamics. Overall, we present research toward a novel infinite cell line to provide more accurate and reproducible approaches towards chemical risk assessments of southern hemisphere humpback whales.

### WE033

#### Ready-to-use recombinant yeast assays for in-field detection of endocrine disruptors

M. Bittner, Masaryk University, Fac. of Science / Faculty of Science RECETOX; S. Jarque, Masaryk University / Faculty of Science RECETOX; K. Hilscherova, Masaryk University, Faculty of Science, RECETOX / RECETOX Research Centre for Toxic Compounds in the Environment

Recombinant yeast assays (RYAs) constitute a suitable tool for the environmental monitoring of compounds with endocrine disrupting activities, notably estrogenicity and androgenicity. Conventional procedures require yeast reconstitution from frozen stock, which usually takes several days and demands sterile conditions and additional equipment. With the aim of applying such assays to field studies and making them more accessible to less-equipped laboratories, we have optimized RYA by the immobilization of recombinant *Saccharomyces cerevisiae* cells using two different strategies – immobilization into biopolymers (gelatin, Bacto agar, and Yeast Extract-Peptone-Dextrose) and freeze-drying. Among the three biopolymers, gelatin showed the best results for both yeast strains for the detection of Androgen Receptor agonists (AR-RYA) and Estrogen Receptor agonists (ER-RYA). AR-RYA was characterized by a limit of detection (LoD), EC<sub>50</sub> and induction factor (IF) of 1 nM, 2.2 nM and 51, respectively. These parameters were 0.4 nM, 1.8 nM, and 63, respectively, in case of ER-RYA. Yeast immobilized in gelatin retained viability and sensitivity for more than 90 days of storage at 4°C. Freeze-dried yeast showed comparable sensitivity to RYAs immobilized in gelatin and shelf-life longer than 10 months. Both immobilization strategies reduced the assay duration to only several hours under non-sterile conditions. Immobilized RYA can be performed either in multiwell microplates or glass tubes, which allows multiple testing and easy adaptation to existing portable luminometers for direct in-field applications. This research was supported by the Ministry of Education of the Czech Republic (LO1214).

### WE034

#### Visualisation of metabolic activities using an integrated living embryo microarray and Fluorescence Ratiometric Imaging (FRIM) system

F. Zhu, RMIT University / School of Applied Sciences; D. Baker, Vancouver Island University / International Centre for Sturgeon Studies; J. Skommer, RMIT University / School of Applied Sciences; M. Sewell, University of Auckland / School of Biological Sciences; D. Włodkowicz, RMIT University / School of Applied Sciences

Significant progress in the development of physico-optical oxygen sensors using luminescence quenching by molecular oxygen has recently been made. Sensing using such microsensors is, however, still performed in small glass chambers that hold single specimens and thus not amenable for high-throughput data acquisition. Moreover, conventional measurements can only be taken along one dimension and provide classical, averaged results of metabolic activities of an entire specimen. As such they do not provide any spatial-temporal information of, for example, 2D and

2D+time oxygen distributions inside the living tissues or medium surrounding the specimen. These profound analytical limitations restrict fundamental studies on how abiotic and pharmacological stimuli affect embryonic physiology, the developmental stage when animals are typically considered to be most sensitive to environmental perturbations. These drawbacks can, however, be experimentally addressed by an emerging field of microfluidic Lab-on-a-Chip (LOC) technologies combined with sophisticated optoelectronic sensors. Lab-on-a-Chip represents a new direction that may miniaturize and revolutionize research on metabolism and physiology *in vivo*. In this work, we present a proof-of-concept approach by using microfluidic Lab-on-a-Chip (LOC) technologies combined with the latest generation of sensor foil oxygen detection system. Our prototype device is capable of immobilising live zebrafish embryos with continuous flow perfusion, while the sensor uses innovative Fluorescence Ratiometric Imaging (FRIM) technology that can kinetically quantify the temporal patterns of aqueous oxygen gradients at a very fine scale based on signals coming from an optical sensor referred to as a sensor foil. Our preliminary objective was to determine whether the sensor foil oxygen detection system can be effectively integrated into the chip-based platform and allow for characterization of oxygen gradients with the accuracy and precision needed to estimate embryonic oxygen consumption rates in zebrafish embryos. We demonstrate that by embedding the sensor foils onto the microfluidic living embryo array system, we were able to perform *in situ* FRIM on developing zebrafish embryos. Future integration of microfluidic chip-based technologies with FRIM technology represents a noteworthy direction to miniaturise and revolutionise research on metabolism and physiology *in vivo*.

### WE035

#### Alternative Methods and Study Design Refinements to Reduce or Replace Animal Use in Wildlife Toxicity Tests

B.A. Rattner, USGS-Patuxent Wildlife Research Ctr / USGS

The development of new and refinement of existing "alternative" testing procedures (3Rs in toxicology) for assessing effects of chemicals on wildlife (amphibians, reptiles, birds and mammals) have been limited in comparison to aquatic species. From a regulatory perspective, one example of a refined testing procedure is the avian acute oral test (OECD 223) which describes limit dose, LD50-slope, and LD50-only tests with as few as 14 test subjects. Another such regulatory example is the tiered testing protocol for the evaluation of candidate non-toxic shot used in hunting in the United States (*Federal Register* 62:63608-63615, 1998). Using extant toxicity data, several candidate shot materials (metals, alloys, polymers) have been approved for use without any animal testing whatsoever. From a research perspective, data from domestic birds and laboratory rodents have been employed to design and conduct small-scale sequential dosing studies to assess toxicity and risk of metals (e.g., vanadium, *J Toxicol Environ Health* 69A:331-351, 2006), pharmaceuticals (e.g., diclofenac, *Environ Toxicol Chem* 27:2341-2345, 2008) and pesticides (e.g., diphacinone, *Environ Toxicol Chem* 30:1213-1222, 2011) in wild birds. Findings from these and other studies have documented remarkable differences in sensitivity among avian species. This presentation will review and highlight some of the challenges in making inter-specific extrapolations, modifying wildlife toxicity tests to reduce animal use, and employing these data to assess risk.

### WE036

#### Fish-gut-on-chip: Development of ultrathin support for intestinal cell culture from rainbow trout

C. Drieschner, Department of Environmental Toxicology; M. Minghetti, Eawag / Environmental Toxicology; P. Renaud, EPF Lausanne School of Architecture Civil and Environmental Engineering; K. Schirmer, Eawag / Environmental Toxicology Transwells (permeable membrane inserts for cell culture) are one of the most used systems to study epithelial barrier functions *in vitro*. The porous membrane allows permeability assays, microscopy and transepithelial electrical resistance measurement (TEER). However, relatively high membrane thickness (25 µm, cell height ~10 µm) and low porosity (< 1 %) can limit full development and sensitive measurement of epithelial barrier properties. In this study we report on the use of newly developed supports for cell culture. Precisely, ultrathin membranes (1 µm) were composed of aluminum oxide. They feature a porosity of 15% and show enhanced permeability for marker molecules such as Lucifer yellow, Dextran FD40 and bovine serum albumin. Moreover, we applied impedance spectroscopy, a non-invasive and label-free bio-sensing tool, to examine the electrical properties of epithelial cells during the formation of a monolayer. Herein, we used the epithelial-like cell line RTgutGC, derived from the hindgut of Rainbow trout, to recreate the intestinal barrier of fish *in vitro*. Our results suggest alumina membranes as biocompatible material for cell culture. The ultrathin membrane, which is realized in a silicon-chip, can be integrated in transwells and in the future in microfluidic bioreactors. For transwell cell cultures we observe polarization of the epithelial cells after 2-3 weeks using confocal microscopy. Impedance spectroscopy indicates tightening of the epithelial monolayer over time by the formation of tight junctions. Additionally, impedance spectroscopy provides information on cell viability, which facilitates the evaluation of toxicant impacts on barrier properties. To summarize, with the newly developed support for cell culture we can overcome some of the shortcomings of conventional cell culture membranes (low permeability, thickness) and allow for more sensitive measurements (microscopy, impedance spectroscopy).

### WE037

#### Immortalized human cells: current approach in organ toxicity testing

R. Grillari, University of Natural Resources and Life Sciences Vienna; J. Grillari, G. Manhart, I. Lämmermann, BOKU University Vienna; M. Uhl, M. Paparella, Umweltbundesamt Environment Agency Austria; M. FÜRHACKER, WAU  
For the detection of emerging contaminants an integrated testing strategy (ITS) with application of in-vitro bioanalytical tools in the context of adverse outcome pathways (AOPs) is discussed for the protection of human and environmental health. However, currently used in vitro test systems show several limitations. Whereas, normal human somatic cells, albeit expressing cell type specific markers and functions, show a limited proliferative capacity, human tumor tissue derived cells in many instances do not express features of the corresponding normal counterpart cells and thus do not represent the in vivo situation accurately. The aim of this study was to evaluate the potential of highly differentiated, continuously growing human cells from the endothelium (HUVEC/TERT7) as well as kidney tissue (RPTEC/TERT1) for ITS. In a first approach, the cellular response to chromate treatment was tested using conventional MTT and apoptosis assay as well as induction of DNA damage using Comet assay or  $\gamma$ -H2AX staining. Additionally, detection of changes of the cell type specific phenotype or of essential cell cycle regulators and heat-shock proteins upon treatment with chromate was envisaged. Moreover, the uptake of chromium into the cells was tested using ICP-MS (total Cr) and a photometric method (CrVI). As a result, both cell lines reproducibly show cytotoxic effects of these substances at IC50 values of 7.4  $\mu$ M and 6.5  $\mu$ M for dichromate; this is in line with literature values observed in mouse NIH-3T3 cells recently. Similarly, both cell lines show a clear increase in  $\gamma$ -H2AX positive cells as indicator of DNA damage. The induction of heat shock proteins (Hsp27, Hsp70, and Hsp90) was cell line dependent and effects could be seen for concentrations as low as 0.5  $\mu$ M of dichromate for RPTEC/TERT1 and 1  $\mu$ M for HUVEC/TERT7 cell line. Whereas, no changes in the expression of cell type specific markers could be observed in RPTEC/TERT1 cells, chromate treatment of HUVEC/TERT7 cells resulted in changes of the expression level of von Willebrand Factor, an endothelial cell type specific marker protein. Therefore, we have shown that human highly differentiated, standardizable cell lines respond to stressors and might have a high potential as novel in vitro test systems for the detection of emerging contaminants in the near future.

### WE038

#### Comparative vitellogenin expression in two alternative fish models using 17 $\alpha$ -Ethinylestradiol

M. Baron, School of Biological Sciences; C. Dummett, University of Plymouth; T.B. Henry, Heriot-Watt University / School of Life Sciences; A.N. Jha, Plymouth University / Biological Sciences

The use of alternative testing strategies is currently receiving world-wide attention to reduce and ultimately, replace live fish testing. In particular, the zebrafish (*Danio rerio*) Fish Embryo Test (FET) has been implemented into OECD guidelines to assess developmental toxicity to embryonic forms, while larval-stage fish are commonly used as a sensitive measure of estrogenicity after exposure to endocrine disrupting chemicals. Three-dimensional tissue culture models offer additional functionality over conventional *in vitro* (i.e. single cell; 2-D) systems, in particular, defined *in-vivo* like tissue architecture and better cell-cell and cell-matrix interactions are longer-lived. As such they have the potential to offer a new *in vitro* screening tool for environmental toxicological monitoring. Here we report a study that compared *vrg* gene expression in both a rainbow trout (*Oncorhynchus mykiss*) 3-D liver spheroid (*in vitro*) and zebrafish larvae (*in vivo*) model, after exposure to the endogenous estrogen 17 $\alpha$ -Ethinylestradiol (EE2). Following optimisation of RNA extraction and reverse transcription for both spheroids and zebrafish larvae, time-course exposures to a range of EE2 concentrations (0.01 – 1  $\mu$ g L<sup>-1</sup>) were applied, and *vrg* gene expression measured using qPCR. Suitable housekeeping genes (i.e. 18S rRNA for spheroids and  $\beta$ -actin for the larvae) for each system were fully validated. Our results suggests that 3-D liver spheroids may be a sensitive model with which to measure *vrg* expression after exposure to endogenous estrogens and compares well with data generated from zebrafish larvae exposures. Keywords: 3-D liver spheroids, zebrafish, vitellogenin, qPCR

### WE039

#### Pharmaceuticals and fish: effects in alternative in vitro cellular and embryonal models

M. Michelova, Masaryk University, RECETOX / Faculty of Science RECETOX; M. Pipal, Masaryk University; A. Jonas, Masaryk University, RECETOX / Faculty of Science; J. Becanova, Masaryk University; L. Blaha, Masaryk University, Faculty of Science / Faculty of Science RECETOX

Pharmaceuticals are major micropollutants in water environment and represent a prevailing problem for European waters. Prediction of environmental effects of pharmaceuticals on non-target species is a complicated issue. Current EU legislations on pharmaceuticals omit the alternatives to acute dish toxicity assays but the efforts are to reduce the numbers of animals used for testing and also associated costs. Therefore, there is a need for simple and fast assays capable to identify and prioritize potential environmental risks of pharmaceuticals. In the present study, two assays considered as alternatives for short term toxicity for fish have been used to investigate effects of 8 different pharmaceuticals

(Carbamazepine, Ciproloxacin, Clofibrac acid, Diclofenac, Hydrochlorothiazide, Ibuprofen, Paracetamol and Sulfamethoxazole). The models included *in vitro* assay with a cell line derived from Rainbow trout gills (RT Gill W1), which currently undergoes validation by inter-laboratory tests, and extended Fish embryo acute toxicity test (FET) with Zebra fish *Danio rerio* embryos. The most pronounced toxicity was observed for Diclofenac (FET EC50=2.1 mg/L, RT Gill W1 EC50=44 mg/L) followed by Ibuprofen and Carbamazepine. Although the EC50 values derived from RT Gill W1 cellular assay were generally higher compared to FET results, they followed the same trend. Similar trends were also observed between the FET results and literature data on acute adult fish toxicity. These findings suggest that – in addition to the acceptance for assessment of industrial chemicals within REACH – both assays may be suitable alternatives also in screening acute toxicity testing of pharmaceuticals. Both FET and RT Gill W1 assays are also suitable for high throughput screenings that further extends the potential for their implementation in the mechanistic environmental risk assessment. (Supported by the South Moravian Centre for International Mobility - <http://www.jcmm.cz/en/>)

### WE040

#### Prediction and screening of fish biotransformation half-lives

E. Papa, Department of Theoretical and Applied Sciences; L. van der Wal, REACH Mastery; J.A. Arnot, ARC Arnot Research & Consulting / Department of Physical Environmental Science; A. Sangion, DiSTA; S. Cassani, P. Gramatica, University of Insubria / DiSTA

The bioaccumulation assessment of new and existing chemicals is a legal requirement for many regulatory agencies and a relevant step in exposure and risk assessment. Biotransformation half-life values (HLs) derived from first-order, whole body, primary biotransformation rate constants ( $k_M$ ), are shown to be key parameters determining the overall bioaccumulation potential of a chemical in fish and in food webs. However, given the limited availability of measured data, the extensive costs associated with bioaccumulation testing, and the need to reduce animal testing, there is a need to develop and evaluate more *in silico* tools for predicting HLs. This work presents new *in silico* models based on Quantitative Structure Activity Relationships (QSARs) for predicting HLs. QSAR models for an *in vivo*  $k_M$  – HL dataset (data for 632 heterogeneous organic compounds) were developed and evaluated in the software QSARINS, using a limited number of theoretical molecular descriptors, and in compliance with the “OECD principles for the validation, for regulatory purpose, of (Q)SAR Models”. In addition, and in order to improve models accuracy, a combinatorial approach was applied to predictions generated by the new QSARs and the EPI Suite  $HL_N$  model. Results show an increase in the percentage of accurate predictions from ~85% for single models, to ~94% for the combined model. Finally, predictions by different models were combined by Principal Component Analysis (PCA) to screen the biotransformation half-lives of an additional dataset of over 1300 chemicals already screened as potential PBTs. Results from the PCA show that the potential, predicted, PBT behaviour of compounds may be overestimated and therefore the potential for biotransformation could be considered to refine PBT assessment procedures. This study is an example of how alternative methods to animal testing, i.e. *in silico* QSAR models, can be successfully used at the screening level in hazard and risk assessment procedures, not only to fill data gaps but also to address uncertainty and refine previous assessments.

### WE041

#### Investigation of anti-estrogenic substances as disrupters of embryonic gonad development in Gallus gallus domesticus

L. Jessl, R. Lenz, F. Massing, Goethe University Frankfurt am Main / Aquatic Ecotoxicology; J. Oehlmann, Johann Wolfgang Goethe-Universität Frankfurt / Aquatic Ecotoxicology

Avian eggs have been shown to be suitable test systems for toxicological assessment of substances. The embryo develops outside the mother whereby changes in development are well observable. One major advantage of the chick embryo as an experimental subject is that in contrast to the recognized rodent assays no parental animals have to be killed. In addition chicken embryos dissected before hatching are not rated as animal experiments and are therefore considered as an *in vitro* system. The endocrine system of birds is largely identical to that of mammals<sup>[1]</sup> and avian eggs are known to be sensitive to a number of endocrine disrupting chemicals. Therefore the Federal Ministry of Education and Research supports the development of an animal replacement system for the assessment of the hormone-toxic potential of chemicals as disrupters of embryonic gonad development. So the present study aims to develop a replacement method for testing hormonally active environmental chemicals on the basis of chicken eggs. Here, results from studies investigating the effects of the anti-estrogens fulvestrant and tamoxifen at doses between of 0.1 and 10  $\mu$ g/g egg on embryonic gonad development of *Gallus gallus domesticus* are presented. Although fulvestrant did not affect sexual differentiation of male and female embryos directly, the feminization of genetic males by the potent estrogen EE2, however, was completely antagonized if fulvestrant was co-exposed to EE2 at a dose of 10  $\mu$ g/g egg. The partial anti-estrogen tamoxifen with its weak estrogenic activity affected especially differentiation of the female gonad whereas male animals showed no significant difference from the control group. A single dose between 0.1 and 10  $\mu$ g/g egg induced malformations of the left cortex of female gonad ranging from significant reduction to completely disappearance in some areas of the gonad. A dose of 10

µg/g egg resulted in a significant size reduction of the left ovary by up to 50% compared with the control group. In general it can be shown that the pure anti-estrogen fulvestrant does not influence sex differentiation in developing chicken embryos while the partial anti-estrogen tamoxifen impairs the differentiation of the gonads. Due to the largely identical hormone system of birds and mammals, an impairment of human sex differentiation cannot be excluded. [1] Lange, Hartel, Meyer. 2002. Evolution of oestrogen functions in vertebrates. J Steroid Biochem Mol Biol. 83:219-226.

## Invertebrate models in environmental toxicology (P)

#### **GammarusChip - customised and automated microperfusion technology for marine ecotoxicity biotests**

R. Carlidge, RMIT; D. Nugegoda, D. Wlodkovic, RMIT University / School of Applied Sciences

Traditional marine ecotoxicity testing is inherently labor intensive, requiring extensive manual procedures to be performed both to set up the tests and more importantly to collect experimental readouts. Moreover, static test procedures offer poor control of water parameters such as toxicant concentration and dissolved oxygen, which affect toxicity and are important considerations in evaluating environmental impacts of aquatic pollution. So far only minimal levels of automation have been adopted in ecotoxicology. Our current work attempts to address the current limitations by capitalizing on latest advances in microfluidics, 3D printing and laser micromachining technologies to develop highly customized, low cost and high-throughput devices. These will for the first time enable automation of ecotoxicity biotests performed on marine test organisms. This work describes an investigation into applications of microfluidic Lab-on-a-Chip technology for highly customised flow through toxicity testing chambers in marine ecotoxicity. We present development of a proof-of-concept laboratory automation system to perform ecotoxicity tests on a native marine amphipod *Allorchestes compressa*. Our innovative system incorporates a flow through design that enables the biotests to be run in a closed or open loop circuits. Automated fluidic control technology allows for concentrations of toxicants to be spiked and diluted using computerized manifold of miniaturized pumps and valves. Miniaturized video cameras monitor the amphipods during the experiment and innovative video analysis algorithms provide us with real time sub-lethal endpoints such as changes in swimming activity that would otherwise go unnoticed. A key advantage of this flow through system as compared to conventional approach is the automation of analysis and emphasis on sub-lethal behavioral parameters. The *GammarusChip* technology is inexpensive, portable, easy to use and require only a small amount of bench space to be operated. Overall waste effluent required is significantly reduced when compared to static renewal testing as well as the time needed to set-up and maintain the experiments.

### WE043

#### **Automation of Artoxkit-M ecotoxicity biotest using a microfluidic Lab-on-a-Chip technology**

Y. Huang, RMIT University / School of Applied Sciences; C.C. Aldasoro, City University London / School of Engineering and Mathematical Sciences; G.A. Persoone, MicroBioTests Inc; D. Wlodkovic, RMIT University / School of Applied Sciences

Despite its critical importance, the broad deployment of high-throughput whole-organism ecotoxicity tests is profoundly limited by the lack of appropriate bio-compatible automation, integrated optoelectronic sensors, and the associated electronics and analysis algorithms. These major shortcomings have not been yet addressed, and as a result all such biotests are still performed manually, are time consuming, laborious and not available for high-throughput analysis. In this work, we present development of a miniaturized Lab-on-a-Chip (LOC) platform for automation of acute ecotoxicity test based on a marine crustacean *Artemia franciscana* (Artoxkit M™). We for the first time demonstrate development of a proof-of-concept technology for rapid assessment of sub-lethal, behavioral ecotoxic effects. The system working principles incorporated a time-resolved video data analysis to dynamically assess impact of the reference toxicant on swimming behavior of marine crustacean *Artemia franciscana*. Our system design combined: (i) innovative LOC flow-through device for on-chip keeping of *Artemia* sp.; (ii) automated mechatronic hardware for LOC fluidic system actuation and data acquisition; and (iii) innovative video analysis algorithms for the segmentation, tracking, visualization and movement analysis. The algorithm are written in Matlab and released open-source at the website [www.phagosight.org](http://www.phagosight.org). The chip-based device supported rapid loading and keeping of free swimming crustacean larvae suspended in a continuous microfluidic perfusion as a mean of toxin delivery in both open-loop and closed-loop modalities. This system was also capable of performing fully programmable time-lapse and video-microscopy of multiple samples for rapid ecotoxicity analysis. Custom video algorithms were then developed for scoring dynamic features of video frames, capturing detailed statistical information on test specimen movements. This enabled development of a new test protocol to dynamically detect sub-lethal behavioral end-points based on a swimming behavior of *Artemia franciscana*. This work provides a foundation for automated high throughput ecotoxicity biotests using innovative Lab-on-a-Chip

technologies. A key advantage of this flow through system as compared to conventional static testing is the miniaturization and automation of analysis and special emphasis on sub-lethal behavioral parameters.

### WE044

#### **Toxic effects of *Chaetoceros calcitrans* extracts on the embryos of three commercially relevant shellfish species**

G. Giménez Papiol; A. Buer, Rostock University; M. Miller, Plant and Food; T. Harwood, H. Kaspar, Cawthron Institute

*Chaetoceros calcitrans* is a marine diatom extensively used as food in aquaculture production facilities. It is considered nutritionally good for shellfish embryos development due to its high content in polyunsaturated fatty acids (PUFA; Miller et al 2013), but some authors suspect it is able to produce polyunsaturated aldehydes (PUA, Ragg et al 2010) which have deleterious effects on marine invertebrates reproduction (Wichard et al 2007) and induce apoptosis in invertebrate embryos and cell cultures from different phyla (Romano et al 2003, Adolph et al 2004). The standardized shellfish embryo-based ecotoxicological assay (ASTM 2004) has been adapted and used as screening tool for the detection of *C. calcitrans* toxicity during its culture growth. The most toxic sample, most likely to contain PUA, was analyzed by GC-MS. Greenshell mussel™ (*Perna canaliculus*), blue mussel (*Mytilus galloprovincialis*) and Pacific oyster (*Crassostrea gigas*) were exposed to the same aqueous extracts of *C. calcitrans* samples and the yield of D-larvae after 48h was recorded and compared to each control group. The extracts did not present any toxic effect on *M. galloprovincialis* embryos (>80% D-larvae), one extract was toxic for *C. gigas* embryos (< 50% D-larvae), and the same extract plus three further extracts were toxic for *P. canaliculus* embryos (< 30% D-larvae). The sample toxic to *C. gigas* and *P. canaliculus* corresponded to the pellet of a 3-day old culture of *C. calcitrans*, but no PUA was detected by GC-MS. The toxicity of *C. calcitrans* on shellfish embryos development, mainly *P. canaliculus*, has been confirmed, but the compound(s) that causes the toxic effect still remain(s) unknown.

### WE045

#### **Investigation of toxicity pathway according to the change in concentration of chlorpyrifos and -oxon in *Caenorhabditis elegans*. : cyp35a2 family genes expression and acetylcholine esterase activity**

J. Roh, Division of Environmental Science and Ecological Engineering / Division of Environmental Science and Ecological Engineering; J. Kwon, Korea University / Division of Environmental Science and Ecological Engineering

Chlorpyrifos (CP) is a well-known organophosphorus pesticide that produces a neurotoxic metabolite, chlorpyrifosoxon (CPO) that inhibits acetylcholinesterase (AChE) activity, by cytochrome P450 isozymes. Time-course changes in cellular processes including metabolic transformation and AChE activity are dependent upon the changes in the concentrations of CP and CPO in the body. The primary goals of this study were (1) to investigate the changes in metabolism-related gene expression and enzyme inhibition by CPO with exposure time and (2) to link these responses to residual CP and CPO concentrations in *Caenorhabditis elegans* under the constant exposure condition using passive dosing and during the recovery regime. Organisms were exposed to CP at 0.3 mg L<sup>-1</sup> up to 8 h to observe cellular responses. Organisms exposed to CP for 4 h were monitored for 48 h in a clean medium to evaluate recovery from CP and CPO exposure. AChE activity was inhibited rapidly by 80 % shortly after the exposure to CP (4 h) at 0.3 mg L<sup>-1</sup>, whereas the AChE activity showed only negligible recovery for 4 h followed by gradual recovery until the end of the depuration test. The expression of *cyp-35a* family genes (*cyp-35a2* and *cyp-35a3*) began to decrease as soon as entering to recovery regime and reached a level similar to that of the control after 9 h. The time lag in toxicity pathway as a response to CP exposure could be explained by the fate of CP and CPO in the body. The concentration of CP decreased in the body during the depuration phase, leading to a decrease in CP metabolism. Therefore, CYP metabolism-related mRNA expression was not needed. However, CPO could be produced until all CP was exhausted, hence, stabilization of enzyme activity could be retarded. The toxicity model of CP on soil nematode *C. elegans* helps to comprehensively understand a correlation among the reaction of metabolism process (i.e. metabolism-related gene expression), toxicological effects by metabolite (i.e. AChE activity) and the fate of chemicals in the body.

### WE046

#### **Individual- and population-level toxicity of the insecticide Chlorantraniliprole (Rynaxypyr®), and its Formulated Product Altacor® to the Cladoceran, *Ceriodaphnia dubia***

J.D. Stark, Washington State University / Dept of Entomology

The effects of the anthranilic diamide insecticide, chlorantraniliprole and its commercial formulated product Altacor® were evaluated on the Cladoceran, *Ceriodaphnia dubia*. These substances were evaluated separately to determine whether the formulated product and active ingredient exhibit differences in toxicity. Acute LC50s were estimated as well as chronic effects on populations. Both products were highly toxic after acute exposure. Chronic exposures reduced the number of founding individuals, survival duration, offspring, final population size, and population growth rate in a concentration-dependent manner. A hazard assessment using a risk quotient approach was also developed comparing acute toxicity to the expected environmental concentration. The risk quotient was

compared to population-level impacts to determine how accurately it predicted effects at the population level. The potential hazard of this product to aquatic ecosystems will be discussed.

#### WE047

##### **Quantifying sublethal effects of glyphosate and Roundup® to *Daphnia magna* using a fluorescence based enzyme activity assay and video tracking**

P. Roslev, L.R. Hansen, M. Ørsted, Aalborg University / Biology and Environmental Science

Glyphosate (N-(phosphonomethyl)glycine) is the active ingredient in a range of popular broad-spectrum, non-selective herbicide formulations. The toxicity of this herbicide to non-target aquatic organisms such as *Daphnia magna* is often evaluated using conventional toxicity assays that focus on endpoints such as immobility and mortality. In this study, we investigated sublethal effects of glyphosate and Roundup® to *D. magna* using video tracking for quantifying behavioral changes, and a novel fluorescence based assay for measuring in vivo hydrolytic enzyme activity (FLEA assay). Roundup® exposure resulted in concentration-dependent inhibition of alkaline phosphatase activity in *D. magna*. The inhibition of alkaline phosphatase by Roundup® was temperature-dependent with lowest inhibition at 14 °C and greater inhibition at 20 and 26 °C. Exposure of *D. magna* to sublethal concentrations of glyphosate resulted in behavioral effects quantified as decreases in average swimming velocity and distance moved whereas the inactive time in defined arenas increased. Exposure of *D. magna* to binary mixtures of glyphosate and copper (Cu) attenuated acute metal toxicity. The results suggest that a combination of assays targeting in vivo enzyme activity and behavioral changes may be applied as a quantitative and sensitive tool for detecting sublethal effects of glyphosate and Roundup® to *D. magna*. The inhibitory effect of Roundup® on alkaline phosphatase in non-target organisms warrants further investigations.

#### WE048

##### **Assessment of response of *Daphnia magna* exposed to contaminated sediments.**

A.S. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiología Laboratorio Alejandro Villalobos

In this study an evaluation of the health status of *Daphnia magna* was performed using 6 biomarkers to detect toxic and genotoxic effects of sediments contaminated with metals and persistent organic compounds, to prove the usefulness of these sensors in biomonitoring studies and ecological risk assessment. 14 sediment samples were assessed levels of metals and PAH, PCB and organochlorine pesticides (OP) and bioassays in parallel, were conducted with *Daphnia magna* neonates to determine the toxicity of sediments, and its effect on the following physiological parameters: Respiration rate, excretion rate, feed rate, Index O:N and 2 biomarkers: lipid peroxidation (MDA) and genetic damage (Comet Assay). The data from the physiological parameters and biomarkers were integrated to calculate the index BRI (Biomarker response index) to establish the state of health of the organisms exposed to sediment. The results showed that average levels of metals in sediments varied from 19.8 to 119.6 mg g<sup>-1</sup> and Cops (PAHs, PCBs OPs) from 0.01 to 827.13 mg g<sup>-1</sup>. In multiple correlation analysis performed with data from BRI index and levels of pollutants, a significant relationship between the concentrations of Cd, Cr, Ni, Pb, V, PAHs, PCBs and the response of biomarkers evaluated was observed. Sample 1 had the lower levels of contaminants and BRI value was similar to the control group. The lowest values of BRI index that showed health status with severe alterations were obtained in tests with samples 3, 4 and 6. In these samples was observed that the concentrations of metals and Cops are higher than the values established in the Sediment Quality Tables (NOAA). (effects range-low causing adverse effects). From the above it is clear that the evaluated biomarkers provided information that matches with the levels of contaminants in sediments. Therefore the battery of biomarkers used could be a useful tool for studies of environmental biomonitoring and ecological risk.

#### WE049

##### **Relative expression of vitellogenin and vitellogenin-receptor genes in *Macrobrachium rosenbergii* exposed to chlordecone: an in-situ study case**

A. Lafontaine, E. Gismondi, Laboratory of Animal Ecology and Ecotoxicology; M. Hanikenne, University of Liege / Center for Protein Engineering; c. Boulange-Lecomte, Laboratory of Ecotoxicology; J. Forget-Leray, University of Le Havre / Laboratory of Ecotoxicology; J. Thome, Liege University / Laboratory of Animal Ecology et Ecotoxicology

In assessment of environmental quality, effects of xenobiotic compounds (e.g. industrial chemicals, pesticides) have an increased concern because they could interfere with endocrine system of organisms. Their effects are extensively described in vertebrates but less studied in invertebrates, while these organisms represent the major part of the aquatic biota. The endocrine system is mediated by hormones which regulate several physiological processes such as reproduction and juvenile growth. Endocrine disruptors could interfere at different steps of the signaling pathway of a hormone by several mechanisms and could thus induce adverse effects on endocrine system of organisms. In this *in-situ* study, we have investigated the effects of chlordecone, an organochlorinated pesticide, on the endocrine system of the crustacean decapod, *Macrobrachium rosenbergii*, by measuring relative expression of the vitellogenin gene in hepatopancreas of

organisms coming from a control site and a contaminated site. In invertebrates, vitellogenin (Vtg) is the precursor of yolk proteins (e.g. vitellins) which supply energy reserves available during embryonic and larval development. Due to its crucial role, vitellogenin have been described as exposure biomarker for endocrine disruptors. In addition, we have evaluated the relative expression of the vitellogenin receptor (VtgR) gene in gonadal tissue. Males and females prawns of *Macrobrachium rosenbergii* were sampled in a control site and an aquaculture pond supply by a contaminated river (0.33 µg.L<sup>-1</sup> of chlordecone). Hepatopancreas and gonadal tissues were dissected and total RNA was extracted and analyzed by quantitative RT-PCR. The results revealed that Vtg and VtgR gene expressions were influenced by chlordecone exposure in *M. rosenbergii*. Indeed, we noticed an increase of both genes, in exposed prawns compared to control one, whatever the gender. This observation suggested that disruption of the endocrine system could therefore occur following an exposure to an estrogenic compound. The prawns reproduction and the population dynamics could thus be indirectly impacted by the environmental presence of this compound. This study allows us to better understand the mechanisms of action of chlordecone and shows also that chlordecone could be an endocrine disruptor compound in crustaceans which could have some adverse effects on hormonal system of crustaceans and thus on populations and ecosystems.

#### WE050

##### **PRELIMINARY DATA ON TOXICOKINETICS OF AN AZO DYE IN THE MARINE AMPHIPOD PARHYALE HAWAIIENSIS**

A. dos Santos; M.C. Artal, University of Sao Paulo - USP / Toxicology and Toxicology analysis; J.A. Vendemiatti, University of Campinas; B. Silva, São Paulo State University UNESP / Chemistry; M.V. zannoni, UNIVERSIDADE ESTADUAL PAULISTA - UNESP / QUIMICA ANALITICA; G.d. Umbuzeiro, FACULTY OF TECHNOLOGY - UNICAMP / LEAL

*Parhyale hawaiiensis* is a marine amphipod worldwide distributed that are starting to be used in ecotoxicology. They are easy to culture in the lab and measure around 8 to 12mm. Disperse azo dyes are extensively used in the textile industry. Dyes are lost during dyeing process and can reach aquatic ecosystems. Moreover, because of its hydrophobicity these compounds tend to accumulate in sediments and biota. We selected the CI Disperse Red 1 (DR1), which has a log Kow 4.2 and is toxic to aquatic organisms. It was already demonstrated that CYP and GST enzymes are involved by biotransformation of DR1 in freshwater organisms such as *Daphnia*. No information was found about absorption and distribution of those compounds in microcrustacean aquatic organisms. Thus, the aim of this study was to obtain data on absorption and biotransformation of DR1 in *P. hawaiiensis*. Adult organisms of *P. hawaiiensis* were exposed to different non-lethal concentrations of commercial DR1 (nominal concentrations of 0.01 to 5 mg.L<sup>-1</sup>) using 4 and 12 hours of exposure and hemolymph was collected. A pool of hemolymph from 10 organisms was diluted in ultrapure water and liquid-liquid extracted (2.5DCM:1MeOH). LC-MS/MS (Linear Ion Trap Quadrupole LC/MS/MS Mass Spectrometer) was employed for quantification of DR1. To verify if CYP and GST were involved in DR1 metabolism in *P. hawaiiensis*, neonates were exposed to 1 mg.L<sup>-1</sup> with and without an enzymatic CYP inhibitor (0.1 mg.L<sup>-1</sup>) for 96 hours. GST activity were measured in a spectrophotometer UV/VIS at 340nm. DR1 was quantified in the hemolymph from < 0.001 to 0.281 mg.L<sup>-1</sup> (LOQ=0.001 mg.L<sup>-1</sup>), and the concentration of the dye in the hemolymph increased with concentration and time of exposure. We observed an increase in GST activity in DR1 exposed organisms, as compared to negative control. When CYP inhibitor was added GST activity was reduced to negative control levels. We conclude that DR1 is absorbed by *P. hawaiiensis* and it is possible to measure its concentration in hemolymph of such small organisms. We also suggest that CYP and GST are involved in DR1 biotransformation also in *P. hawaiiensis*. More experiments are being conducted with different times of exposure to understand the absorption behavior of DR1. Also metabolites of DR1 will be analyzed in hemolymph and in other tissues.

#### WE051

##### **Proteome variations in *Macrobrachium rosenbergii* exposed to chlordecone: a gel-free proteomic approach**

A. Lafontaine, Laboratory of Animal Ecology and Ecotoxicology; G. Mazzucchelli, University of Liege; E. De Pauw, University of Liege / Center for Analytical Research and Technology; J. Forget-Leray, University of Le Havre / Laboratory of Ecotoxicology; J. Thome, Liege University / Laboratory of Animal Ecology et Ecotoxicology

Some xenobiotic compounds (e.g. industrial chemicals, pesticides) are well known to interfere with endocrine system of organisms in various ways. Their effects are extensively described in vertebrates but less studied in invertebrates, while these organisms represent the major part of the aquatic biota. Endocrine disruptors could interfere at different steps of the signaling pathway of a hormone by several mechanisms. They can modify the metabolism of circulating hormones, which regulate several physiological processes (e.g. reproduction, growth). Therefore, the endocrine system of organisms could be disrupted. During the last decades, proteomic approach has been developed progressively in the field of ecotoxicology. Proteomics allow assessing changes in the expression of specific proteins and/or protein groups, occurring in response stress conditions, as for example chemical exposure. Proteomics could also allow elucidation of the underlying molecular pathways leading to adverse effects for organisms. In this study, we have

investigated the effects of chlordecone, an organochlorinated pesticide, on the endocrine system of the crustacean decapod, *Macrobrachium rosenbergii* by measuring variations of protein expression in hepatopancreas tissue of organisms coming from a control tank and a contaminated tank using a “gel-free” proteomic analysis. The prawns of *M. rosenbergii* were exposed for one month to chlordecone at three environmental relevant concentrations (0.2 µg.L<sup>-1</sup>, 2 µg.L<sup>-1</sup>, 20 µg.L<sup>-1</sup>). The results revealed that the proteome of *M. rosenbergii* is influenced by chlordecone exposure. Expression of several proteins was significantly modified between the different treatments. Most of these proteins are cytoskeletal proteins or proteins involved in energy or immune metabolism. But, other proteins involved in reproduction or development processes showed significant changes in their expression. Due to the fact that these proteins play an important role in the hormonal system of crustaceans, results suggest that chlordecone is likely to be an endocrine disruptor for crustaceans. This study shows that chlordecone is an endocrine disruptor in crustaceans which could have some adverse effects on hormonal system and thus on the populations and ecosystems. Results also highlight that proteomics is an appropriate way to better understand the mechanism of action of endocrine disruptor compounds and their impacts on population dynamics.

## WE052

### Responses of antioxidant genes and survival in the crab *Macrobrachium japonicus* following to perfluorooctane sulfonate exposure

K. Park, Department of Fisheries and Ocean Science; W. Kim, University of South Florida; C. Nikapitiya, I. Kwak, Chonnam National University / Faculty of Marine Technology

Perfluorooctane sulfonate (PFOS) is used as a degradation product of many perfluorinated compounds. It is persistent in the environment and bioaccumulates in soil, water, air, and living organisms. The crab *Macrobrachium japonicus*, is a potential bio-indicator to reflect the quality of marine sediment environments and is a commercially important species living along coastal areas. To investigate the relationship between oxidative stress responses and crab survival, we investigated the transcription levels of antioxidant and detoxification signals in *M. japonicus* crabs exposed to PFOS toxicity. Survival of crabs decreased to 80% after 24 h and to 64% after 96 h of relatively high concentrations of PFOS exposure. Significant up-regulation of superoxide dismutases and catalase (CAT) was observed after 24 and 96 h exposure to PFOS at different concentrations. The gene expression levels of glutathione peroxidase, phospholipid hydroperoxide glutathione peroxidase (PHGPx), and thioredoxin reductase were significantly up-regulated after exposure to PFOS for 96 h. The transcript levels of CAT and PHGPx were induced in dose- and time-dependent manners after PFOS treatments. However, peroxiredoxin gene expression was significantly up-regulated in *M. japonicus* crabs exposed to 10 and 30 µg L<sup>-1</sup> PFOS for 96 h. In general, expression of genes related to oxidative stress and detoxification was more substantially induced by long-term than short-term PFOS treatments. *M. japonicus* survival was measured, and there was a slow, gradual decrease during exposure, reflecting a time-dependent manner of up-regulation in the seven genes in an effort to eliminate the induced reactive oxygen species caused by PFOS treatments. In terms of gene expression, we suggest analyzing parallel or binding short and/or long-term exposure using eco-toxicological approach.

## WE053

### Addressing the recovery of feeding rates in post-exposure feeding bioassays: *Cyathura carinata* as a case study

A. Pais-Costa, MARE Marine and Environmental Sciences Centre / Department of Life Sciences IMAR CMA; P. Acevedo, Instituto de Investigacion en Recursos Cinegeticos / SaBio IREC; J. Marques, MARE Marine and Environmental Sciences Centre / Department of Life Sciences IMAR CMA; M. Martinez-Haro, IMAR-CMA (Marine and Environmental Research Centre / Department of Life Sciences

Post-exposure bioassays are used in environmental assessment as a cost-effective tool, but the effects of organism's recovery after exposure to pollutant has not yet been addressed in detail. The objective of this research was therefore to determine the time period during which the feeding rate (FR) of a test species remains inhibited after the exposure period, i.e., without contact with the pollutant (post-exposure time), in order to establish a safe window in which the FR endpoint signals the contact with the toxicant. This led us to evaluate the stability of the post-exposure FR response up to 24 hours after two different contaminant exposure periods (48 h and 96 h) for two sublethal concentrations of cadmium (Cd [0.5 mg/l and 5 mg/l], as a reference toxicant) in laboratory conditions. The experiments were performed using the isopod *Cyathura carinata*. For this purpose, five different experimental groups were designed: one control group without exposure to Cd, plus two more for each of the Cd concentrations, one for each exposure period. Feeding tests were carried out at five different times in each experimental group: a) the control group feeding tests were performed immediately before starting the experiment (0 h - the result from this test represented the baseline for all experimental groups), and at 48 h, 72 h, 96 h and 120 h after the start of the experiment; b) for animals exposed to Cd, the tests were carried out after the exposure period (EP), and at EP+3 h, EP+6 h, EP+12 h and EP+24 h (post-exposure times). The mean FR in the control group did not differ over time ( $p > 0.05$ ). With regard to controls, mean FRs were statistically lower in the organisms exposed to 5

mg Cd/l for all the post-exposure times tested for both 48 h and 96 h exposure periods ( $p < 0.05$ ). However, no statistical differences were detected for any of the organisms exposed to 0.5 mg Cd/l except for the post-exposure times EP+12 h and EP+24 h of the 96 h exposure period ( $p < 0.05$ ). For the groups exposed to Cd, no significant differences between FR at EP and all the remaining post-exposure time intervals were detected at any of the exposure periods ( $p < 0.05$ ). Although not significant, a slight increase on the feeding rate was detected at EP+6 h for 48 h exposure period. Results showed that feeding depression was a stable endpoint up to 24 h after Cd exposure, which is useful for ecotoxicological bioassays.

## WE054

### Cyproterone acetate and flutamide effects on egg and juveniles development of *Gammarus pulex*

E. Gismondi, Laboratory of Animal Ecology and Ecotoxicology; J. Thome, C. Joaquim-Justo, Liege University / Laboratory of Animal Ecology et Ecotoxicology  
Several pollutants are well known to cause endocrine disruption which could lead to modify some biological processes such as reproduction or the development of exposed organisms. However, the limited knowledge of the endocrine systems of invertebrates makes difficult the assessment of effects of xenobiotics considered as endocrine disruptors. The aim of this study was to compare the effects of two anti-androgens: cyproterone acetate (CPA, anti-androgenic steroid) and flutamide (anti-androgenic non-steroid) on *Gammarus pulex*. The parameters recorded were egg development (i.e. hatching time, neonate length), juvenile development (i.e. time of first molt, growth) and spermatozoa number in males. Eggs were removed from the marsupium of females and individually exposed at each xenobiotic at 0.1 µg.L<sup>-1</sup> and 10 µg.L<sup>-1</sup>. In parallel, males were exposed to the same conditions for 5 days (i.e. time of spermatogenesis) just after copulation (i.e. precopulate separation), and spermatozoa were counted. Results revealed that CPA and flutamide affect the development of egg and juveniles, as well as spermatogenesis. Indeed, although the time of hatching was not affected for both compounds and concentrations, length of neonates was higher in CPA exposures and had a tendency to be smaller in flutamide exposures. In addition, growth in juveniles was slower in CPA conditions and seems to be higher in flutamide conditions. No difference was observed on the time of first molt except in juveniles exposed to CPA at 10 µg.L<sup>-1</sup> for which the first molt was delayed. Finally, spermatozoa numbers tend to be lower in CPA 0.1 µg.L<sup>-1</sup>, but higher in CPA 10 µg.L<sup>-1</sup>. The present study shows that cyproterone acetate and flutamide affect egg development and juvenile growth. Knowing that these processes are hormonally controlled in amphipods, results suggest that these compounds, in addition to be endocrine disruptors in vertebrates, are likely to be endocrine disruptors in invertebrates as well. However, although both compounds are anti-androgenic in vertebrates, their effects on *G. pulex* are different, and further studies are needed to understand their mechanisms of action.

## WE055

### Effects of sublethal concentrations of methoprene and 4-nonylphenol on chitinase activity in the freshwater amphipod *Gammarus pulex*

S. Horion, University of Liege / Biology Ecology and Evolution; J. Thome, Liege University / Laboratory of Animal Ecology et Ecotoxicology; E. Gismondi, Laboratory of Animal Ecology and Ecotoxicology

Nowadays in ecotoxicology, endocrine disruptive effects of organic micropollutants (e.g. pesticides, industrial chemicals) are increasingly studied because they could have impacts at low concentrations (e.g. ng.L<sup>-1</sup>). However, if effects of endocrine disruptors are well documented on vertebrates, few information is given on invertebrates, although they constitute essential components of aquatic ecosystems, as for example amphipod gammarids, commonly used as biological models in ecotoxicology. In amphipods, reproduction is strongly related to molt process which is controlled by hormones (i.e. hydrocortisone). Chitinase is a chitinolytic enzyme involved in the exoskeleton degradation in arthropods, and plays a crucial role in molting, growth, reproduction of amphipods, and thus population longevity. Consequently, chitinase activity in gammarids could be used as a biomarker of exposure in endocrine disruption assessments. This work aimed to study the effects of sublethal concentrations of 4-nonylphenol and methoprene on the endocrine system of *Gammarus pulex* by measuring chitinase activity according to gender, pollutant concentrations and time of exposure. Results revealed that exposure to low concentrations of nonylphenol (0.05, 0.5, 5 µg.L<sup>-1</sup>) affects chitinase activity in *G. pulex* differently according to gender. Indeed, chitinase activity was increased in exposed males and decreased in exposed females, as compared to respective controls. These results were correlated with the number of individuals having molted. However, even if trends were less clear for methoprene, a decrease of chitinase activity was measured in both genders. The present study revealed that exposition to low concentrations of 4-nonylphenol and methoprene affects the molting process of *G. pulex*, differently according to gender, suggesting impact on the endocrine system. We can hypothesize that, at long term, the *G. pulex* populations could be affected (e.g. alteration of reproduction), what may cause a dysfunction of ecosystem. Nevertheless, further studies are needed to understand the mechanisms of action of these xenobiotics and predict the impact on *G. pulex* populations. Finally, this study underlines the importance to consider the sex in ecotoxicological studies.

## WE056

### DNA INTEGRITY IN THE BIVALVE SCROBICULARIA PLANA

## EXPOSED TO BENZO[a]PYRENE

a. chate, Université Catholique de l'Ouest / Sciences Environnement; M. Bruneau, H. Perrein-Ettajani, Université Catholique de l'Ouest; C. Mouneyrac, Université Catholique de l'Ouest / MMS EA

In the perspective of a biomonitoring application for assessing genotoxicity of estuarine ecosystems, the Comet assay has been developed on spermatozoa, gills and digestive glands of the bivalve *Scrobicularia plana*, in order to propose a sensitive and reliable genotoxicity biomarker in an ecologically relevant estuarine species. This comet assay was developed on *S. plana* exposed to a model contaminant, Benzo[a]pyrene (B[a]P), which DNA damage effects have been largely demonstrated on many cell types. Animals were exposed to 10 and 100 µg/L of B[a]P for 24 h and 5 days. In addition, so as to get a better understanding of cell mechanisms induced in response to DNA damage, expression of genes implicated in DNA repair, recently characterized in this species, was assessed by qRT-PCR and apoptosis induction was determined by measuring caspase 3 activity. Results showed tissue-specific responses in terms of DNA strand breaks following animal exposure to B[a]P. Expression of genes implicated in DNA damage as well as caspase 3 activity enable to identify cell response triggered to compensate genotoxicity. These preliminary data converge towards the fact that genotoxicity represent a very promising biomarker of pollution in the bivalve *Scrobicularia plana*. The development of the Comet assay on sperm cell will also allow to predict impact of pollutants on reproduction at a molecular level, their consequences at individual level for the subsequent generation and at a larger scale, for the population dynamic.

### Effects of biological and molecular gene responses on the abalone *Haliotis discus hannai* responding to temperature stress

K. Park, Department of Fisheries and Ocean Science; J. Lee, Chonnam National University / Department of Aquatic Life Medicine; J. Kang, Pukyong National University / Department of Aquatic Life Medicine; J. Kim, Gangwon Provincial College / Department of Marine Life Science and Aquaculture; I. Kwak, Chonnam National University / Faculty of Marine Technology

Temperature changes are one of the most significant environmental threats impacting global ecosystems. Abalone, *Haliotis discus hannai*, is a marine gastropod, and an important fishery and food industrial resource in Asia. To investigate the potential ecological risk posed by temperature stress, we measured biological responses such as survival rate, falling rate of abalones, and histological changes in the Pacific abalone *Haliotis discus hannai*. Additionally, biochemical and molecular responses were evaluated in *H. discus hannai* exposed to various temperature gradients. The survival rate was reduced in abalones exposed to more 26°C temperatures. Increased temperature stress induced higher falling rate of abalones and histological changes in the foot. Furthermore, increased antioxidant enzyme activities were observed in abalones exposed to relative high temperatures. The activities of superoxide dismutase were induced in a time-dependent manner after high temperature stress. Generally, heat shock protein 90 also increased significantly in *H. discus hannai* exposed to temperature gradients for 12 h. These results provide valuable information regarding stress responses to increased temperatures, in *H. discus hannai*: adverse biological and molecular outcomes could be utilized as risk assessments and stress monitoring of marine ecosystems under increased water temperatures.

### Assessment of the response of *Physa acuta* (Physidae) to emerging contaminants

A.S. Sobrino-Figueroa, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiología Laboratorio Alejandro Villalobos

Emerging contaminants (EC's) are a diverse group of compounds which are included Pharmaceutical and Personal Care Products (PPCP's) as soaps, creams, shampoos, deodorants, toothpastes, mouthwashes, detergents, drugs and perfumes. Also belong in this group products such as disinfectants and cosmetics. The studies on the effects of PPCP's are scarce, for this reason the aim of this work was to evaluate the toxic effects of 6 products Personal Care (3 toothpaste: Colgate, Crest and Freska and 3 mouthwashes: Astringosol, Colgate and Listerine), 3 detergent (Ariel, Roma and Salvo) and 2 drugs (aspirin and paracetamol) on juveniles of *Physa acuta* gastropod to determine their sensitivity to these products. Toxicity bioassays were carried out with juvenile *Physa acuta*. The organisms were exposed to five concentrations of each product plus a control group, to determine the LC<sub>50</sub> (lethal concentration 50). Furthermore the degree of lipid peroxidation in the tissues of gastropods was evaluated by measuring the concentration of MDA (malondialdehyde) in sublethal tests, where gastropod was exposed to the LC<sub>10</sub> for 30 days. The toxicity of the products tested ranged from highly toxic and toxic (mouthwashes), harmful products (detergents), potentially harmful compounds (analgesic) and non-toxic products (toothpastes). The degree of lipid peroxidation in sublethal tests was (the most toxic to least toxic): Drugs > Detergents > Mouthwashes > Toothpastes. The results indicate that it is probable that a risk exists by the presence of the components of these products in the wastewater are discharged into aquatic systems, which could cause adverse effects to the populations of *Physa acuta*.

### Investigating potential combined toxic effects of Roundup and genetically modified maize in the aquatic environment of South Africa

K. Minnaar, North-West University / Zoology; H. Bouwman, North-West University / Environmental Sciences and Development

The global population is constantly increasing, with seven billion mouths to feed, and an estimated nine billion in thirty years. This increase in population places stress on crop production, with a higher demand for crops and less workable land areas. The successful production of crops therefore, depends on the correct applications of inputs that will sustain the raising demands for food. This is achieved by combining technological advances, genetically modified (GM) crops, with the current practices of using herbicides and pesticides. The chemical broad-leaf herbicide Roundup has been reported to have effects on the development, and survival of invertebrates. However, GM crops, such as Bt-maize, are promoted as safer for the environment since no chemical pesticides are needed. This study aimed to determine the chronic effects of combining Bt-crop residues and Roundup on the development, fecundity, and survival of the freshwater gastropod snail *Bulinus tropicus*. A static renewal toxicity test was used to expose one generation of *B. tropicus* to 50 cm<sup>2</sup> of dried maize leaves (either non-Bt or Bt isolate) in 900 ml of synthesized freshwater, in different combination with 0.7 mg/L glyphosate. All treatments received the same amount of fish food every fourth day for the duration of the exposure, eliminating any nutritional differences between treatments. There was no indication of difference in the development, measured in growth, of the embryos irrespective of the presence of Roundup or Bt maize leaves. No decrease in survival of the embryos was found, indicating no adverse effects of either Roundup nor Bt on the development and survival of the embryo of *B. tropicus*.

### Ecotoxicological effects of organotin compounds: a Finnish view

O. Penttinen, University of Helsinki / Faculty of Biological and Environmental Sciences; L. Gaspar Rull, Universidad Autónoma de Madrid / Departamento De Biología; M. Dahl, University of Helsinki; V. Malk, Palmenia Centre for Continuing Education; J. Mannio, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production; A. Witick, Nab Labs Oy Ltd Ambiotica; S. Penttinen, University of Helsinki

Organotin compounds are used as stabilisers for PVC and as catalysts for various products, and historically as biocides and ingredients of antifouling boat paints. Therefore especially tributyltin (TBT), triphenyltin (TPT) and their degradation products dibutyltin (DBT) and monobutyltin (MBT) are abundant in sediments of coastal and inland water areas with high shipbuilding and harbor or industrial activities. These compounds meet both persistence and bioaccumulation criteria, and produce acute and chronic toxicity through specific mechanisms at very low environmental concentrations posing risk to non-target species, especially to prosobranch molluscs. In this study, screening of organotin compounds in the sediments were performed using GC-ICP-MS, and the linkage between acute and chronic adverse effects of TBT and TPT and toxicity modifying factors including performance of test organism (mudsnail *Potamopyrgus antipodarum*) were investigated for different aquatic organisms. In Baltic Proper, surface sediment organotin concentrations were in the range from 1 to 70 µg/kg dry sediment (normalized to 10 % OM). In Helsinki marine area concentrations up to 350 µg/kg were detected. In the lake and river sediments levels of organotin concentrations were in the range from 0-315, 8-1585, 0.9-73, and 0-0.9 µg/kg for MBT, DBT, TBT and TPT, respectively. Results also demonstrated very high acute (species independent) and chronic toxicity for TBT and TPT. In acute toxicity testing, using *L. variegatus* as a test organism, median lethal concentrations ranged from 2.9 to 3.8 µg/L, and from 40.0 to 63.2 for TBT and TPT, respectively but neither pH (range 6-8) nor water hardness (Ca+Mg range 0.1-2.5 mmol/L) affected the LC<sub>50</sub> values. In sediment assessment, performance of *P. antipodarum* in different types of lake sediments was investigated. Relatively uncontaminated sediment from the Lake Vanajavesi was suitable for reproduction test, and sediment quality has only minor effects of reproduction. *P. antipodarum* showed sensitivity to the organotins during eight week's chronic test by reducing the production of embryos during the experiment. The results also support contention that mudsnail is suitable for 1) sediment toxicity studies and 2) for reproduction tests focusing on the effects of endocrine disruptors. Organotin analyses from sediment samples revealed widespread butyltin and phenyltin contamination in Finnish environment.

### Physiological and biochemical responses of *Theodoxus fluviatilis* to in situ exposure to antifouling paints

M.A. Bighiu, Applied Environmental Science; B. Eklund, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; A. Eriksson-Wiklund, Stockholm University / Applied Environmental Science We investigated the effects of antifouling paints on a common snail species in the Baltic Sea – *Theodoxus fluviatilis*. The exposure was done in situ, in one marina and one guest harbor in the Stockholm archipelago, Sweden. In addition, a clean reference area was chosen at Askö, which also served as sampling site for the snails. Plastic cages (30 replicates per site), each containing 5 snails of different sizes and young tips of bladderwrack (*Fucus vesiculosus*), were placed in water at a depth of 1 m for 8 weeks. During this time the cages were checked periodically for dead snails and the fouling was brushed off to ensure good water exchange. The number

of egg capsules laid after two weeks was counted and the weight and shell growth were determined at the end of the exposure. Water and sediment samples were taken from the three sites for chemical analysis (Cu, Zn, TBT, Diuron and Irgarol). The results show that the highest toxicity was towards the snails exposed in the marina, where the mortality was highest (i.e. 10 times higher than at the reference site), the reproduction rate was lowest (average 0.24 egg capsules/cage compared to 22 at the reference site) and the growth rate was negative. The fact that the water in that marina had the highest concentration of copper from all sites might contribute to the observed effects. Future analysis will be performed to investigate the biochemical responses of the snails, by measuring metallothionein, catalase and Cu/Zn superoxide dismutase. Our results show that the in situ exposure method is a good tool for observing the long term effects of marinas on gastropods, which are highly relevant test organisms, as they are the second most abundant group of animals.

##### **Preliminary experiments for the assessment of *Littorina littorea* sensitivity towards xenoestrogenic chemicals**

P. Sanchez Marin, University of Aveiro & CESAM / INRSETE; S. Galante-Oliveira, C. Barroso, University of Aveiro / Biology Department CESAM

Prosobranch gastropods are widely used as sentinel species in endocrine disruption pollutants monitoring, in particular due to their sensitivity towards the biocidal tributyltin, the causative agent of the imposex/intersex phenomena in these organisms. Other endocrine disrupting compounds (EDCs), such as birth control pharmaceuticals (synthetic hormones such as ethinyl estradiol), plasticizers and additives (such as PCBs, phthalates, bisphenol A), surfactants (such as alkylphenols), or insecticides (such as dioxin or metoxychlor), are gaining attention due to their generalized use and their presence in the environment. Except for tributyltin, the above EDCs have been described as estrogenic, and some studies have described effects of superfeminization or even imposex (by negative feedback interactions) upon exposure of prosobranch gastropods to some of these chemicals. The aim of this study is to explore the effects that a model xenoestrogenic chemical may cause in the periwinkle *Littorina littorea*, for its possible use in the risk assessment of this type of chemicals. For that, forty individuals (20 males and 20 females) were injected with 4  $\mu\text{L g}^{-1}$  fresh weight (fw) of a solvent control (DMSO) or ethinyl estradiol (EE2) at concentrations of 1 and 10 ng  $\text{g}^{-1}$  fw. Non-injected control animals were also included and all individuals were maintained for 96 days in the laboratory. The following parameters were recorded in males: penis shedding, penis growth, and dimensions of prostate gland and seminal vesicle. In females, the dimensions of pallial oviduct and ovipositor were registered. In addition, histological analysis of gonads was done to assess the effect of the tested compounds on gametogenesis and possible anomalies in gonad tissues. The main observed effect of EE2 was an increase in the gametogenesis activity in males. A paradoxical result was an increase in penis growth rate in injected animals (DMSO, 1 and 10 ng EE2  $\text{g}^{-1}$  fw) compared with non-injected ones, questioning the use of DMSO as a carrier in injection experiments.
